4	Chrome pickle(g)	$Na_2Cr_2O_7 \cdot 2H_2O$ HNO_3 (sp gr 1.42) Na_2HF_2, KHF_2, or NH_4HF_2 Water(d)	180 (24) 120-180 (16-24) 15 (2.0) bal	21-32 (70-90) 49-60 (120-140)(h)	$\frac{1}{2}$-2(i)	Type 316 stainless steel(j)
6	Hot rinse	Water	. . .	71-82 (160-180)(k)	. . .	Low-carbon steel

(a) Type and strength of solution used governed by degree of surface contamination.

(b) Rinse thoroughly with adequate inflow of fresh water; agitate.

(c) For wrought materials, all alloys, not to be hot formed, and for wrought materials, all alloys, for which tolerances permit removal of approximately 15 μm (0.6 mil) of stock. When treatment is used on alloys M1A and ZK60A to provide paint base, use fresh solutions.

(d) Use water from steam condensate or water treated by ion exchange, when available, instead of well or hard tap water.

(e) For well-controlled bath, 1 min is standard.

(f) Tank material can be of stainless steel or low-carbon steel lined with glass, ceramic, synthetic rubber, or vinyl-based materials. Racks and baskets for use with Solution 3 may be stainless steel or Monel.

(g) For sand and permanent mold castings of all alloys for which tolerances permit stock removal of approximately 15 μm (0.6 mil); die castings, all alloys, of 3 to 8 μm (0.1 to 0.3 mil). Dip die castings for 15 to 30 s in water 71 to 82 °C (160 to 180 °F) before immersing in solution.

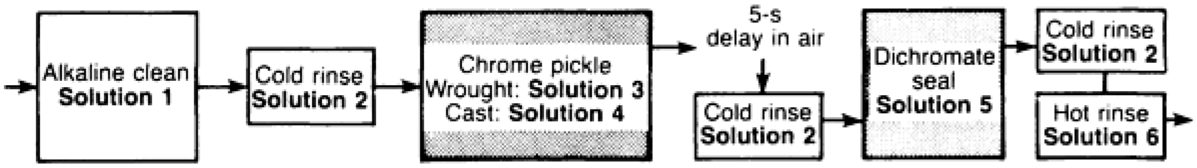
(h) For die castings.

(i) For well-controlled bath, 1 min is standard on all products except die castings. Immerse die castings only 10 s.

(j) Racks and baskets for use with Solution 4 can be type 316 stainless steel or phosphor bronze.

(k) Immerse long enough to heat parts sufficiently to facilitate rapid drying; keep rinse clean with inflowing fresh water.

Fig. 3 Chrome pickle treatment (chemical treatment No. 1; MIL-M-3171, type I). Applicable to all alloys and product forms. Used to provide a base for paint or short-time protection for shipment or storage



Solution No.	Type of solution	Constituents	Amount, g/L (oz/gal)	Operating temperature, °C (°F)	Cycle time, min	Tank material

Fig. 4 Sealed chrome pickle treatment. Applicable to all alloys and product forms. Used as a substitute for dichromate coating or for more protection than is provided by the chrome pickle treatment

When a magnesium alloy product is used bare or with a clear finish, it is desirable to improve the corrosion resistance of the metal surface in addition to providing an attractive appearance. This can be accomplished by the use of ferric nitrate, acetic-nitrate, or phosphoric acid pickle (Table 2). The ferric nitrate pickle deposits an invisible chromium oxide film that passivates the surface and improves corrosion resistance. The acetic-nitrate and phosphoric acid pickles act as sequestering agents that effectively remove even invisible traces of other metals from the magnesium surface and thus prevent localized galvanic corrosion. Although all of these methods are effective in improving corrosion resistance, ferric nitrate and phosphoric acid pickles give best results.

Mechanical Finishing

Depending on required appearance, the most frequently used methods of mechanical finishing are barrel tumbling, polishing and buffing, vibratory finishing, fiber brushing, and shot blasting. Shot blasting with 0.10 to 0.25 mm (0.003 to 0.009 in.) glass spheres produces a satin finish. Plastic and chopped aluminum wire blasting media are also used. Sand or steel shot blasting should be excluded as means for producing a desired mechanical finish. If these media are used, heavy pickling (1 to 2 mils of metal removal) is required to restore corrosion resistance, and such pickling can seriously alter the mechanical finish produced. Surface contamination by plastic, chopped aluminum, or glass bead media is less damaging and the effects can be easily removed by subsequent mild etching treatments such as ferric nitrate pickling. Wet blasting with glass beads or aluminum oxide is less contaminating than any dry blasting process. (See the article "Corrosion of Magnesium and Magnesium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* and Ref 3, 5, and 9.)

Mass (Barrel) Finishing. The use of dry barrel finishing is usually limited to the production of a final finish on magnesium alloy parts that are small and relatively thin and for which metal removal must be held to a minimum. Wet barrel finishing is used for deburring, grinding, polishing, burnishing, and coloring. Procedures used in wet and dry barrel finishing are discussed in the article on mass finishing.

Vibratory finishing combines smoothing and brightening with cleaning to remove dirt, oxides, thin flash, and casting skin. Ceramic and other media are used depending on the surface condition of the part and the finish required. Acid additives etch magnesium surfaces and should never be used. Proper rinsing and drying are important.

Polishing and buffing are not used for final finishing, but for preparing magnesium alloy surfaces for other finishes, such as chemical treatments, anodizing, plating, or painting. As shown in Table 3, the procedures used to produce a highly polished or buffed surface on magnesium alloys are similar to those used for aluminum-base alloys. However, because most magnesium alloys are appreciably harder than aluminum alloys and tend to drag or tear to a lesser degree, it is unnecessary to use as much lubrication as is usually required with aluminum alloys. When polishing die castings, the metal removal is kept at a minimum to preserve the relatively thin nonporous outer layer of the casting.

Table 3 Procedures for polishing and buffing magnesium alloys

Operation	Abrasive grit size	Wheel				
		Type	Diam		Speed	
			mm	in.	m/s	sfm
Rough polishing[(a)]	60-100[(b)]	Canvas, felt, sheepskin	150-360	6-14	15.3-25.5	3000-5000
Medium polishing[(c)]	100-320[(b)]	Built-up cloth	150-360	6-14	20.4-30.6	4000-6000
Fine polishing	240-400	Cloth or sheepskin	250-360	10-14	22.9-38.2	4500-7500
Satin finishing[(d)]	50-320[(e)]	Full-disk buffs[(f)]	150-300	6-12	15.3-25.5	3000-5000
Buffing[(g)]	[(h)]	Cotton buffs	150-410	6-16	20.4-40.8	4000-8000

(a) For rough surfaces only, such as sand castings.

(b) Aluminum oxide or silicon carbide; grease stick may be used.

(c) For less severe surface condition and before buffing.

(d) For final finish or before plating.

(e) Greaseless compound.

(f) Loose or folded cotton cloth.

(g) A cutdown operation to produce a smooth finish with an intermediate degree of brightness.

(h) Tripoli or aluminum oxide buffing compound

Standard polishing wheels and abrasive belts are used to remove rough surfaces, parting lines, and other surface imperfections from magnesium alloy pieces. Aluminum oxide or silicon carbide abrasives are used, in grit sizes from 60 to 320, depending on the surface roughness and the final finish desired.

Particles of free iron or other heavy metals must not be used in abrasives for the polishing of magnesium alloys, because these metals, when embedded in the surface, can cause cell corrosion effects while parts are in storage or cause a pitting condition in pickling processes used before chemical treatments or electroplating.

Large castings require polishing of significant surfaces before buffing. Fine polishing belts are used on parts with little contour. Parts with more intricate contour are polished on setup wheels or on cloth wheels, using a greaseless compound. Grit sizes from 220 to 320 are most commonly used in polishing operations prior to buffing.

Satin finishing or flexible-wheel polishing is also used on magnesium alloys. This finish is produced by applying a greaseless compound to the surface of a clot wheel as it is slowly revolved. No lubricant is required.

Magnesium alloys can be buffed to a smooth, bright finish using aluminum oxide or tripoli compounds on a light-count sewed wheel. For color buffing, a dry lime compound may be used. Buffing compounds containing free iron or other heavy metal abrasives should not be used.

A ferric nitrate bright pickle, as shown in Table 2, is used on polished or buffed surfaces prior to the application of a clear organic coating. Using a ferric nitrate bright pickle produces a bright, passive surface that increases the adhesion and corrosion protection of the coating; it also serves to prevent blemishes such as spotting, blooming, and worm tracking in the coating after it has dried.

Precautions that must be exercised in the polishing and buffing of magnesium alloys are discussed in the section "Health and Safety" in this article.

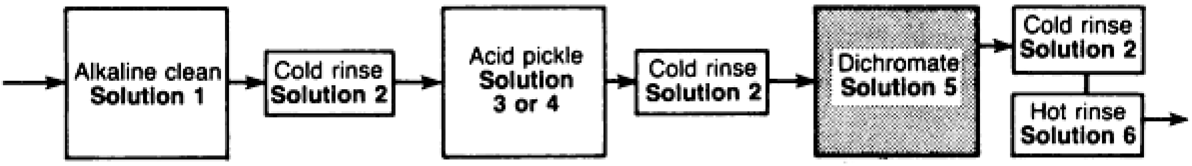
Chemical Finishing Treatments

Chemical finishing treatments for magnesium alloys are used either to provide short-time protection against corrosion and abrasion during shipment and storage, or as pretreatments to additional finishing systems.

Figures 3, 4, 5, and 6 present flow charts of processing steps in four frequently used chemical treatments; tabular data accompanying each of these charts indicate operating conditions and applicability of the respective treatments. Note that the chrome pickle and sealed chrome pickle treatments cannot be used on close-tolerance machined parts unless tolerances will permit or allowances for metal removal have been made. The dichromate treatment (Fig. 5) involves no appreciable dimensional changes. Moreover, when a hydrofluoric-sulfuric acid pretreatment and brief exposure to the chrome pickling solution are used, the modified chrome pickle treatment (Fig. 6) involves no appreciable dimensional changes.



Solution	Type of solution	Constituents	Amount, g/L (oz/gal)	Operating temperature, °C (°F)	Cycle time, min	Tank material
1	Alkaline cleaner	(a)	(a)	88-100 (190-212)	3-10	Low-carbon steel
2	Cold rinse	Water	. . .	Ambient	(b)	Low-carbon steel
3	Acid pickle(c)	60% HF water(d)	180 (24) bal	21-32 (70-90)	5(e)	Low-carbon steel(f)
4	Acid pickle(g)	$NaHF_2$, KHF_2, or water(d)	50 (6.7)	21-32 (70-90)	5	Low-carbon steel(f)
5	Dichromate	$Na_2Cr_2O_7{\cdot}2H_2O$ CaF_2 or MgF_2 water(d)	120-180 (16-24) 2.48 (0.33) bal	99-100 (210-212) (boiling)	30(h)	Low-carbon steel
6	Hot rinse	Water	. . .	71-82 (160-180)	(i)	Low-carbon steel

Note: Racks and baskets for use with all tank materials should be Monel, type 316 stainless steel, or phosphor bronze.

(a) Type and strength of solution used governed by degree of surface contamination.

(b) Rinse thoroughly with adequate inflow of fresh water; agitate.

(c) This bath may be used for all treatable alloys in all forms. This bath must be used for castings that have not been pickled after being sand blasted.

(d) Water from steam condensate or water treated by ion exchange should be used when available instead of well or hard tap water.

(e) For AZ31A and B, $\frac{1}{2}$ to 1 min.

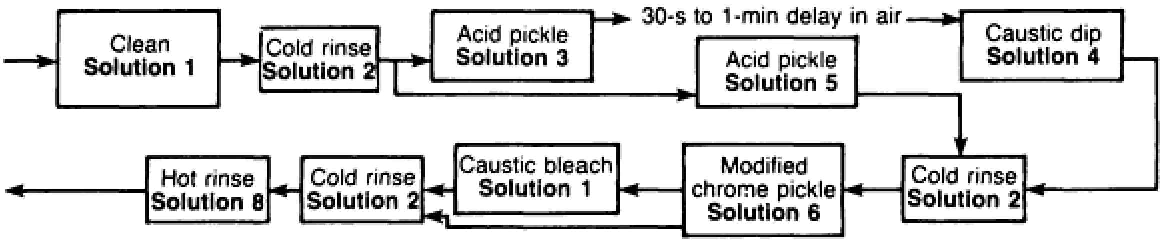
(f) Line tanks with lead or with natural or synthetic rubber.

(g) This pickle is preferred for AZ31B and C; an alternate pickle for wrought products and for castings that have been pickled after being sand blasted.

(h) For ZK60A. 15 min.

(i) Immerse long enough to heat parts sufficiently to facilitate rapid drying; keep rinse clean with inflowing fresh water.

Fig. 5 Dichromate treatment (chemical treatment No. 9; MIL-M-3171, Type III). Used for maximum corrosion protection and to provide a paint base. Results in no appreciable change in dimensions and can be used on finish-machined wrought and cast products of all alloys except EK30A, EK41A, HK31A, and M1A



Solution No.	Type of solution	Constituents	Amount, g/L (oz/gal)	Operating temperature, °C (°F)	Cycle time, min	Tank material
1	Cleaner[(a)]	$Na_4P_2O_7$ $Na_2B_4O_7 \cdot 10H_2O$ NaF Water[(b)]	30 (4) 68 (9) 8 (1) bal	77-82 (170-180)	2-5	Low-carbon steel
2	Cold rinse	Water	. . .	Ambient	[(c)]	Low-carbon steel
3	Acid pickle[(d)]	100% H_3PO_4 Water[(b)]	481-820 (65-110) bal	21-32 (70-90)	$\frac{1}{6}$ - $\frac{1}{4}$	Low-carbon steel[(e)]
4	Caustic dip	NaOH	50 (6.6)	21-82 (70-180)	$\frac{1}{2}$	Low-carbon steel

5	Acid pickle(f)	100% HF H_2SO_4 Water(b)	143-196 (20-25) 48 (6.4) bal	21-32 (70-90)	2-5	Low-carbon steel(e)
6	Modified chrome pickle(g)	$NaHF_2$ $NaCr_2O_7 \cdot 2H_2O$ $Al_2(SO_4) \cdot 14H_2O$ HNO_3 (sp gr 1.42) Water(b)	15 (2) 180 (24) 10 (1.3) 120 (16) bal	21-32 (70-90)	$\frac{1}{12}$-2	Type 316 stainless steel or low-carbon steel with vinyl
7	Caustic bleach(h)	NaOH, 5-10%	. . .	82-100 (180-212)(i)	$\frac{1}{2}$	Low-carbon steel
8	Hot rinse(j)	Water	. . .	71-82 (160-180)	(k)	Low-carbon steel

(a) Vapor degreasing, solvent washing, or conventional alkaline cleaning may be used instead of this special mild-etching cleaner. Metal removal in 5 min, 2.5 to 5.0 µm (0.1 to 0.2 mil).

(b) Use water from steam condensate or water treated by ion exchange, when available, instead of well or hard tap water.

(c) Rinse thoroughly with adequate inflow of fresh water; agitate.

(d) Acid pickle using this solution is preferred pretreatment if metal loss of 13 µm (0.5 mil) can be tolerated.

(e) Lined with rubber or vinyl.

(f) Alternative treatment; for use if metal loss of 13 µm (0.5 mil) is unacceptable.

(g) Metal removal rate, 1.2 µm (0.5 mil) per min.

(h) Optional; provides bright appearance.

(i) For castings; wrought products are best treated in a room-temperature solution.

(j) Oven drying, at temperatures not exceeding 150 °C (300 °F),may be substituted for hot water rinse.

(k) Immerse long enough to heat parts sufficiently to facilitate rapid drying; keep rinse clean.

Fig. 6 Modified chrome pickle treatment (chemical treatment No. 20). Used to provide a base for paint or for protection during shipment or storage. Provides a more uniform coating than chrome pickle treatment. Applicable to all alloys and product forms, particularly die castings, for which slight metal losses are acceptable

Traditionally chrome-free phosphates have not been recommended for use with magnesium components, however with the introduction of the new higher-purity die cast alloys (AZ91D, AM50A, AM60B, and AS41B; see Ref 10) a number of commercial phosphatizing treatments and simple phosphate formulations have been found to provide performance competitive with the best chromate-based surface treatments. These chrome-free treatments have been employed commercially with increasing frequency in finishing magnesium parts for a variety of markets including automotive, sporting goods, and power lawn equipment (Ref 1, 2, 9).

Anodic Treatments

Of the many anodizing treatments developed for magnesium, only a few have achieved commercial significance. Chemical Treatment No. 9 (galvanic anodizing) is a low-voltage dc treatment that produces a thin black conversion coating, which is used mainly as a paint base. Chemical Treatment No. 17 and HAE treatment produce more substantial coatings (thicknesses of 5 to 30 μm) and are more widely used, primarily as bases for heavy-duty paint systems for rigorous service conditions, such as in military and aerospace applications. The heavier anodized coatings also provide significant resistance to abrasion. The Cr-22 treatment is a high-voltage process that is not currently used, but derivative proprietary processes are commercially available. Anodized coatings have varying degrees of porosity and must be sealed for use in severely corrosive salt environments. The coatings can be infused with various polymers to produce special properties such as lubricity.

Two proprietary chrome-free anodizing treatments have been introduced recently. Both have been demonstrated to provide excellent wear resistance, and when evaluated for a military application, one was found superior to both the HAE and No. 17 anodizing treatments in coated corrosion performance (Ref 11, 12, 13).

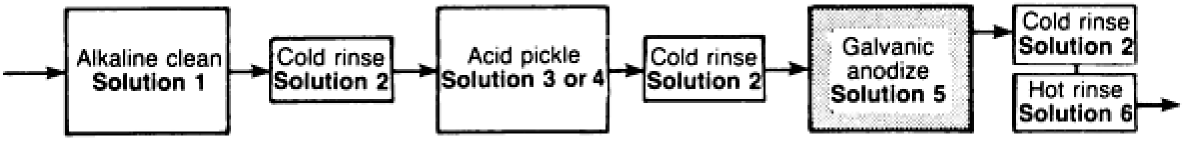
Surface Preparation. Before conversion coating, all surfaces must be scrupulously clean and free of contamination. Remove oil, grease, and other organic contaminants with suitable solvent cleaners, or with hot alkaline cleaning solutions such as those previously described in the section on chemical cleaning. Scales, oxides, burned-on drawing lubricants, and inorganic corrosion products should be removed in acid pickling solutions of prescribed composition and in accordance with the recommendations given in Table 2.

Parts that have been fabricated by stamping should be deburred to ensure that a coating is not applied to feathered edges that might break off and expose bare metal. Sharp edges and round corners should be made smooth before anodizing. Wherever close dimensional tolerances are entailed, adequate provision for buildup that results from coating should be made.

Chemical Treatment No. 9. A galvanic anodizing treatment in which a source of electric power is not required, Chemical Treatment No. 9 is applied to all forms and alloys of magnesium to produce a protective black coating with good paint-base characteristics. Parts with attachments of other metals may also be treated. Because this process does not result in appreciable dimensional change, the parts are machined to close tolerances before treatment.

Proper galvanic action requires the use of racks, made of stainless steel, Monel, or phosphor bronze. When the workpieces are immersed in the anodizing solution, they are made the anodes, and the tank, if made of low-carbon steel, acts as cathode. If the tank is equipped with a nonmetallic lining, separate steel cathodes must be used.

A processing diagram, together with details of solution compositions and operating conditions for Chemical Treatment No. 9, is presented in Fig. 7



Solution No.	Type of solution	Constituents	Amount, g/L (oz/gal)	Operating temperature, °C (°F)	Cycle time, min	Tank material
1	Alkaline cleaner	(a)	(a)	88-100 (190-212)	3-10	Low-carbon steel
2	Cold rinse	Water	. . .	Ambient	(b)	Low-carbon steel
3	Acid pickle(c)	60% HF Water(d)	180 (24) bal	21-32 (70-90)	5(e)	Low-carbon steel(f)
4	Acid pickle(g)	$NaHF_2$, KHF_2, or NH_4HF_2 Water(d)	50 (6.6) bal	21-32 (70-90)	5	Low-carbon steel(f)
5	Galvanic anodize(h)	$(NH_4)_2SO_4$ $Na_2Cr_2O_7 \cdot 2H_2O$ NH_4OH (sp gr 0.880) Water(d)	30 (4) 30 (4) 2.2 (0.3) bal	49-60 (120-140)	10-30(i)	(j)
6	Hot rinse	Water	. . .	71-82 (160-180)	(k)	Low-carbon steel

Note: Racks and baskets for use with all tank materials may be stainless steel, Monel, or phosphor bronze.

(a) Type and strength of solution governed by degree of surface contamination.

(b) Rinse thoroughly; agitate.

(c) May be used for all alloys in all forms; must be used for castings that have not been pickled after being sand blasted.

(d) Water from steam condensate or water treated by ion exchange should be used, when available, instead of well or hard tap water.

(e) For AZ31A and B, $\frac{1}{2}$ to 1 min.

(f) Lined with lead or with natural or synthetic rubber.

(g) An alternative pickle for wrought products and for castings that have been pickled after sand blasting; preferred for AZ31B and C.

(h) Current density should not exceed 1 A/dm^2 (10 A/ft^2); at least 753 A · min/m^2 (70 A · min/ft^2) is required for uniform coating.Maintain solution at pH 5.6 to 6.0 by adding solution containing 5% CrO_3 and concentrated H_2SO_4.

(i) Treat parts until a uniform black coating is obtained.

(j) If made of low-carbon steel, the tank acts as a cathode. If tank is made of or lined with nonmetallic material, use steel cathode plates.

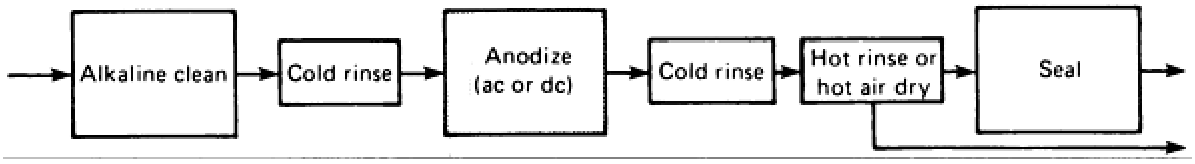
(k) Immerse long enough to sufficiently heat parts to facilitate rapid drying; keep rinse clean with adequate flow of fresh water.

Fig. 7 Chemical treatment No. 9 (MIL-M-3171A) galvanic anodizing

Chemical Treatment No. 17, which can be applied to all forms and alloys of magnesium, produces a two-phase, two-layer coating. A light green or greenish tan undercoating, about 5.0 μm (0.2 mil) thick, forms at lower voltages. This is covered by a much heavier, second-phase coating about 30.4 μm (1.2 mils) thick, vitreous, and dark green. The second-phase coating is relatively brittle and highly abrasion resistant. Formed at higher voltages, its corrosion resistance and paint-based properties are excellent. However, according to ASTM D 1732, the dark green, thick coating is preferable to the light green thin coating only when:

- Preliminary removal of surface contamination is not convenient.
- The highest degree of abrasion resistance is required from the coating.
- A dimensional increase of about 0.02 mm (0.001 in.) can be tolerated.
- The part is not to be subjected in service to severe impact, deformation, or flexing, which can cause spalling of the coating.

Details of solution compositions and operating conditions for this treatment are given in Fig. 8, which also shows a flow diagram of the processing steps.



Operating conditions	Alternating current treatment	Direct current treatment
For coatings of both colors and thicknesses		

Composition of aqueous anodizing solution[a]:		
NH_4HF_2, g/L (oz/gal)	240 (32)	360 (48)
$Na_2Cr_2O_7 \cdot 2H_2O$, g/L (oz/gal)	100 (13.3)	100 (13.3)
85% H_3PO_4, mL/L (fl oz/gal)	90 (12)	90 (12)
Operating temperature[b], °C (°F)	71-82 (160-180)	71-82 (160-180)
Current density, A/dm^2 (A/ft^2)	0.5-5 (5-50)	0.5-5 (5-50)
For light green coating, thin[c]		
Current consumption[d], A · min/m^2 (A · min/ft^2)	860-1075 (80-100)	540-645 (50-60)
Terminating voltage[d], V	75	75
Treatment time[d], min	4-5	$2\frac{1}{2}$-3
For dark green coating, thick[e]		
Current consumption[d], A · min/m^2 (A · min/ft^2)	4950 (460)	3230 (300)
Terminating voltage[d], V	100	100
Treatment time[d], min	23[f]	15[f]
Sealing post-treatment[g]		
Aqueous solution, sodium tetrasilicate ($Na_2Si_4O_9$), g/L (oz/gal)	53 (7)	
Temperature, °C (°F)	93-100 (200-212)	
Immersion time, min	15	

(a) Use water from steam condensate or water treated by ion exchange, when available, instead of well or hard tap water.

(b) Solution will not operate below 60 °C (140 °F). It may be operated up to the boiling point without adversely affecting results.

(c) Formed in first phase of treatment. Usual thickness, 5.0 μm (0.2 mil); range, 2.5 to 7.5 μm (0.1 to 0.3 mil).

(d) Terminating voltage and treatment time vary, but the number of ampere minutes per unit area remains constant for any one alloy.

(e) Formed in second phase of treatment. Usual thickness 30.4 μm (1.2 mils); range, 23 to 38.1 μm (0.9 to 1.5 mils).

(f) A denser coating is produced by maintaining the voltage, allowing the current to decrease for 20 min (ac) or 15 min (dc) after the indicated minimum amperage per square metre (foot) has been applied.

(g) Optional; to increase corrosion resistance, apply to parts not to receive organic finishes. Immerse in solution,rinse parts in cold, then in hot, water. Air dry.

Fig. 8 Chemical treatment No. 17 (MIL-M-45202) anodizing treatment. Conditions for cleaning and rinsing same as for galvanic anodizing treatment

Bath Preparation. Half the amount of water required should be heated to 71 °C (160 °F), then slowly add ammonium acid fluoride. Add other chemicals and the remainder of the water. The solution should be heated to 82 °C (180 °F), and stirred vigorously for 5 to 10 min. Reheating to 82 °C (180 °F) and stirring should be repeated each time the solution cools to room temperature.

Bath Replenishment. Rise of terminating voltage indicates depletion of bath. Usually, an adjustment in bath composition is required after about 0.5 m^2/L (20 ft^2/gal) of bath has been treated. The amounts of ingredients added are determined by standard methods of chemical analysis of the depleted solution.

Equipment. The anodizing tank and heating coils usually are made of low-carbon steel. However, tanks lined with synthetic rubber or a vinyl-based material may be used, provided the cathodes are of low-carbon steel and a sufficient distance is allowed between the work and the sides of the tank to prevent contact and burning.

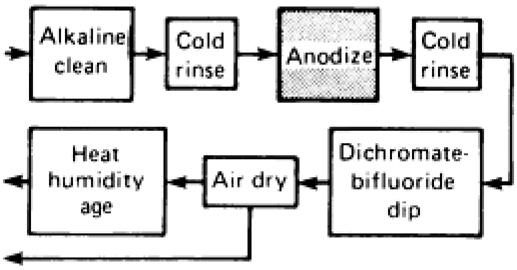
Most racks are made of magnesium alloys, and the coating formed on these racks during anodizing can be stripped in an aqueous solution containing 20% chromic acid. Aluminum alloys 5052, 5056, and 220 are also acceptable rack materials, but to avoid chemical attack, these alloys must not be immersed in the solution on open circuit.

Motor generators may be used to supply power for either alternating-current or direct-current installations. Rectifiers are suitable for supplying direct current only. A saturable reactor may be used to generate alternating current.

HAE treatment also produces a two-phase coating and is applied to all forms and alloys of magnesium, provided they contain no attachments or inserts of other metals. A light tan subcoating, about 5.0 μm (0.2 mil) thick, is produced at lower voltages. The thicker phase, formed at higher voltages, is normally dark brown in color and usually about 30 μm (1.2 mil) thick. Both phases have excellent paint-based characteristics.

The dark brown coating is hard and exhibits exceptionally good abrasion resistance, but it spalls under compressive deformation and can adversely affect the fatigue strength of a base metal less than about 2.5 mm (0.1 in.) thick. The subcoating has no effect on fatigue strength and does not spall.

Solution compositions and operating conditions for the HAE treatment are given in the table that accompanies the flow chart for the process in Fig. 9. The dichromate-bifluoride post-treatment that is part of the HAE treatment, as shown in Fig. 9, provides the coating with high resistance to corrosion.



Anodizing[a]	
Composition of solution, g/L (oz/gal):	
Potassium hydroxide (KOH)	165 (22)
Aluminum hydroxide ($Al(OH)_3$)	34 (4.5)[b]
Potassium fluoride (K_2F_2)	34 (4.5)
Trisodium phosphate (Na_3PO_4)	34 (4.5)
Potassium manganate (K_2MnO_4)[c]	19 (2.5)
Water	bal to 3.7 L (to 1 gal)
Operating temperature, °C (°F)	Room temperature to 25 (to 77)
Current density, A/dm^2 (A/ft^2)	1.5-2.5 (15-25)
Terminating voltage, V:	
First-phase coating	65-70
Second-phase coating	80-90
Treatment time[d], min:	
First-phase coating	7-10
Second-phase coating	60

Dichromate-bifluoride dip	
Composition of solution, g/L (oz/gal):	
Sodium dichromate, ($Na_2Cr_2O_7 \cdot 2H_2O$)	20 (2.7)
Ammonium bifluoride (NH_4HF_2)	100 (13.3)
Water	bal to 3.7 L (to 1 gal)
Operating temperature, °C (°F)	21-32 (70-90)
Immersion time, min	1
Heat-humidity aging(e)	
Temperature, °C (°F)	77-85 (170-185)
Relative humidity, %	~85
Time, h	7-15

(a) Acid pickling is not required before anodizing because of the chemical action of the anodizing bath on the alkaline-cleaned surface. Use alternating current for anodizing. Coatings are deposited in two phases: first a light tan coating 5.0 μm (0.2 mil) thick, then a dark brown coating usually 30.4 μm (1.2 mils) thick.

(b) For an exceptionally hard, abrasion resistant, dark brown coating, use 45 to 53 g/L (6 to 7 oz/gal) $Al(OH)_3$.

(c) An equal weight of potassium permanganate ($KMnO_4$) may be used instead of potassium manganate; dissolve the permanganate completely in water before adding to the solution; an additional 43 g (1.5 oz) of potassium hydroxide must also be added.

(d) Treatment time varies with current density. Increasing current density decreases treatment time; for uniform coating, 2 A/dm^2 (20 A/ft^2) is recommended.

(e) Improves corrosion resistance of coated parts

Fig. 9 HAE anodizing treatment (MIL-C-13335, amendment 1; MIL-M-45202). Conditions for cleaning and rinsing same as for galvanic anodizing treatment

Bath Preparation. As the first step in preparing the HAE solution, the anhydrous potassium fluoride and trisodium phosphate are dissolved in about half the amount of water required. To this is added an aqueous solution of potassium hydroxide in which aluminum hydroxide has been dissolved. It is difficult to dissolve commercially obtained aluminum hydroxide in a potassium hydroxide solution at room temperature, but it can be dissolved by boiling it in the potassium hydroxide solution for 15 to 20 min.

Metallic aluminum may be dissolved in potassium hydroxide in place of aluminum hydroxide. The reaction, which should be performed under an exhaust hood or in a well-ventilated location, forms a clear liquid and black residue; only the clear liquid is added to the main solution.

Either potassium manganate or potassium permanganate, which is unstable in alkaline solutions and converts to the manganate, is added last. Conversion of the permanganate is evidenced by a color change from purple to green. Conversion can be accelerated by dissolving the permanganate in boiling water and then adding this solution to the bath, or by adding it to the potassium hydroxide solution and boiling. Finally, water is added to make the required volume of solution; continuous agitation is necessary to put all ingredients into solution.

Bath Replenishment. Expensive analyses are not required for maintaining the bath, because depletion of the manganese compound is indicated by a lightening of the characteristic dark brown color of the coating and serves as a bath control. It should be noted, however, that coatings of the lighter brown color have the same properties as those of dark brown color. To maintain the dark brown color of the coating, bath adjustments should be made after about 0.4 m^2/L (15 ft^2/gal) of bath has been treated.

To replenish, 3.7 to 7.5 g/L (0.5 to 1 oz/gal) of potassium manganate or permanganate is added while the bath is being constantly agitated. Additions of aluminum are made at 15 to 20% of the original quantities or aluminum hydroxide (11 g/L, or $1\frac{1}{2}$ oz/gal to solution) as previously described. The fluoride and phosphate ingredients deplete at a very slow rate and may be added at six-month intervals if the bath is used continually at the rate of 15 to 20% of original quantities.

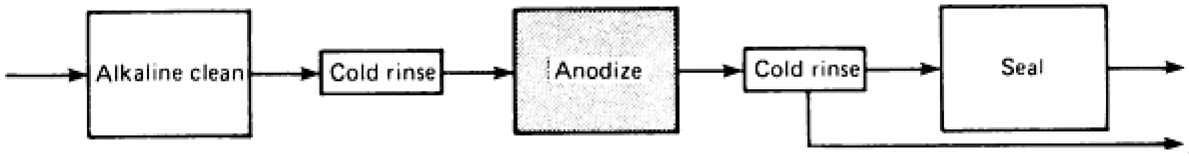
Post-Treatment. After anodizing, parts are rinsed thoroughly in water and immersed for 1 min in an aqueous solution containing 77 g (2.7 oz) of sodium dichromate and 377 g (13.3 oz) of ammonium bifluoride per 3.7 L (1 gal) of water. To dry parts, hot air may be used, without rinsing, and parts may be aged in an oven for 7 to 15 h. Aging at about 79 °C (175 °F) and about 85% relative humidity greatly improves the corrosion-protective quality of the coating. Heating of parts, particularly those with thick wall sections, should be done at low humidity until the surface is hot, after which aging is continued at higher humidity.

Equipment. The anodizing tank of double-welded construction and cooling plates or coils are made of black iron. Racks should be of magnesium alloy and should be protected by a suitable vinyl tape at solution level. Steel clamps can be used to clamp the racks to busbars. Galvanized iron, brass, bronze, tin, zinc, and rubber should not be used for equipment that comes in contact with the bath.

Alternating current at 60 Hz is supplied from a constant current regulator capable of delivering the required current over a range of 0 to 110 V.

The post-treatment dip tank must be lined with polyethylene or similar inert material. An oven or humidity cabinet, capable of maintaining temperatures to 86 °C (185 °F) and humidity to 85%, is used for aging.

Cr-22 Treatment. A flow chart of processing steps for the Cr-22 treatment is presented in Fig. 10, together with a table listing bath compositions and operating conditions. The green and black coatings obtainable by varying solution composition, operating temperature, and current density may be applied to all alloys, and although intended primarily as bases for organic finishes, these coatings provide excellent corrosion resistance to unpainted parts when sealed as described in Fig. 10. Inclusions or residual stresses in the magnesium surface occasionally result in the appearance of small nodules in the Cr-22 coating, but the presence of these nodules has no apparent effect on the corrosion protection provided by the coating. Heavier coatings produced by the Cr-22 treatment, like those produced by Chemical Treatment No. 17 and HAE treatments, spall under compressive deformation.



Operating conditions	**Type of coating**	
	Green[a]	**Black**[b]
Composition of anodizing solution:		
CrO_3, g/L (oz/gal)	25 (3.3)	50 (6.7)
50% HF (sp gr, 1.20), mL/L (fl oz/gal)	36 (4.7)	35 (4.7)
85% H_3PO_4 (sp gr, 1.70), mL/L (fl oz/gal)	50 (6.7)	50 (6.7)
NH_4OH (sp gr, 0.90), mL/L (fl oz/gal)	220 (29)	220 (28)
Water[c]	bal	bal
Operating temperature, °C (°F)	88-91 (190-195)[d]	85 (185)[d]
Current density	1.5 (15)[e]	2.5 (25)[f]
Terminating voltage, V		
For normal thickness	320	320
For heavy coatings	350-380	350-380
Treatment time, min	12-15	12-15
Sealing post-treatment[g]		
Solution, vol% sodium silicate (42° Bé)	10	
Temperature, °C (°F)	85-100 (185-212)	
Immersion time, min	2	

(a) Green coating, conforming to MIL-M-45202, type II, class B, ranges in thicknesses from 10 to 28 μm (0.4 to 1.1 mil); usual thickness, 20 μm (0.8 mil).

(b) Black coating, conforming to MIL-M-45202; type II, class C, ranges in thickness from 5 to 25 μm (0.2 to 1.0 mil); usual thickness, 13 μm (0.5 mil).

(c) Use water from steam condensate or water treated by ion exchange, when available, instead of well or hard tap water.

(d) Recommended; effective range, 74 to 93 °C (165 to 200 °F).

(e) Recommended; effective range, 1.0 to 3.0 A/dm^2 (10 to 30 A/ft^2).

(f) Recommended; effective range, 2.0 to 3.0 A/dm^2 (20 to 30 A/ft^2).

(g) Optional for both types; to increase corrosion resistance, apply to parts not to receive organic finishes

Fig. 10 Cr-22 (MIL-M-45202) anodizing treatment. Conditions for cleaning and rinsing same as for galvanic anodizing treatment

Bath Preparation. To half the required volume of water, the constituents of the bath are added in the order listed in Fig. 10, stirring continuously. When the chemicals are completely dissolved, water is added to bring the bath to the required volume, then sufficient ammonium hydroxide is added to raise the pH to 8.

Bath replenishment can be affected by adding the initial preparation chemicals in quantities determined by conventional chemical analyses for ammonia, phosphorus, fluorine, and hexavalent chromium. Replenishment after the anodizing of 0.6 m^2/L (30 ft^2/gal) of electrolyte, at 1.5 A/dm^2 (15 A/ft^2), has been found satisfactory. To minimize vapor losses at the high operating temperature of Cr-22 baths, polyethylene floats are used to cover bath surfaces.

Equipment. Tanks and heating coils should be made of low-carbon steel. Do not use copper, brass, or zinc for equipment that will come into contact with the bath. Racks should be made of magnesium alloys, and as in all anodizing treatments, electrical contact points should be clean and firm.

The power supply should be capable of delivering a current of 1.5 A/dm^2 (15 A/ft^2) of work area at a maximum of 350 V (60 cycles/s, alternating current).

Repair of Damaged Anodic Coatings. Touch-up procedures depend on the nature and extent of damage. Minor damage, scratches, or very small areas where magnesium metal is exposed can be treated as follows:

1. Clean damaged area with organic solvent.
2. Brush with chrome pickle solution (Fig. 3, solution 4); or with a solution containing 9.7 g/L (1.3 oz/gal) of chromic acid with water and 28 g (1 oz) of calcium sulfate, added in that order and stirred vigorously for 15 min.
3. Apply suitable primer and finish paint coat after thoroughly rinsing and drying.

Larger areas, several square inches, can be reanodized without removing the old coating, or the old coating can be stripped in a 20% solution of chromic acid and the entire part reanodized.

Process Control of Chemical and Anodic Treatments

To achieve desired results with any acid pickle, chemical, or anodic treatment, proper control of temperature and concentration must be maintained. In these treatments, solution temperature governs the rate of metal removal or of film formation. Acid pickles and chemical treatments are conventionally formulated to be used at room temperature to avoid the expense of heating or cooling. Elevated temperatures are required only when chemical action is too slow at ambient temperature, as in alkaline cleaning, chromic acid pickling, and anodizing.

The rate of metal removal by acid pickling also increases with acid concentration. Solutions are usually formulated so that the pickling rate is fast enough to be economical, but not so fast that metal removal is difficult to control or that localized pitting results. As the bath is used, magnesium is dissolved and acid is consumed. Concentrated acid must be added periodically to replenish what is consumed and to maintain the solution within recommended composition limits. As the magnesium content of the solution increases, the pickling rate becomes slower, and eventually the rate becomes too slow, no matter how high the acid content. Chemical treatments cause staining when the magnesium content of solutions used is too high. These conditions can be avoided by discarding solution when its magnesium content reaches about 30 g/L (4 oz/gal).

When only one acid is present in a pickling solution, its concentration may be determined analytically by titration with standard sodium hydroxide solution. Magnesium content can be determined rapidly with atomic absorption spectroscopy or a flame photometer. Other components of the chemical baths can be determined by standard analytical procedures. In the absence of analytical facilities, it is necessary to fortify pickling solutions periodically to maintain the desired reaction rate; solutions for chemical treatment may be maintained by periodically replacing one-fourth of the volume with fresh solution.

Table 4 summarizes process control for various acid pickling, chemical, and anodic treatments and indicates the unfavorable effects that result when operating variables are above or below recommended ranges.

Table 4 Effects of lack of control of process variables in acid pickling, chemical, and anodic treatments

Treatment	**Solution constituent or condition**	**Recommended range**	**Effect of operating out of recommended range**	
			Too low	**Too high**
Acid pickling treatments				
Acetic-nitrate	Glacial acetic acid	115-300 g/L (15-40 oz/gal)	Slow rate	Uneconomical
	Sodium nitrate	30.0-75 g/L (4-10 oz/gal)	Smut	Slow rate
Chromic acid	Chromic acid	115-375 g/L (15-50 oz/gal)	Slow rate	Uneconomical

Chromic-sulfuric	Chromic acid	150.4-240.6 g/L (20-32 oz/gal)	Unknown(a)	Unknown(a)
	96% sulfuric acid	0.37-0.60 g/L (0.05-0.08 oz/gal)	Unknown(a)	Unknown(a)
	pH	0.4-1.0	Unknown(a)	Unknown(a)
Ferric nitrate(b)	Chromic acid	150.4-225 g/L (20-30 oz/gal)	Rapid rate; yellow stain	Slow rate
	Ferric nitrate	22.5-45.1 g/L (3-6 oz/gal)	Slow rate; rough or frosted	Rapid rate; yellow stain
	Sodium fluoride	2.2-6.7 g/L (0.3-0.9 oz/gal)	Slow rate; smut; rough or frosted appearance	Rapid rate; yellow or gray film
Glycolic-nitrate	70% glycolic acid	115-375 g/L (15-50 oz/gal)	Poor corrosion resistance	Uneconomical
	70% nitric acid	22.5-90.2 g/L (3-12 oz/gal)	Slow rate	Rapid rate
	Sodium nitrate	30.0-75.2 g/L (4-10 oz/gal)	Smut	Slow rate
Hydrofluoric acid	50% hydrofluoric acid	190-565 g/L (25-75 oz/gal)	Powdery dichromate treatment; incomplete MgF_2 film	Uneconomical
Nitric acid	70% nitric acid	30.0-75.2 g/L (4-10 oz/gal)	Slow rate	Rapid rate; rough surface
Nitric-sulfuric	70% nitric acid	30.0-90.2 g/L (4-12 oz/gal)	Smut	Rapid rate
	96% sulfuric acid	9.5-30.0 g/L (1.3-4 oz/gal)	Slow rate	Rapid rate
Phosphoric acid(c)	85% phosphoric acid	865-965 g/L (115-128 oz/gal)	Rapid rate	. . .
Sulfuric acid	96% sulfuric acid	15.0-45.1 g/L (2-6 oz/gal)	Slow rate	Rapid rate; rough surface
Chemical treatments				

Chrome pickle and sealed chrome pickle	Sodium dichromate	135.3-205 g/L (18-27 oz/gal)	Powdery coating	Shallow etch
	70% nitric acid	60.1-180.4 g/L (8-24 oz/gal)	Shallow etch	Powdery coating
	Temperature	21-49 °C (70-120 °F)	Shallow etch	Powdery coating
	Magnesium	30.0 g/L max (4 oz/gal max)	. . .	Shallow etch
	Prerinse delay in air	5 s max(d)	. . .	Powdery coating
Dichromate	Sodium dichromate	120-205 g/L (16-27 oz/gal)(e)	Nonuniform or no coating	Uneconomical
	Calcium fluoride		Powdery coating	No problem
	Free fluoride	0.2% max	. . .	No coating(f)
	pH(g)	4.1-5.5	Heavy or powdery coating	Nonuniform or no coating
	Temperature	93-100 °C (200-212 °F)	No coating	. . .
Modified chrome pickle(h)	Sodium acid fluoride	11.2-15.0 g/L (1.5-2 oz/gal)	Powdery smut	Powdery coating
	Sodium dichromate	135.3-205.0 g/L (18-27 oz/gal)	Pale color; too reactive	Slow rate
	Aluminum sulfate	7.5-11.2 g/L (1.0-1.5 oz/gal)(i)	Poor coating color on castings	Rapid rate; poor etch
	70% nitric acid	22.5-120.3 g/L (3-16 oz/gal)	Poor etch; slow rate	Pale color; poor etch
	Temperature	21-38 °C (70-100 °F)	Slow rate	Too reactive
Anodic treatments				
Chemical Treatment No. 9	Ammonium sulfate	16.5-24.0 g/L (2.2-3.2 oz/gal)(j)	Slow rate	Powdery coating
	Sodium dichromate	16.5-24.0 g/L (2.2-3.2	Thin coating	Slow rate

		oz/gal)(k)		
	pH(l)	5.6-6.0	Powdery coating	Slow rate
	Temperature	49-60 °C (120-140 °F)	Slow rate	Rapid rate
Chemical Treatment No. 17	Ammonium acid fluoride(m)	300.8-451.2 g/L(n) (40-60 oz/gal)	Local pitting	Insoluble
	Sodium dichromate(m)	53-120 g/L (7-16 oz/gal)	Thin coating	Uneconomical
	85% phosphoric acid(m)	53-105.2 g/L (7-14 oz/gal)	Soft coating	Uneconomical
	Chloride contamination	3% max	. . .	Soft coating
	Current density	0.5-5 A/dm^2 (5-50 A/ft^2)	Attack at liquid level	Pitting or burning
	Temperature	71-82 °C (160-180 °F)	No coating	No problem
HAE	Potassium hydroxide	105-190 g/L (14-25 oz/gal)	Pitting; burning; nonuniformity	Pitting; burning; roughness
	Potassium fluoride(o)	15.0-150.4 g/L (2-20 oz/gal)	Spottiness; nonuniformity	Uneconomical
	Trisodium phosphate(p)	15.0-225.6 g/L (2-30 oz/gal)	Light and dark areas	Uneconomical
	Aluminum hydroxide(p)	7.5-53 g/L (1-7 oz/gal)(q)	Coating hardness lowered	Hard, rough coating
	Potassium manganate	3.7-22.5 g/L (0.5-3 oz/gal)	Light brown coating	Dark brown, rough coating
	Current density	0.5-5 A/dm^2 (5-50 A/ft^2)	Slow rate	Nonuniformity in recesses(r)
	Temperature	25-38 °C (77-100 °F)(s)	. . .	Lower corrosion resistance
Cr-22	Chromic acid(t)	22.5-30.0 g/L (3-4 oz/gal)	Nonuniform or pale coating	Dark coating

	50% hydrofluoric acid(t)	30.0-53 g/L (4-7 oz/gal)	Low voltage, nonuniform coating	Pale coating
	85% phosphoric acid(t)	45.1-90.2 g/L (6-12 oz/gal)	Nonuniform coating	Uneconomical; rough coating
	pH(u)	6.0-6.5	. . .	Uneconomical
	Current density	1.0-3.0 A/dm^2 (10-30 A/ft^2)	Slow rate	Dark coating
	Temperature	74-93 °C (165-200 °F)	Slower corrosion resistance	. . .

(a) Effects of operation outside recommended ranges are not known. Depletion of solution is indicated by the formation of a brassy film and by a pH in excess of 1.0; at this point, add chromic and sulfuric acids, or discard solution.

(b) Discard solution when depleted or periodically add one fourth of volume of solution.

(c) Dragout loss prevents excessive salt buildup.

(d) Do not allow surface to dry out before rinsing.

(e) Limited solubility regulates fluoride.

(f) Add 0.2% calcium chromate if fluoride is too high.

(g) Correct pH with additions of sodium hydroxide or chromic acid.

(h) Fortify bath by additions of sodium dichromate to restore original concentration of 180.4 g/L (24 oz/gal) of nitric acid to maintain concentration of used bath at 60 g/L (8 oz/gal) and of 28 g (1 oz) of sodium acid fluoride for every 310 g (11 oz) of nitric acid added. Bath is considered depleted when concentration of nitric acid is below 22.5 g/L (3 oz/gal) and is indicated by poor color and nonuniformity of coating.

(i) For fresh bath; no additions required when fortifying.

(j) As H_2SO_4.

(k) As CrO_3.

(l) Control of pH achieved by additions of a solution containing, by weight, 5% CrO_3 and 5% H_2SO_4 (concentrated).

(m) Fortify after preparing 0.4 m^2/L (20 ft^2/gal) of solution.

(n) Local pitting begins at 1020 g (36 oz), particularly with thorium-containing alloys.

(o) Anhydrous.

(p) Fortify after treating 0.3 m^2/L (15 ft^2/gal) of solution to maintain dark brown color of coating.

(q) 2.2 to 15.0 g/L (0.3 to 2 oz/gal) as Al.

(r) Use 1.5 A/dm^2 (15 A/ft^2) for uniformity of coating in recesses.

(s) Ideal temperature, 27 °C (80 °F); 38 °C (100 °F) is satisfactory for alloys containing aluminum.

(t) Fortify after treating 0.7 m^2/L (36 ft^2/gal) to maintain deposition rate.

(u) Control of pH achieved by adding 28% solution of ammonium hydroxide

In-Process Corrosion. During periods of high humidity, magnesium parts in process often exhibit corrosion products, even though protected with a chrome pickle. This is especially true of sand castings. The corrosion products are readily removed by treating the parts in a boiling dichromate solution as shown in Fig. 5. The parts are then protected from further corrosion by slushing oil.

Difficulties with Chemical and Anodic Treatments

Difficulties experienced with chemical and anodic treatments result from the lack of control of processing variables. One difficulty common to all treatments, chemical or anodic, is nonuniformity of coating or actual failure to coat on certain areas of a part. This is most likely to occur on complex parts and is caused by the entrapment of air in pockets or blind holes. The remedy is to agitate parts when first placing them in the bath and to reposition them periodically to make sure the bath is brought into contact with all areas.

Other difficulties and their corrections vary for each chemical or anodic treatment. Tables 5, 6, and 7 describe the usual appearance of coatings produced by the chrome pickle, sealed chrome pickle, dichromate, Chemical Treatment No. 9, Chemical Treatment No. 17, and HAE treatments, and list common difficulties, as evidenced by deviations from usual coating appearance, together with causes of these difficulties and procedures to be followed for their correction.

Table 5 Causes and corrections of difficulties with coatings produced by the chrome pickle and sealed chrome pickle treatments

Normal appearance of coating, matte gray to yellow red iridescent

Difficulty	Cause	Corrective procedure
Pale color, shallow etch, slow reaction of solution with metal	Depletion of the chrome pickle bath. Paleness of color should not be confused with the lack of color from insufficient exposure to air during transfer to rinse	Revivify bath by additions of nitric acid and sodium dichromate to restore to proper operating level. Control bath by periodic chemical analysis of ingredients

Bright, brassy--smooth surface with occasional pits(a)	Excess of nitric acid in the bath	Adjust with additions of sodium dichromate to restore proper ratio of dichromate to acid
	Buildup of excessive amount of magnesium nitrate in the bath	Bath has been revivified too many times; discard and use fresh bath
Brown, nonadherent, powdery coatings	Work held in air too long before rinsing	Delay in air; 5 s max; surface should not dry before rinsing
	Ratio of acid to sodium dichromate concentration too high	Adjust concentrations to restore proper ratio
	Solution too hot because of small volume in relation to work	Cool solution or increase volume of solution used
	Metal not properly degreased	Use recommended cleaning method
	Oil film on solution	Prevent by using recommended cleaning procedures(b)
	Solution revivified too often	Discard; use fresh solution

Note: When viewed under magnification, coating exhibits a network of pebbled etching. The appearance of a properly applied chrome pickle coating is influenced to some degree by the age of the solution and by the composition and temper of the alloy treated.

(a) When examined under magnification.

(b) Correct by skimming off oil and adding small amount, 0.05%, of fluorinated-hydrocarbon wetting agent

Table 6 Causes and corrections of difficulties with dichromate coatings

Normal appearance varies from light to dark brown, depending on alloy composition

Difficulty	**Cause**	**Corrective procedure**
Abnormally heavy coatings	pH of dichromate bath too low, below 4.1	Raise pH by addition of NaOH
	Contact between work and tank	Insulate parts and rack from tank
Loose, powdery coatings	Acid fluoride or HF bath too dilute	Adjust fluoride content
	pH of dichromate bath <4.1	Raise pH by addition of NaOH
	Parts oxidized, corroded, or flux-contaminated	Chromic acid clean parts prior to dichromating

	Contact between work and tank	Insulate parts and rack from tank
Failure to coat, or nonuniform coatings	pH of dichromate bath >5.5	Lower pH by addition of CrO_3
	Dichromate concentration too low	Do not allow dichromate to fall below 120 g/L (16 oz/gal); maintain as high as economical
	Oily matter not removed; previous chrome pickle coating not completely removed	Careful rinsing after alkaline cleaning; use chromic acid pickle to supplement alkaline cleaning for complete removal of chrome pickle coating
	Part not fluoride treated	Give part acid fluoride or HF pickle before dichromating
	Part is made of EK30A, EK41A, HK31A, HM21A, HM31A, or M1A	Dichromate treatment does not coat these alloys; use another treatment
	Dichromate bath not kept boiling during treatment period	Solution should actually boil; minimum bath temperature, 93 °C (200 °F)
	High carryover of acid fluoride or HF into dichromate bath	Thoroughly rinse parts after acid fluoride or HF pickle
	Hydrofluoric acid dip too long	Use $\frac{1}{2}$ to 1 min for AZ31A and B; if 5 min dip is used, extend cold water rinse to 5.7 min
Pitting or other attack on aluminum inserts or attachments	Hydrofluoric acid dip reacts on aluminum	Use sodium, potassium, or ammonium acid fluoride solution in place of hydrofluoric acid dip

Table 7 Causes and corrections of difficulties with coatings produced by anodizing treatments

Difficulty	**Cause**	**Corrective procedure**
Chemical treatment No. 9[(a)]		
Grayish, nonuniform appearance	Insufficient or improper cleaning of work before treatment	Use proper methods for adequate cleaning
	Treating solutions depleted	Check pickling bath, HF or acid fluoride, for proper pH[(b)]
Failure to coat on certain alloys[(c)]	Lack of good external electrical contact of work with tank or cathode plates	Ensure good external electrical contact between work and cathode
	Work touching tank walls or bottom (or cathode plates)	Prevent work from contacting cathode in electrolyte

Chemical treatment No. 17(d)		
Deviation from characteristic appearance	Improper balance in content of bath ingredients(e)	Adjust bath ingredients to proper operating range; use chemical analysis to determine need
Spalling of dark green coating	Unusually thick coatings may spall when substrate is bent or otherwise deformed	Spalling can be minimized by sealing coating with an organic finish having low surface tension, low viscosity, and slow drying rate
HAE anodizing treatment(f)		
Significant color lightening	Depletion of the chemical ingredients of the bath(e)	Adjust aluminum and manganese contents to proper level(g)

(a) Usual appearance of thin coating; light tan; thick coating; dark brown.

(b) Galvanic anodizing bath is maintained at a pH of 5.6 to 6.0 with additions of a solution containing, by weight, 5% H_2SO_4 (concentrated).

(c) Especially alloys without aluminum content such as EK30A, EK41A, HK31A, HM21A, HM31A, and HZ32A.

(d) Usual appearance of a thin coating: light green; thick coating: dark green. A clear, colorless coating can also be deposited by Chemical treatment No. 17 by use of 40 V as terminal voltage.

(e) Solution unbalance may occur after treatment of as little as 0.4 m^2/L (20 ft^2/gal) of solution; however, when applying clear or thin coatings, 2 to 2.6 m^2/L (100 to 130 ft^2/gal) of solution usually can be treated before bath adjustment is indicated.

(f) Usual appearance of thin coating: light tan; thick coating: dark brown.

(g) Fluoride and phosphate become depleted at an extremely low rate and require adjustment only every few months in production.

For example, the adhesion of paint films applied to dichromated parts can be adversely affected by the presence of a dusty material on the parts after final rinsing and drying. Chemical analysis might indicate this material to be a sulfate precipitated from the domestic water that was being used to replace evaporation losses in the dichromating solution. The problem can be solved by recycling: storing the steam condensate obtained from heating the solution and installing an automatic level-control system to feed this condensate into the dichromating tank.

Although dichromating usually treats the metal satisfactorily, another example of special difficulties might involve a residue of dye-penetrant developer that can remain on the surfaces of castings and interfere with the adhesion of paint films. In this situation, vapor degreasing, either before or after the dichromating treatment, would only set the developer, rather than effect its removal. Thorough cleaning of parts to remove all developer residue immediately after penetrant inspection, and before vapor degreasing, can solve the problem. This cleaning would entail the use of an alkaline cleaner and, if necessary, scrubbing with a bristle brush.

Another example involves corrosion products that were observed surrounding stainless steel hardware that had been inserted into sand castings of alloy AZ91A before dichromating. The parts were free from corrosion immediately after application of the finish; corrosion occurred while parts were in storage.

The corrosion of the magnesium was found to be the result of a galvanic couple set up between the magnesium and stainless steel, caused by the entrapment of acid solution during dichromating. This condition was eliminated by applying the dichromate treatment to the castings before inserting the stainless steel parts, and by applying a coating of zinc chromate primer to the stainless steel parts just before inserting them into the castings.

Precision-machined parts that were given a chromic acid pickle might present another example of difficulty if the parts were found to have an etched surface. Analysis of the bath might indicate the presence of a high concentration of chloride and sulfate ions, 0.5 g/L (0.07 oz/gal), of Cl, as NaCl, and 1.7 g/L (0.2 oz/gal) of SO_4, as H_2SO_4,the source of which might be traced to the prepared water. Because chloride and sulfate ions cannot be readily removed, the bath would probably be discarded. To prevent further loss of parts, baths must be checked frequently and test panels treated for 15 to 30 s and examined; an evolution of gas during treatment and a dimensional change indicate that a bath is contaminated and must be discarded.

As another example, spacecraft parts were only given a Chemical Treatment No. 17 anodize for corrosion protection. Although this treatment was satisfactory during indoor in-plant processing, white corrosion appeared during stand-by in the salt air and fog atmosphere at the launch pad. This attractive anodic coating is porous and not corrosion-protective. Parts were sealed with a paint system to correct the problem.

Inspection Methods. Examine coatings on treated parts visually for complete and uniform coverage and for color peculiar to the type of treatment being checked. Buildup caused by the coating is determined most simply and reliably by measurement of the parts, before and after treatment, with a micrometer accurate to 2.5 μm (0.1 mil). If this is not possible, measure test panels that have been treated simultaneously with the parts before and after treatment.

Process test panels together with panels through all the steps of cleaning, pretreatment coating, and where applicable, post-treatment. Post-treatment should not consist of an additional film of coating, organic or inorganic, applied either by spraying or dipping. After processing for the time required to produce the coating, test panels should be subjected to the following tests:

- *Abrasion resistance:* The test panels should be rubbed by the tip of a 4.7 mm ($\frac{3}{16}$ in.) diam Pyrex rod, the end of which has been heated in a blast flame until it is fire polished and hemispherical. Press the rod against the coating and rub back and forth by hand with just enough pressure to abrade the surface of the rod. The coating should not break or show scratches that penetrate to the base metal.
- *Salt spray (fog) exposure:* The treated test panels, when exposed to salt spray in accordance with Federal Test Method 151 for a specified number of hours, rinsed in tap water, and air dried, should show an average of no more than eight corrosion spots, none larger than 0.8 mm ($\frac{1}{32}$ in.) in greatest dimension. Corrosion appearing at the electrical-contact area or at the edges of the test panels may be disregarded.

Plating

All commercial plating systems can be applied to magnesium alloys after proper preplating operations. However, zinc and nickel are the only metals that can be plated directly on magnesium. These deposits are not used commercially, but instead serve as undercoatings upon which other commonly plated metals are deposited. Standard practice for plating magnesium involves surface conditioning, zinc immersion plating (zincate solution), and a cyanide copper strike to a thickness of 8 μm (0.3 mil), followed by any standard plating process.

The preparation of magnesium for electroplating is similar in principle to that prescribed for many other metals. First, magnesium must be cleaned to remove all surface contaminants. Then, depending on the surface finish desired, it must be conditioned. This may be accomplished by one or more of the following finishing methods: glass or plastic bead blasting, pickling, barrel finishing, and polishing and buffing. Surface contaminants resulting from these treatments must be removed by additional cleaning. Depending on the type of soil, suitable cleaning methods include vapor degreasing, emulsion cleaning, alkaline soak cleaning, and water rinsing. Finally, the magnesium surface must be activated chemically before it can accept either of the recommended metal undercoatings.

Nickel Undercoating. The deposition of nickel on magnesium must be preceded by two acid etching treatments, one in a chromic-nitric acid solution and another in a solution of hydrofluoric acid. These pretreatments of magnesium, in combination with the deposition of a nickel undercoating, are generally referred to as the chemical-etching process.

Figure 11 illustrates the successive steps involved in alkaline cleaning, etching, and nickel plating. Operating conditions and pertinent data are given in the accompanying table. The nickel undercoating may be deposited from either an electrolytic, acid-fluoride, plating bath, or an electroless immersion bath as shown:

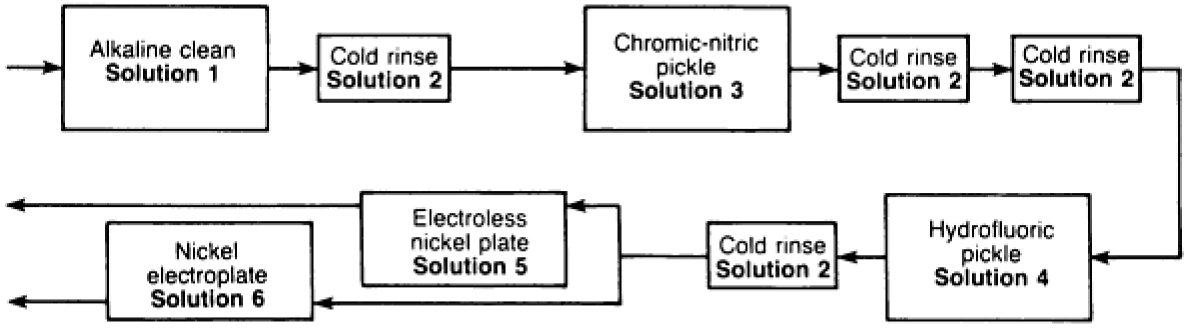
Constituent or condition	**Value or range**
Electroless nickel	
Basic nickel carbonate, g/L (oz/gal)	9.7 (1.3)
Hydrofluoric acid as 70% HF, mL/L (fl oz/gal)	6.4 (0.85)
Citric acid, mL/L (fl oz/gal)	5.2 (0.7)
Ammonium acid fluoride, g/L (oz/gal)	15 (2.0)
Sodium hypophosphite, g/L (oz/gal)	20.3 (2.7)
Ammonium hydroxide, mL/L (fl oz/gal)	30.4 (4.06)
Water	bal
pH (colorimetric)	4.5-6.8(a)
Operating temperature, °C (°F)	76-82 (170-180)
Agitation required	Mild mechanical
Rate of deposition (approx), μm/h (mil/h)	20 (0.8)
Nickel electroplate	
Basic nickel carbonate, g/L (oz/gal)	120 (16.0)
Hydrofluoric acid as 100% HF, mL/L (fl oz/gal)	43 (5.7)

Citric acid, g/L (oz/gal)	40.6 (5.4)
Wetting agent[(b)], g/L (oz/gal)	0.7 (0.1)[(c)]
Water	bal
pH (colorimetric)	3.0
Operating temperature, °C (°F)	48-60 (120-140)
Current density, A/dm^2 (A/ft^2)	3-10 (30-100)
Cathode-rod agitation, m/s (ft/min)	0.06-0.08 (12-16)

(a) Preferred, 6.5.

(b) Example, sodium lauryl sulfate.

(c) 1 g/L (0.134 oz/gal)



Solution No.	Type of solution	Composition	Amount	Operating temperature, °C (°F)	Cycle time, min	Tank material
1	Alkaline cleaner[(a)]	[(b)]	[(b)]	82-100 (180-212)	3-10	Low-carbon steel
2	Cold rinse	Water	. . .	Ambient	$\frac{1}{2}$-1	Low-carbon steel[(e)]

3	Chrome-nitric pickle(c)	CrO_3	125 mL/L (16 fl oz/gal)(d)	21-32 (70-90)	$\frac{1}{2}$-2	. . .
		70% HNO_3	110 mL/L (14 fl oz/gal)(d)			
4	Hydrofluoric pickle	70% HF	220 mL/L (28.2 fl oz/gal)(f)	21-32 (70-90)	10	Low-carbon steel(g)
5	Electroless nickel(h)	Basic nickel carbonate	9.7 g/L (1.3 oz/gal)	77-82 (170-180)	(i)	Low-carbon steel(j)
		Hydrofluoric acid (as 70% HF)	6.2 mL/L (0.8 fl oz/gal)			
		Citric acid	5.2 g/L (0.7 oz/gal)			
		Ammonium acid fluoride	15 g/L (2.0 oz/gal)			
		Sodium hypophosphite	20.3 g/L (2.7 oz/gal)			
		Ammonium hydroxide	30.4 mL/L (4.0 fl oz/gal)			
		Water	bal			
		pH (colorimetric)	4.5-6.8(k)			
6	Nickel electroplate(l)	Basic nickel carbonate	120 g/L (16.0 oz/gal)	49-60 (120-140)	(i)	Low-carbon steel(m)
		Hydrofluoric acid (as 100% HF)	43 mL/L (5.7 fl oz/gal)			
		Citric acid	40 g/L (5.4 oz/gal)			
		Wetting agent(n)	0.7 g/L (0.01 oz/gal)(o)			
		pH (colorimetric)	3.0			

(a) Alkaline cleaning may be preceded by vapor degreasing, emulsion cleaning, or mechanical cleaning.

(b) Type and strength of solution governed by degree of surface contamination.

(c) Solution must be ventilated.

(d) For aluminum-containing alloys. For alloys containing no aluminum, concentrations are 226 g (8 oz) CrO_3 and 326 g (11.5 oz) of 70% HNO_3 and water to make 3.8 L (1 gal).

(e) Stainless steel or low-carbon steel lined with polyethylene.

(f) For alloys containing more than 5% Al. For all other alloys, solution contains 195 g (6.9 oz) 70% HF and water to make 3.8 L (1 gal).

(g) Lined with polyethylene, synthetic rubber, or vinyl-based material.

(h) Agitation of work is recommended.

(i) Time determined by required thickness of nickel deposit.

(j) Lined with polyethylene, saran, or Lucite.

(k) Preferred, 6.5.

(l) Direct current required; agitation of cathode bar recommended.

(m) Lined with synthetic rubber or vinyl-based material.

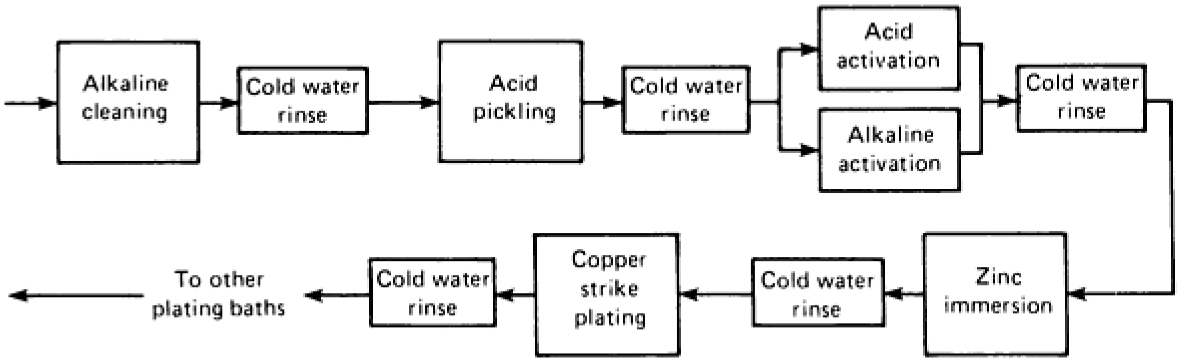
(n) Example, sodium lauryl sulfate.

(o) 1 g/L (0.13 oz/gal)

Fig. 11 Preparing magnesium alloys for nickel plating

To some extent, the two etching treatments undercut surface pits to provide mechanical anchorage for the plated deposits. After a nickel undercoating is applied to this roughened surface, the surface of the coating is not as bright or as smooth as that obtained with the zinc immersion process. However, in common with zinc coating, nickel coating can accept any of the standard electrodeposits, including cadmium, zinc, copper, brass, nickel, black nickel, chromium, gold, silver, and rhodium. Electroless deposits, such as gold or copper, also may be applied over the initial nickel plate.

Zinc Undercoating. After being alkaline cleaned, acid pickled, and surface-activated, magnesium can be prepared for plating by being immersed in a nonelectrolytic chemical bath that produces a thin deposit of zinc directly on the base metal. The basic steps, operating conditions, and tank materials required for the zinc immersion process are summarized in the flow chart and table of Fig. 12. After the immersion treatment, the very light zinc coating about 2.5 μm (0.1 mil) thick must be protected by a copper strike plate before any other standard electrodeposit may be applied. The following are the various steps that comprise the zinc immersion process, as well as the various solutions used.



Operation	Cycle time, min	Solution temperature		Tank material
		°C	°F	
Alkaline cleaning[a]	3-10	87-100	190-212	Low-carbon steel
Acid pickling	$\frac{1}{2}$-1	21-32	70-90	Ceramic or stainless steel[b]
Acid activation	1-5	21-32	70-90	Rubber, polyethylene, or vinyl plastisol
Alkaline activation	2-5	76	170	Stainless steel
Zinc immersion	1-3	79-85[c]	175-185[c]	Stainless steel
Copper strike plating[d]	6-10	65-71	150-160	Low-carbon steel; rubber
Cold water rinses	$\frac{1}{2}$-1	Ambient	Ambient	Low-carbon steel

(a) May be preceded by solvent cleaning, mechanical cleaning, or both.

(b) Mixtures containing fluorides require polyethylene, vinyl-based or synthetic rubber linings.

(c) Automatic temperature control preferred.

(d) Cathode agitation, constant filtration, and automatic temperature control preferred

Fig. 12 Preparing magnesium alloys for copper plating. See text for details of solution composition and other

operating conditions.

Alkaline cleaning, as used in the electroplating of magnesium, consists of soak cleaning or cathodic electrocleaning, or a combination of both. These processes are described in detail in the article on alkaline cleaning in this Volume. Strong caustic solutions are used to remove segregated metal, graphite, and other surface contaminants. The composition and operating conditions for one water solution of this type are:

Sodium hydroxide (NaOH), g/L (oz/gal)	120-720 (1-6)
Temperature, °C (°F)	99-170 (210-340)
Time, min	10-20

Follow this treatment by an acid dip to remove the heavy film of hydroxide.

Acid Pickling. Depending on magnesium alloy composition and product form, the following acid pickling solutions can be used prior to plating. All standard alloys and forms of magnesium can be pickled and chemically brightened by the use of the aqueous solution that follows:

Chromic trioxide (CrO_3), g/L (oz/gal)	180 (24.0)
Ferric nitrate ($Fe(NO_3)_3 \cdot 9H_2O$), g/L (oz/gal)	40 (5.3)
Potassium fluoride (KF), g/L (oz/gal)	3.5-7 (0.05-0.9)
Temperature, °C (°F)	Room temperature, 21-32 (70-90)
Time, min	$\frac{1}{4}$-2

All magnesium alloys and forms can be pickled under the following conditions:

Phosphoric acid, 85% H_3PO_4	No dilution
Temperature, °C (°F)	Room temperature, 21-32 (70-90)

Time, min	$\frac{1}{4}$-5

Sheet, extrusions, and forgings can be pickled in the following aqueous solution:

Glacial acetic acid (CH_3COOH), mL/L (fl oz/gal)	280 (37.4)
Sodium nitrate, g/L (oz/gal)	80 (10.7)
Temperature, °C (°F)	Room temperature, 21-32 (70-90)
Time, min	$\frac{1}{2}$-2

Where little or no dimensional change is permitted, parts may be pickled in an aqueous solution of chromic acid, 180 g/L (24.0 oz/gal) of chromic trioxide of water at any temperature from room to boiling temperatures. This dip removes graphite, oxides, and other soils without removing an appreciable amount of metal.

Surface Activation. To obtain an adherent and uniform coating of zinc on magnesium, the surface of the magnesium must be activated by immersion in a special acid or alkaline solution. The acid activating bath removes thin oxide or chromate films left by prior pickling or cleaning operations with a minimum of etching of the base metal. It also produces an equipotentialized surface on which the zinc immersion coating can deposit uniformly. The composition and operating characteristics of an aqueous acid activating solution in common use are:

Phosphoric acid, 85% H_3PO_4, mL/L (fl oz/gal)	200 (26.7)
Ammonium acid fluoride (NH_4HF_2), g/L (oz/gal)	100 (13.3)
Temperature, °C (°F)	Room temperature, 21-32 (70-90)
Time	25 s to 2 min

Operation of acid fluoride activating baths at appreciably below 21 °C (70 °F) may result in poor adhesion of the electroplated deposit.

An alkaline pyrophosphate activating solution also removes oxides and other films; by virtue of its alkalinity, it does not dissolve the metals employed for rack contacts. Thus, there is little or no danger that metals such as iron or copper can plate out by immersion at locations adjacent to rack contacts. This form of stray plating prevents the proper deposition of the subsequent zinc immersion coating. The composition and operating characteristics of the alkaline solution are:

Tetrasodium pyrophosphate ($Na_4P_2O_7$), g/L (oz/gal)	40 (5.3)
Sodium tetraborate ($Na_2B_4O_7$), g/L (oz/gal)	70 (9.3)
Sodium fluoride (NaF), g/L (oz/gal)	20 (2.7)
Temperature, °C (°F)	76 (170)
Time, min	2-5

The bath should not be operated much above 76 °C (170 °F), as the alkaline solution has a tendency to dry on the parts prior to rinsing. For this reason, the transfer from hot activator to water rinse should be as rapid as possible.

Zinc Immersion Coating. Standard zinc immersion baths (Table 8) are based on aqueous solutions of pyrophosphate, a zinc salt, a fluoride salt, and, if required, a small amount of carbonate for adjusting alkalinity to the proper range. The pyrophosphate dissolves oxide and hydroxide films to form water-soluble complexes. By effecting film removal under specific conditions of pH, temperature, and bath concentration, a thin, adherent coating of metallic zinc is deposited. Fluoride is added to control the rate of zinc deposition. To a considerable extent, the quality and adhesion of the zinc deposit depends on the rate of deposition; too rapid a rate usually produces less adherent coatings.

Table 8 Composition of zinc immersion bath

Activator	**Constituent**	**Concentration**			
		Nominal		**Range**	
		g/L	**oz/gal**	**g/L**	**oz/gal**
Acid	Oxalic acid $(CO_2H)_2$	5	0.7	2-10	0.3-1.3
Alkaline	Potassium pyrophosphate ($K_4P_2O_7$)	60	8	50-150	6.5-10.0
	Sodium carbonate (Na_2CO_3)	15	2	10-20	1.3-2.6

The most commonly used zinc immersion solution has composition and pH as follows:

Zinc sulfate monohydrate ($ZnSO_4 \cdot H_2O$), g/L (oz/gal)	30 (4.0)

Tetrasodium pyrophosphate ($Na_4P_2O_7$), g/L (oz/gal)	120 (16.0)
Sodium fluoride (NaF), g/L (oz/gal)	5 (0.7)
or	
Lithium fluoride (LiF), g/L (oz/gal)	3 (0.4)
Sodium carbonate (Na_2CO_3), g/L (oz/gal)	5 (0.7)
pH	10.0-10.6 (10.2-10.4 preferred)

Within limits, the bath constituents can vary from the above formula provided the ratio of pyrophosphate to zinc is kept to the proper range and fluoride concentration is maintained at the level indicated. Water for preparing the bath should be reasonably free from iron and other heavy-metal salts. Ordinary tap water may be used, but deionized water is preferred.

The bath is prepared by first dissolving the zinc sulfate monohydrate in water at room temperature. The solution is then heated to 60 to 82 °C (140 to 180 °F), and tetrasodium pyrophosphate is added slowly, while stirring. The white, fluffy precipitate (sodium zinc pyrophosphate) that first forms dissolves after further stirring for 5 to 10 min or longer, depending on the degree of agitation and temperature. Next, fluoride is added and then carbonate. The amount of carbonate added is the average required to produce the proper pH and should be determined by the actual pH of the solution. Sulfuric or phosphoric acid can be added to reduce pH, when necessary. The pH values given above are those determined by colorimetric methods; electrometric values, using a standard glass electrode, are 0.5 pH lower.

The bath is operated at 79 to 85 °C (175 to 185 °F). Mild agitation is used to prevent stratification, particularly when water is added to replace evaporation losses. Immersion time depends on alloy composition, bath temperature, surface preparation, and other variables; usually it ranges from 1 to 3 min, but it may be as long as 10 min for aluminum-containing alloys.

As indicated in Fig. 12, the tank should be made of stainless steel. Low-carbon steel, unless it is heavily nickel plated, will cause excessive iron contamination of the solution.

The zinc immersion bath has a fairly long life and can be maintained by analysis and regular additions. Eventually, it becomes contaminated with dissolved magnesium and other impurities and must be discarded.

Copper strike plating in a cyanide bath should follow immediately after the application of the zinc coating. The work should make electrical contact with the cathode bar before being immersed in the plating bath. If the work is to be subsequently plated in an alkaline bath or in a modified noncorrosive fluoride nickel bath, flash copper deposits of 3 μm (0.1 mil) or less are adequate. However, if an acid bath is to be used, copper deposits of 8 μm (0.3 mil) minimum are required to protect the base metal from chemical attack, and the work must be thoroughly neutralized and rinsed after the flash plating cycle.

In some applications, because of the complexity of the parts or porosity of the base metal, increasing the minimum thickness of the copper strike plate could be necessary. Castings, because of porosity, generally require a slightly higher minimum thickness of copper when the subsequent plating bath is to be an acid type.

A high current density 3 to 4 A/dm^2 (30 to 40 A/ft^2) is applied for $\frac{1}{2}$ to 1 min, and then reduced to 1.5 to 2.5 A/dm^2 (15 to 25 A/ft^2). Prolonged strike plating at high current density causes poor adhesion and blistering. Any other metal usually electrodeposited can be applied after flash copper plating is completed.

Zinc Undercoating for Die Castings. Whereas AZ91 with 9% Al is frequently used for die castings, any surface areas with aluminum-rich segregates are difficult to zincate. The best compromise for castability and plating characteristics is the AZ71 composition with a lower aluminum content of 7%. The section of this article on surface activation outlines normal practice of either an acid or alkaline activation after acid pickling and before zinc immersion plating (Fig. 12). Hot chamber magnesium die castings can be successfully plated using an acid activation followed by an alkaline activation. The patented process follows:

1. Acid activation, 0.3 to 1 min, 21 to 29 °C (70 to 85 °F)
2. Cold water rinse, minimum 1 min
3. Alkaline activation, 0.3 to 1 min, 60 to 65 °C (140 to 150 °F)
4. Cold water rinse
5. Zinc immersion bath, 60 to 65 °C (140 to 150 °F)

Acid copper is more efficient than semi-bright nickel for leveling and filling pits in the castings.

Uses of Plated Magnesium. Copper-nickel-chromium plating systems on magnesium satisfy decorative and protective requirements for interior and mild exterior environments. They have not found application for parts exposed to severe marine or salt splash conditions because of the accelerated galvanic corrosion that can occur wherever small areas of magnesium may be exposed by porosity or mechanical damage to the plating. Hard chromium plating provides excellent wear resistance and long working life for magnesium photoengraving plates. Electroless nickel plating on magnesium has found use in the computer and electronics industries for applications requiring corrosion and wear resistance, solderability, and stable electronic contacts; copper plus hot-flowed tin plating are also used. Gold over electroless nickel is used in space applications of magnesium.

Corrosion Resistance. Satisfactory corrosion resistance, especially in marine exposures or with salt-spray testing, is obtained only when the plated deposit is pore-free. Porosity in the base metal promotes porosity in the plated deposits; consequently, corrosion resistance of plated magnesium alloy parts having appreciable surface porosity is less than that of parts that have a minimum of surface porosity. This is evident from the results of salt-spray corrosion studies of plated wrought and sand cast alloys. Less total plate thickness is required to give comparable corrosion resistance over wrought alloys than over cast alloys. The results with wrought alloys are much more consistent over a number of tests than are those with cast alloys, undoubtedly because of the amount of variation in surface porosity or surface quality of the sand castings tested.

In general, on the same type of base metal, either wrought or cast, corrosion resistance is a function of total plate thickness. Service tests should be conducted to determine the best systems and plate thicknesses to give satisfactory corrosion resistance. Suggested minimum total plate thicknesses for decorative chromium plating and copper-nickel-chromium are shown in Table 9.

Table 9 Minimum total plate thicknesses for decorative chromium plating

Service environment	**Wrought alloys**		**Cast alloys**	
	µm	**mils**	**µm**	**mils**
Interior	13	0.5	19	0.75
Mild exterior	25	1.0	38	1.5
Average exterior	32	1.25	50	2.0

Severe exterior	38	1.5	64	2.5

Quality Control. The most widely used methods for determining the quality of plated deposits on magnesium alloys are adhesion, relative-humidity, and salt-spray tests. Relative-humidity and salt-spray tests are considered standard acceptance tests where corrosion resistance is required.

Adhesion tests are conducted by either baking the plated parts at 175 to 260 °C (350 to 500 °F) for 1 h followed by air cooling or immersing the plated parts in an oil bath at about 260 °C (500 °F) for a sufficient time for the parts to reach the temperature of the bath followed by quenching in a room-temperature kerosene bath, and then inspecting the parts for evidence of blistering. The absence of blistering of the plate generally indicates that proper adhesion of the plate has been obtained. These heat tests are simple, effective, and inexpensive nondestructive methods for determining adhesion and are particularly convenient where 100% testing of parts is required.

Stripping of Plated Deposits. Plated deposits can be satisfactorily stripped from magnesium alloys with little if any attack of the base metal.

Zinc immersion deposits can be stripped in a room-temperature bath containing 10 to 15 vol% of 70% hydrofluoric acid (HF). The standard acid activator as used prior to zinc immersion coating can also be used.

Chromium can be stripped by reverse current in a hot alkaline solution, such as one containing 60 to 75 g/L (8 to 10 oz/gal) of sodium hydroxide (NaOH), or combinations of sodium hydroxide and sodium carbonate, in water.

Copper can be stripped by immersion in hot alkaline polysulfide followed by a dip in cyanide, as in stripping copper from steel or die cast zinc.

Nickel can be stripped in a bath containing 15 to 25% HF and 2% sodium nitrate ($NaNO_3$), using 4 to 6 V. Work to be stripped is made anodic; cathodes can be carbon, lead, or magnesium.

Copper, nickel, tin, cadmium, and zinc can be stripped by immersion in the following solution, operated at room temperature: nitric acid (sp gr, 1.42), 1 part by volume; hydrofluoric acid, 70%, 2 parts; water, 2 parts. The tank for containing the solution should be made of polyethylene or some similar material.

Gold, silver, copper, and nickel can be stripped by immersion in proprietary alkaline chemical strippers containing cyanide. Add 15 g/L (2 oz/gal) of sodium hydroxide (NaOH) per gallon of prepared solution to aid in preventing possible etching of the magnesium base metal. Operating temperature of the bath may range from 21 to 60 °C (70 to 140 °F). Low-carbon steel tanks and heating coils are used.

Organic Finishing

Organic finishes are used on magnesium alloys to attain various effects in appearance and to provide durability. Organic finishing systems require careful adherence to manufacturers' recommendations on solvents, baking schedules, and compatibility of prime and finish coats to achieve desired film properties and adhesion.

A chemical conversion coating or anodizing treatment is required prior to application of organic coatings if the optimum in corrosion durability is desired. These treatments roughen and chemically modify the metal surface so that a good stable bond can be achieved with the paint coating applied. Surface treatments are not used for every application, however, as indicated in Table 1. Some commercial parts are coated with no more than mechanical cleaning. Oven drying should be used following spray or immersion surface treatment of castings to ensure that all moisture is driven from the porosity of the cast surfaces prior to applying bake-cured finishes. It has also been found that anodized components provide greatly improved corrosion durability, if the porosity, common to all, is sealed with a penetrating resin sealer prior to the application of primer and top coats (Ref 13).

Table 10 contains information on various appearance effects that are attainable with the mechanical or chemical pretreatment and organic finishing systems required for interior and exterior applications. Military finishing is controlled by specifications; Table 11 lists the various finishing steps involved and indicates the appropriate Government specifications.

Table 10 Organic finishing systems for magnesium alloys

Appearance effect	**Typical finishing system for**	
	Interior service[a]	**Exterior service**[b]
Bright metal	Buff + ferric nitrate bright pickle + clear epoxy or acrylic	Buff + ferric nitrate bright pickle + clear epoxy or acrylic
Satin finish	Wire brush + ferric nitrate bright pickle + clear epoxy or acrylic	Wire brush + ferric nitrate bright pickle + clear epoxy or acrylic
Tinted clear	Ferric nitrate bright pickle + tinted epoxy or acrylic	Not recommended
Dyed clear	Ferric nitrate bright pickle + clear epoxy or acrylic + dye dip	Not recommended
Metallic	Chrome pickle or dilute chromic acid + epoxy, acrylic, polyvinyl butyral or vinyl pigmented with metal powder or paste	Chrome pickle or dilute chromic acid + 1 coat polyvinyl butyral primer + epoxy or acrylic pigmented with metal powder(c)
Wrinkle	Chrome pickle or dilute chromic acid + standard wrinkle finish	Not generally used in outdoor service
High-gloss enameled	Chrome pickle or dilute chromic acid + epoxy, acrylic, polyurethane or alkyd enamel	Chrome pickle or dilute chromic acid + 1 coat polyvinyl butyral primer + acrylic, alkyd or polyurethane enamel
Leatherette (smooth or textured)	Chrome pickle or dilute chromic acid + vinyl cladding	Chrome pickle or dilute chromic acid + vinyl cladding
	Chrome pickle or dilute chromic acid + vinyl organosol	Chrome pickle or dilute chromic acid + polyvinyl butyral or vinyl primer + vinyl organosol

(a) Suggested minimum total film thickness, 25 μm (1 mil).

(b) Suggested minimum total film thickness, 50 μm (2 mils); marine environments may require total film thickness of 75 μm (3 mils).

(c) Or metal paste

	Gloss	TT-E-489

Selection of Paint. Both air-drying and baking paints are currently in use. Baking paints are harder and more resistant to attack by solvents. Vinyl alkyds have been used for their resistance to alkali, acrylics for resistance to salt spray, alkyd enamels for exterior durability, and epoxies for good abrasion resistance. Vinyls can withstand temperatures up to about 150 °C (300 °F). Other finishes have increasing temperature resistance in this order: modified vinyls, epoxies, modified epoxies, epoxy-silicones, and silicones.

Primers for magnesium should be based on such alkali-resistant vehicles as polyvinyl butyral, acrylic, polyurethane, vinyl epoxy, and baked phenolic. Zinc chromate or titanium dioxide pigments are commonly used in these vehicles for corrosion inhibition. Finish coats are chosen to have:

- Compatibility with primer
- Adaptability to shop conditions and to finishing equipment available
- Ability to perform in service
- Economy consistent to compliance with service requirements

For a detailed discussion of types of paints and methods of application, see the article on painting in this Volume.

Examples of problems that might arise in productive painting of magnesium alloy products are given below, together with details of the methods used to solve them.

The first problem, masking multiple threaded inserts in castings before painting, was solved by this method:

1. A chemical-resistant finish was applied before drilling and tapping the castings for inserts.
2. Holes were then tapped and drilled.
3. Castings were reprocessed through the dichromate to treat threaded holes.
4. Inserts were set in zinc chromate sealer.

Another example involves bubbles and fisheyes appearing in the baked wrinkle-finish paint on dichromated magnesium alloy die castings. This condition was eliminated by lowering the paint-baking temperature from 150 °C (300 °F) to 120 °C (250 °F) and adding a baking cycle of 2 h at 175 °C (350 °F) after the dichromating treatment.

Die castings given a chrome pickle treatment followed by baked coats of primer and wrinkle-finish enamel present another example of problems that might arise. When the primer was applied and baked, small bubbles formed on the film surface; these would later break, leaving an unsightly ring on the surface and affecting uniformity and appearance of the wrinkle finish. Preheating the castings to drive out entrapped air and painting them after they had cooled, greatly reduced the number of bubbles but did not completely eliminate their formation. Painting the castings while they were still hot from the preheating solved the problem.

Stripping of Paint. The ability of magnesium alloys to withstand strong alkalis lessens the problem of paint removal. After painted parts are soaked in a hot, 82 °C (180 °F), solution containing 360 g/L (3 lb/gal) of sodium hydroxide in water, most paints dissolve or lose adhesion to the extent that they can be removed by flushing with water, hand brushing, or other mechanical means. Paint strippers with a phenol or methylene chloride base may be used, but extended soaking of more than 24 h causes slight etching of the magnesium alloy, which is undesirable for close-tolerance machined areas.

Stripping vinyl-based enamels from dichromate-treated magnesium is more difficult. One method entails softening the coating and weakening the bond by soaking in methylene chloride for $\frac{1}{2}$ to 1 h, then resetting the paint by soaking in hot alkalis for 5 to 30 min. The loose paint is then brushed off, and any remaining paint is removed by wet blasting with 150-mesh aluminum oxide. This stripping operation should be followed as soon as possible by a dichromate treatment.

Chrome pickle and dichromate coatings can usually be removed in hot sodium hydroxide. Old chromate coatings are usually more difficult to remove and work to be stripped of them may require soaking in sodium hydroxide solution followed by immersion in a chromic acid pickling solution.

Special baked primers and other finishes that are difficult to remove in a sodium hydroxide solution may be stripped by being immersed for 5 min or longer in the following solution, at 82 to 100 ° C (180 to 212 °F):

Sodium hydroxide, vol%	10-20
Diethylene glycol, vol% or ethylene glycol, vol%	10 20
Water	bal

Coatings that are difficult to remove by the methods described above can be effectively stripped by mild abrasive blasting using plastic media. Plastic media blasting is widely used for stripping of aircraft and aerospace components with little or no damage to the substrate.

Health and Safety

Magnesium and magnesium oxide dusts are considered nontoxic. The usual precautions taken to prevent gross inhalation of dirt, dust, and other foreign matter are required. No unusual health hazard has been found associated with the handling, mechanical finishing, or pickling of magnesium alloys, including those containing thorium or beryllium.

Some of the chemical baths used contain chromate or fluorides. Because of the toxic nature of these materials, adequate ventilation is required when baths containing chromate or fluorides are used.

Although bulk magnesium is difficult to ignite unless temperatures are near the melting point, finer particles, such as chips, sawings, and especially sanding dust, are more easily ignited. Proper handling of these materials is required to prevent ignition.

Polishing and Buffing. Special precautions must be followed in the polishing and buffing of magnesium alloys. Magnesium dust or powder must not be allowed to accumulate because it will create extreme fire and explosion hazards. The fire hazards produced in buffing are somewhat less than those produced in polishing. Belt polishing is potentially more dangerous than wheel polishing because the resulting dust is more difficult to collect.

Under no circumstances should steel be polished in the same setup that is used for polishing magnesium, because the polishing of steel causes sparks that can ignite magnesium dust. Because of strong oxidizing properties, heavy chromate coatings also cause sparking when magnesium alloy parts to which they have been applied are being polished.

A system considered safe for the collection of magnesium grinding and polishing dust is one in which the dust is precipitated by a heavy spray of water or low-viscosity mineral oil to form a sludge with a great excess of liquid. The equipment must be designed so that the sludge does not accumulate and dry out and thus become flammable. Inspect the dust-collecting system periodically to ensure that the dust is kept moist.

The best collectors for grinding or polishing stands are small units that serve one or two stands and have the power supply for the grinder or polisher, water circulation, and air blower interconnected so that the grinder or polisher cannot operate unless the collector system is operating. Connect the grinding or polishing machine to the collector by short, straight ducts. Do not allow dry dust to accumulate in the ducts. Clean all polishing machines each day, dust collector and suction pipes at least once a week.

Hydrogen is formed in the reaction of magnesium with water. Ventilate sludge pits adequately to prevent the accumulation of hydrogen. The sludge that collects under the hood frequently must be removed and spread out in thin layers on a noncombustible surface in a safe, isolated area. The sludge may be burned in small quantities. Sludge from dust collectors may be rendered noncombustible by reacting it with a 5% solution of ferrous chloride ($FeCl_2 \cdot 2H_2O$) in an open container placed outdoors.

Central collecting systems in which the dust is passed through long dry ducts, or conventional dust collectors using dry filters, are definitely not recommended, because accident records have indicated dry systems of these types to be extremely dangerous.

Wire Brushing. The dust generated during wire brushing also must be trapped in a water-wash dust collector to minimize fire hazards and prevent the formation of explosive concentrations. This same method of collection has proved suitable for removing the dust during the wire brushing of sheet containing thorium (HK31A and HM21A) and preventing contamination of the air and work area with low-level radioactive dust.

Surface Engineering of Titanium and Titanium Alloys

A. Bloyce, P.H. Morton, and T. Bell, University of Birmingham, U.K.

Introduction

TITANIUM AND ITS ALLOYS are characterized by low density relative to other structural metals and alloys, excellent corrosion resistance, and high specific proof strengths. Since titanium first became available in the mid-twentieth century, its major area of application has been in the aerospace industry, which makes up about 80% of its usage. Its level of use in chemical and petrochemical applications is also significant, and the combination of chemical and specific mechanical properties make titanium alloys ideal candidates for prosthetics in joint replacements. The desire to reduce moving mass in machinery is increasing interest in its use outside of these sectors (e.g., for use in general engineering applications, where titanium-base material is often a direct replacement for ferrous materials).

The first part of this article is concerned with cleaning and finishing operations that are used throughout titanium-related industry and are widely applied to semifabricated products (see Ref 1 and *Materials Properties Handbook: Titanium Alloys*, ASM International, 1994). The second part of the article describes surface engineering processes and their application to titanium-base materials, which are, in the main, applied to near-finished components. These processes are used either to improve the wear resistance of the titanium-base material or to improve its oxidation resistance:

- The poor wear resistance of titanium (Ref 2) is caused by its low c/a ratio as a hexagonal close-packed metal. The slip systems produce relatively low shear strengths and a high coefficient of friction. Lower tensile strengths allow relatively easy material transfer to conterfaces in adhesive wear. Low hardness allows damage by abrasive and related wear mechanisms.
- The oxidation (Ref 3) and general corrosion resistance of titanium and its alloys are excellent at relatively low temperatures, but for conventional alloys, at around 430 °C (800 °F) and above, depending on exposure time, oxygen is taken up by the substrate, which causes embrittlement. Titanium γ-aluminide alloys have useful mechanical properties up to ~900 °C (1650 °F), but their oxidation resistance is satisfactory to only ~815 °C (1500 °F).

Some of the processes described in this article, such as electroplating and thermal spraying, are widely used; others, such as ion implantation, are starting to find industrial applications; still other processes are as yet used only for prototyping or producing relatively small numbers of products, such as for use in racing cars.

The dominant engineering characteristics of the metal and its alloys are their ability to form a tenacious surface oxide film in air that dissolves in the titanium and the fact that titanium reacts with all but the most stable materials at some temperature.

Cleaning and Finishing

Cleaning and finishing processes for titanium and its alloys are similar to those for other metals. Proper selection of processes, methods, and cleaning solutions are of major importance to procure maximum use of the finished metal and to maintain safe procedure during the working of titanium materials.

Generally, a heavy oxide layer resulting from hot working of the metal is removed by grit blasting or other mechanical means, or by salt bath descaling. After removal of the scale, further mechanical or chemical treatment is applied to remove the hardened, oxygen-rich metallic case beneath the scale in order to avoid cracking during subsequent working operations. Heavy grease, oil, and black lubricant coatings resulting from cold working are removed by alkaline or caustic soaking, followed by acid pickling. To remove soil or light oil from a metal, cleaning by detergents, solvent washing, or vapor degreasing is generally applied.

Cleaning and Descaling Problems

The metallurgical and chemical properties of titanium create a number of very special cleaning problems:

- Affinity of titanium to common gases
- Galvanic effects caused by discontinuities in scaled surfaces
- Metallurgical restrictions on the temperature of the descaling media

- Variety of scales encountered in titanium descaling
- Protective coatings used in titanium manufacturing

Gas Absorption. The property that causes the most difficulty is the capacity of titanium to absorb common gases, including oxygen, hydrogen, and nitrogen, all of which tend to embrittle the product. Because tightly packed hot-rolling scale acts as partial protection against additional gas absorption, some mills perform two or three heat treatments over the scale. Each additional heat treatment toughens the scale and compounds descaling difficulties. An additional problem is that heat-treating furnace atmospheres are maintained on the oxidizing side to prevent hydrogen pickup. A layer of oxygen-rich metal (Fig. 1) develops beneath the resulting scale formation, varying in thickness from 0.05 to 0.07 mm (0.002 to 0.003 in.) in the heat-treated condition to 0.15 to 0.20 mm (0.006 to 0.008 in.) in the hot-rolled condition. This brittle surface is usually removed by acid or electrolytic chemical pickling.

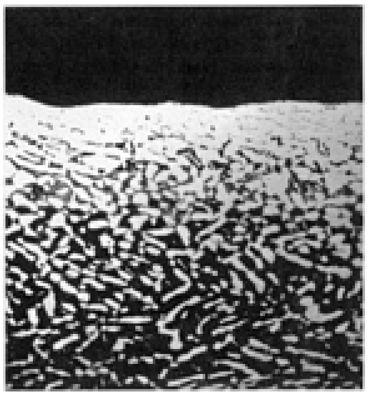

Fig. 1 Ti-6Al-4V alpha case. 250×

Galvanic effects and discontinuities in the surface scale are encountered in all types of metal descaling, but they appear to be more pronounced in titanium. Although the exact cause of small pits or cells formed in descaled material is debatable, possibilities include alloy or nonmetallic segregations, scale porosity, and surface contamination. A more severe galvanic attack problem is created by patch scale conditions on titanium surfaces when areas of heavy scale flake away from an apparently uniform surface. The same problem has been observed with superimposed oxides, even though the surface layer may be quite thin and powder-like. Surface contamination with oil, grease, or fingerprints can also create a patch scale condition. All of these factors promote severe localized attack when areas of the substrate metal are exposed selectively during descaling. Some producers have considered reoxidation of the product during processing as a possible solution.

Metallurgical Restrictions on Descaling. Solution-treated, age-hardenable titanium alloys are sensitive to time-temperature reactions and the temperatures of descaling media. The metastable or high-beta alloys, which are solution treated and aged at temperatures ranging from 370 to 540 °C (700 to 1000 °F) for $\frac{1}{2}$ h or more, may undergo a subsequent aging effect and cause a change in mechanical properties. This is particularly true in thin-gage sheet materials and may cause property changes of as much as 70 MPa (10 ksi) in tensile strength. These alloys normally should not be allowed to exceed 260 °C (500 °F).

Variety of Scale. Another factor that contributes appreciably to titanium descaling problems is the wide variety of scale encountered, including scale formed by annealing, forging, solution treating, stress relieving, extruding, rolling, aging, hot forming, or a combination of several of these operations. With processing temperatures ranging from 425 to 1150 °C (800 to 2100 °F), the scale spectrum for titanium is far broader than for most other difficult-to-descale materials.

Protective coatings are often used in titanium manufacturing operations. These coatings, which are an asset and a necessity in manufacturing operations, become a liability and a contaminant in cleaning operations. They are soluble and removable if the proper techniques are used. Protective coatings are applied to titanium surfaces during manufacturing operations to:

- Lubricate and aid in metal flow, good die contouring, and forming operations
- Act as barrier films, reducing gas contamination during high-temperature forming and heat-treating cycles
- Reduce surface flaws caused by nicking and scratching during manufacturing operations

The gas protective films are usually applied directly to the titanium surface. They are silicate-based materials that deposit uniform fusible films through solvent evaporation. These films form glassy barriers at treatment temperatures up to 815 °C (1500 °F) and are quite effective in reducing oxygen, hydrogen, and nitrogen contamination. Above 815 °C (1500 °F), most of these films are less effective, because speroidizing creates voids in the film. Lubricant films or abrasion-protective films are applied over a silica-based coating. This process has the advantage of providing double protection against scratching and scoring. During hot forming operations and metal surface stretching, some voiding and penetration occurs, creating a titanium oxide on the surface. The contaminant then consists of organic bond or residues, graphite, molybdenum disulfide, silicates, and titanium oxides.

Removal of Scale

Scale is removed from titanium products by several mechanical methods. Abrasive methods, such as grinding and grit blasting, are preferred for removing heavy scale from large sections. Centerless grinding is used for finishing round bars, and wide-belt grinding is used for finishing sheet and strip. Grinding is usually most efficient when it is performed at low wheel and belt speeds.

Most alloy sheet materials with a high aluminum content, such as Ti-5Al-2.5Sn, are ground to eliminate pits and a rippled condition that develops in hot rolling as a result of discontinuous slip during plastic deformation. Grinding is frequently used to eliminate surface defects before cold rolling. Originally, strip was ground on standard strip grinders, using various oil lubricants; however, oils contributed to fire hazard and several grinding machines were partially or wholly destroyed when the oil ignited. When titanium was ground with aluminum oxide belts, a water lubricant was less effective than air. The water reacted with the aluminum oxide to form a weak hydroxide that proved ineffective as a grinding lubricant.

Belt Grinding. Dry belt grinding is dangerous because fine titanium powder can explode or ignite. Dry belt grinding is also uneconomical because of poor belt life. When stock is removed during dry grinding, small globules of molten metal and oxide roll along the sheet, causing a type of pitting by burning that is not removed by the grinding. Weld grit scratches and embedded grit result when titanium welds to the dry grit.

A 5% aqueous solution of potassium orthophosphate, K_3PO_4, is widely used as a grinding lubricant. It is applied as a flood at both the entrance and exit sides of the contact line. Water-soluble oils, particularly highly chlorinated and sulfochlorinated oils, have also been successful as lubricants. These compounds should be used with care because of the possibility of chloride residues remaining as an integral part of the surface. Both types of lubricants improve grinding efficiency when the belts are coated with aluminum oxide or silicon carbide.

Flooding the work with lubricant is recommended; however, machines built for flooding are equipped with a recirculating and filtering system and waterproof cloth belts, and they are expensive. An alternative is to spray a water-soluble wax fog through atomizing nozzles on the line of contact at both the entrance and exit sides of the belt. The solution should not be sprayed through an ejector that mixes it with air and increases the fire hazard; instead, it should be sprayed as an atomized liquid. Application of the spray can be controlled to volatilize the lubricant during grinding. This eliminates the need for waterproof belts. Care must be exercised to avoid a buildup of titanium chips that may cause a fire. Chips that would wash away in a flood are not removed by the spray.

Titanium should be ground at belt speeds not exceeding rates of 8 m/s (25 ft/s). Using a 5% solution of potassium orthophosphate as a lubricant, maximum efficiency is achieved at about 6 m/s (18 ft/s). Both billy roll and flat table grinding machines have been successful in grinding titanium. Sheet grinding machines, equipped with feed rolls, sometimes leave a ground line on the sheet where the feed rolls, on the exit side of the machine, and interrupt uniform travel when they grip the sheet. A high degree of grinding uniformity is obtained on machines equipped with a flat table and vacuum chuck. On these machines, the table holding the sheet usually oscillates. Traveling-head machines are available also.

The belt grinding sequence is usually begun with an 80-grit belt when it is necessary to remove more than 0.07 mm (0.003 in.) of stock from the surface of the sheet. Descaling and pickling the sheet before grinding prolongs belt life. Following the initial grit, each successive grit must remove enough stock to eliminate the scratches caused by the previous grit. The alpha alloys, such as Ti-5Al-2.5Sn, are less sensitive to surface condition than the alpha-beta alloys, such as Ti-6Al-4V. Surface pits on Ti-6Al-4V sheet, caused by weld grit scratches, seriously detract from bend ductility. A flow chart for the belt grinding of Ti-6Al-4V sheet is shown in Fig. 2.

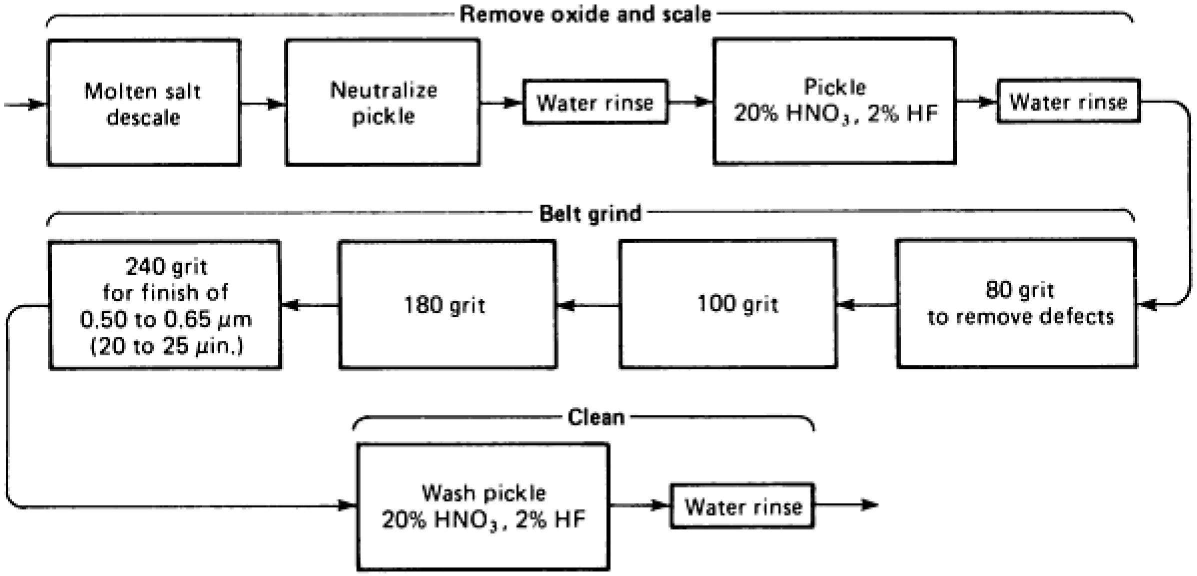

Fig. 2 Cleaning and belt grinding sequences for Ti-6Al-4V sheet

Abrasive blast cleaning techniques, either wet or dry, are convenient for removing scale from a variety of titanium products, ranging from massive ingots to small parts. Because it can be used at lower velocities and is less likely to be embedded in the surface, alumina sand is preferred to silica sand.

Sheet thicknesses to about 0.50 mm (0.020 in.) can be descaled without distortion if fine sand and low velocities are used. Mill scale on titanium products can be removed with coarse high-carbon steel shot or grit, whereas finished compressor blades can be cleaned with zircon sand of 150- to 200-grit. The type of product to be cleaned, the cleaning rate, and the cost of the abrasive must be balanced in the selection of a specific blast cleaning method.

Mineral abrasive particles, such as silica, zircon, or alumina sands, are used more commonly than metal abrasives for blasting finished or semifinished products. Although these abrasives are more expensive, they produce the finer finish that is required in final processing or service. Adequate safety precautions must be observed to avoid inhalation of fine sand particles. Air-circulating and dust-collecting systems must be cleaned frequently and equipped to cope with the fire hazard associated with titanium dust.

A fine dust remains on the titanium from the blasting operation, particularly when mineral abrasives have been used. This is not considered detrimental, although a washing or pickling cycle following the blast is desirable if the part is to be welded subsequently. The following describes a wet blasting procedure and a dry blasting procedure used for descaling titanium parts:

- *Wet blasting:* Parts are wet blast cleaned, using a slurry that consists of 400-grit aluminum oxide (40 vol%) and water. Air pressure of 655 kPa (95 psi) is used to pump the slurry in a steady stream with a pressure of about 34 kPa (5 psi). The descaling rate, normally about 50 min/m^2 (5 min/ft^2), depends on the complexity of the part. Distortion and the need for planishing are held to a minimum by placing the blast nozzle approximately 50 mm (2 in.) from the workpiece and by using a 60° angle of impingement.

- *Dry blasting:* Rocket motor case assemblies are dry blasted after final stress relieving at 480 to 540 °C (895 to 1005 °F). Blasting is accomplished with 100- to 150-grit zircon sand at an air pressure of 275 kPa (40 psi). Each assembly is rotated at 2.5 rpm and is passed at a speed of 65 mm/min (2.5 in./min) between two diametrically opposed fixed-position blasting nozzles. The nozzles blast the inside and outside surfaces simultaneously at the same wall location. To prevent distortion, each nozzle is placed at the same distance, 300 mm (12 in.), from the metal surface.

Molten salt descaling baths are primarily used for descaling, bar, sheet products, and tubing. With the most effective barrier films available today, some gas penetration of titanium surfaces can be expected at the elevated temperatures required for working and heat treatment. The alpha case or oxygen-enriched layer resulting from this gas reaction is extremely hard and brittle and must be removed. Bar products used for machining finished parts must have this hard scale and oxide removed because they are very abrasive and cause rapid tool wear. These scales must be removed before welding or forming, or poor and small welds will be made and forming (hot or cold) will be virtually impossible without surface rupture or failure of parts. Removal presents no serious problems, because chemical milling techniques have been perfected by the aircraft industry to effect weight savings. In the case of titanium, the purpose is to improve the structural soundness of metal, and the solvent materials applied are of a different chemical composition.

One specific problem encountered in alpha case removal is that the titanium oxide formed is substantially more insoluble in the nitric hydrofluoric etchant than the base metal. Residues of oxide on the surface develop areas resembling craters on the finished product. Figure 3 illustrates the effect of surface condition on etched metal surfaces.

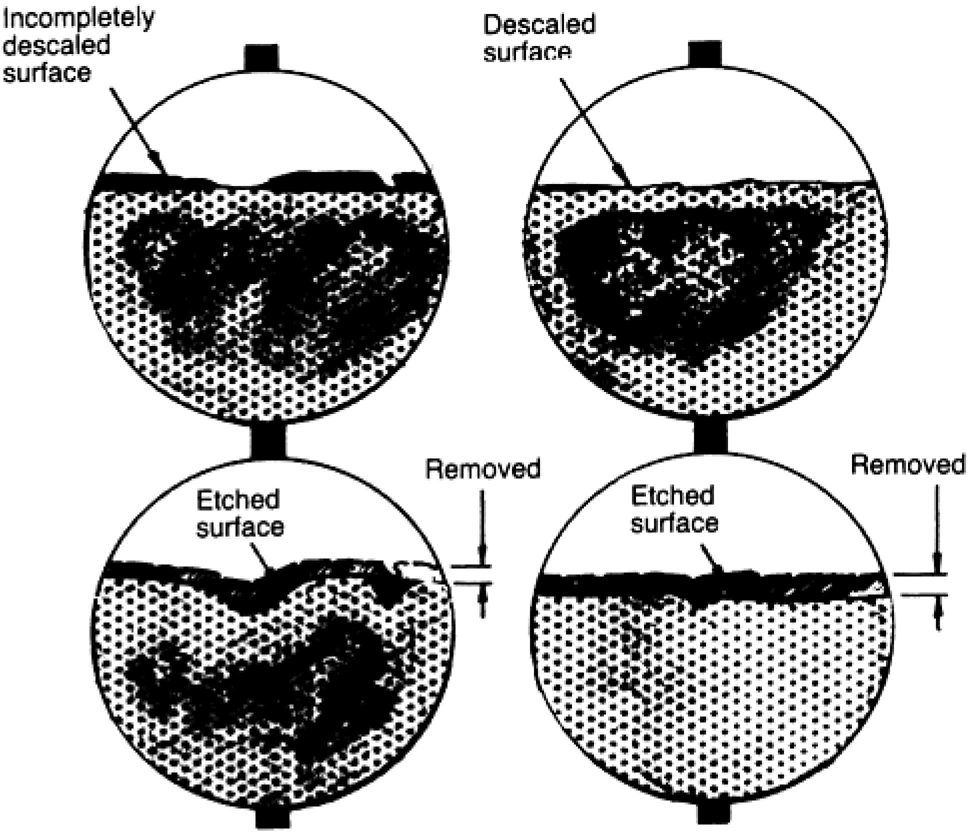

Fig. 3 Effect of surface condition on etched metal surface

Where alpha case removal is required, salt bath cleaning is specified, because proper cycling practically guarantees a chemically clean surface. Conditioning salt baths fall into two basic categories: high-temperature salt baths and low-temperature salt baths.

High-temperature salt baths may vary in chemical reaction and effectiveness, depending on composition. All types operate at a range of 370 to 480 °C (700 to 895 °F). The temperature range is sufficiently high to produce the most rapid reaction possible for soil and oxide films. High-temperature oxidizing salt baths are also capable of reacting chemically with organic films to destroy them. These baths are also excellent solvents for silicate barrier films. They do require special fixturing to reduce the strong galvanic effects present at these temperatures, and for this reason, they are used in cleaning primary forming operation products, such as forgings, extrusions, rolled plate, and sheet. The major advantage of high-temperature oxidizing or reducing salt baths for titanium descaling is their great speed in removing extremely tenacious scale. Although reducing baths have the inherent disadvantage of promoting hydrogen absorption, this can be overcome or minimized by chemical additions. Vacuum degassing is another solution.

A primary producer of titanium sheet uses an oxidizing salt bath for removing the hot-work scale in the following sequence of operations:

1. Immerse in oxidizing salt for 5 to 20 min at 400 to 480 °C (750 to 895 °F).
2. Quench with water 1 min.
3. Immerse in sulfuric acid, 10 to 40 vol%, for 2 to 5 min at 50 to 60 °C (120 to 140 °F).
4. Rinse with water 1 min.
5. Recycle if necessary.
6. Pickle in nitric-hydrofluoric acid solution, time and concentration as required.

The same producer also uses a sodium hydride reducing salt bath for descaling high-beta or metastable beta alloys. A typical cycle using this type of salt is:

1. Immerse in reducing salt for 1 to 3 min at 370 °C (700 °F).
2. Quench in water 1 min.
3. Immerse in sulfuric acid (10 to 40 vol%) for 2 to 5 min at 50 to 60 °C (120 to 140 °F).
4. Rinse in water.
5. Pickle in nitric-hydrofluoric acid solution, time and concentration as required.
6. Vacuum degas or decontaminate titanium beta alloys that absorb hydrogen in reducing baths.

These baths are used by one major aerospace contractor for cleaning titanium blades for jet engines. The blade materials are Ti-6Al-4V and Ti-8Al-1Mo-1V. The descaling cycles for removing oxides and proprietary glass-like compounds from these blades are:

1. Immerse in oxidizing salt for 15 min at 455 °C (850 °F).
2. Rinse in cold water.
3. Pickle in solution of 35% nitric acid and 3.5% hydrofluoric acid for 1 min max at 20 °C (70 °F).
4. Rinse in hot water.

Low-Temperature Baths. The temperature range used for cleaning fabricated parts is 200 to 220 °C (390 to 430 °F). Descaling systems based on salts in this temperature range eliminate some of the possible problems associated with higher-temperature baths, including:

- Age hardening
- Dissimilar metal reactions
- Chemical attack
- Metal distortion

- Hydrogen embrittlement

Salts in this range have a very limited composition because of the effect of various compounds on the melting point. Although they contain oxidizing agents, the effect of these materials is not as aggressive as it is in the high-temperature fused salts. Consequently, organic materials are not destroyed, but are saponified and absorbed. Silicate barrier films and molybdenum disulfide are soluble in these low-temperature salts. The temperature range permits cycling between salt and acid to reduce cleaning times and costs. Examples of salt bath and acid cycle times are given in Table 1.

Table 1 Low-temperature salt bath and acid bath conditions for cleaning titanium alloys

Sample composition	**Scale formation temperature**		**Salt bath immersion time[a], min**	**Acid cleaning bath time[b], min**	**Acid cleaning bath time[c], s**
	°C	**°F**			
Ti-6Al-4V	650	1200	2	2	30
Ti-8Al-1Mo-1V	650	1200	2	2	30
Ti-8Al-1Mo-1V	820	1510	5	2	30
Ti-6Al-4V[d]	820	1510	5	5	30
Ti-6Al-4V[e]	950	1745	5	5	60
Ti-8Al-1Mo-1V[f]	950	1745	5	5	60

(a) Salt bath temperature 205 °C (400 °F).

(b) Bath composition, 30% sulfuric acid.

(c) Bath composition, 30% nitric acid, 3% hydrofluoric acid.

(d) Sample recycled in salt bath for 5 min, in sulfuric acid bath for 5 min, in nitric acid-hydrofluoric acid bath for 30 s.

(e) Sample recycled in salt bath for 5 min, in sulfuric acid bath for 5 min, in nitric acid-hydrofluoric acid bath for 60 s.

(f) Sample recycled in salt bath for 5 min, in sulfuric acid bath for 5 min, in nitric acid-hydrofluoric acid bath for 60 s

Aqueous caustic descaling baths have been developed to remove light scale and tarnish from titanium alloys. Aqueous caustic solutions containing 40 to 50% sodium hydroxide have been used successfully to descale many titanium alloys. One bath containing 40 to 43% sodium hydroxide operates at a temperature near its boiling point (125 °C, or 260 °F). Descaling normally requires from 5 to 30 min. Immersion time is not critical because little weight loss is encountered after the first 5 min. Caustic descaling conditions the scale so that it is removed readily during subsequent acid pickling.

A more effective aqueous solution contains either copper sulfate or sodium sulfate in addition to sodium hydroxide. This bath operates at lower temperature (105 °C, or 220 °F). A composition of this solution by weight is: 50% sodium hydroxide, 10% copper sulfate pentahydrate ($CuSO_45H_2O$), and 40% water. Using immersion times of 10 to 20 min, this bath has proved effective in descaling Ti-6Al-4V and Ti-2.5Al-16V alloys.

Pickling Procedures following Descaling

All advantages gained through proper conditioning and handling of titanium parts during cleaning can be lost if the composition of the final pickling acid is not controlled. Cold spent acid solutions increase appreciably the time required for pickling and the possible quality problems experienced with hydrogen pickup. Highly concentrated hot acids can be overly aggressive, resulting in surface finish problems such as a rough and pitted surface caused by preferential acid attack. Sulfuric acid, 35 vol% at 65 °C (150 °F), is recommended for pickling immediately following salt bath conditioning and rinsing to remove molten salt and residual softened scales. An acid of this formula has very little effect on titanium metal. Metal salts in the original and additional acid solutions further minimize these base metal attacks. Table 2 gives conditions for corrosion of titanium in various sulfuric acid pickle baths.

Table 2 Corrosion of titanium in sulfuric acid pickle baths

A nitric-hydrofluoric acid solution, which is the final stage brightening in most alloy cleaning lines, should be maintained at a minimum ratio of 15 parts nitric acid to 1 part hydrofluoric acid to reduce hydrogen pickup effects. The concentration of hydrofluoric acid may vary from 1 to 5%, or even higher as long as the ratio is not exceeded. The activity of these pickle solutions is affected by titanium content, and the acids are frequently discarded at a level of 26 g/L (3 oz/gal). The solution used for final brightening can be used for the required alpha case removal also, with careful watch of titanium content.

Sulfuric acid concentration, %	**Acid addition**	**Bath temperature**		**Corrosion rate**	
		°C	**°F**	**µm/yr**	**mils/yr**
30	0.5% copper sulfate	38	100	100	4.0
30	1% copper sulfate	38	100	20	0.8
30	10% copper sulfate	38	100	400	16.0
30	0.25% copper sulfate	95	205	76	3.0
10	2% ferrous sulfate	Boiling point	Boiling point	125	5.0
17	7-8% ferrous sulfate	60	140	125	5.0

Removal of Tarnish Films

Tarnish films are thin oxide films that form on titanium in air temperatures between 315 and 650 °C (600 and 1200 °F). After exposure at 315 °C (600 °F), the film is barely perceptible, but with increasing temperature and time at temperature, it becomes thicker and darker. The film acquires a distinct straw yellow color at about 370 °C (700 °F) and a blue color at 480 °C (900 °F). At about 650 °C (1200 °F), it assumes the dull gray appearance of a light scale. Alloying elements and surface contaminants also influence the color and characteristics.

Tarnish films are readily removed by abrasive methods, and all but the heaviest films can be removed by acid pickling. Prolonged exposures at temperatures above about 595 °C (1105 °F), in combination with surface contaminants, result in heavier surface films that are not removed satisfactorily by acid pickling and so require descaling treatments.

Acid pickling removes a light amount of metal, usually a few microns. It is used to remove smeared metal, which could affect penetrant inspection. Titanium and titanium alloys can be satisfactorily pickled by the following procedure:

1. Clean thoroughly in alkaline solution to remove all shop soils, soap drawing compounds, and identification inks. If coated with heavy oil, grease, or other petroleum-based compounds, parts may be degreased in trichloroethylene before alkaline cleaning. Degreasing will not be harmful to the part in subsequent processing.
2. Rinse thoroughly in clean running water after alkaline immersion cleaning.
3. Pickle for 1 to 5 min in an aqueous nitric-hydrofluoric acid solution containing 15 to 40% nitric acid and 1.0 to 2.0% hydrofluoric acid by weight, and operated at a temperature of 24 to 60 °C (75 to 140 °F). The preferred acid content of the pickling solution, particularly for alpha-beta and beta alloys, is usually near the middle of the above ranges. A solution of 33.2% nitric acid and 1.6% hydrofluoric acid has been found effective. When the buildup of titanium in the solution reaches 12 g/L (2 oz/gal), discard the solution.
4. Rinse the parts thoroughly in clean water.
5. High-pressure spray wash thoroughly with clean water at 55 ± 6 °C (130 ± 10 °F).
6. Rinse in hot water to aid in drying. Allow to dry.

To avoid excessive stock removal, the recommended immersion times for pickling solutions should not be exceeded. It is equally important to maintain the composition and operating temperature of the bath within the limits prescribed to prevent an excessive amount of hydrogen pickup. Gage loss from all acid pickling after descaling is estimated to be less than 0.025 mm/min (0.001 in./min), depending on the combination of variables used.

Hydrogen contamination is estimated to be 0 to 15 ppm per 0.025 mm (0.001 in.) of metal removed, depending on alloy composition and gage material pickled. Table 3 gives data on hydrogen pickup for an alpha, an alpha-beta, and a beta alloy pickled in a 15% nitric acid, 1% hydrofluoric acid bath at 49 to 60 °C (120 to 140 °F). Hydrogen contamination can be held to a minimum by maintaining an acid ratio of 10 to 1 or greater of nitric acid to hydrofluoric acid. Hydrogen diffuses more rapidly into the beta phase. Alpha-beta alloys that have α+ β microstructures, which have been heat treated to complete equilibrium, pick up less hydrogen than microstructures of transformed beta and/or simple mill-annealed structures.

Table 3 Effect of titanium alloy composition on hydrogen pickup in acid pickling

Pickling bath is an aqueous solution containing 15% nitric acid and 1% hydrofluoric acid by weight; operating temperature is 49 to 60 °C (120 to 140 °F).

Alloy	**Thickness**		**Hydrogen pickup (gage removed), ppm/0.0250 mm (ppm/0.001 in.)**
	mm	**in.**	
Alpha alloy			
Ti-5Al-2.5Sn	0.50	0.020	0-4
Ti-5Al-2.5Sn	1.00	0.040	0-3
Alpha-beta alloy			

Ti-6Al-4V	0.50	0.020	4-7
Ti-6Al-4V	1.00	0.040	3-5
Beta alloy			
Ti-13V-11Cr-3Al	0.50	0.020	10-15
Ti-13V-11Cr-3Al	1.00	0.040	5-8

Mass Finishing (Barrel Finishing). Oxide films formed by heating to temperatures as high as 650 °C (1200 °F) for 30 min have been effectively removed from Ti-8Mn alloy parts by wet mass finishing. At barrel speeds of 43,000 to 51,000 mm/min (1700 to 2000 in./min), parts have been cleaned satisfactorily in about 1 h. Complete barrel loading procedures for three barrels, ranging from 0.02 to 0.25 m^3 (0.75 to 8.85 ft^3) capacity, are given in Table 4.

Table 4 Mass finishing conditions for titanium parts

Barrel size						Speed, rev/min	Part load		Medium(a)		Water		Abrasive compound(b)		Alkaline cleaner(c)	
Capacity		Diameter		Width												
m^3	ft^3	mm	in.	mm	in.		kg	lb	kg	lb	L	qt	kg	lb	kg	lb
0.02	0.75	381	15	178	7	36	1-2	3-4	18	40	1.2	1.25	0.2	0.5	0.2	0.5
0.07	2.33	559	22	240	10	28	4-5	8-12	54	120	4	4	0.7	1.5	0.34	0.75
0.25	8.85	813	32	457	18	20	14-18	30-40	209	460	14	15	2.3	5	0.5	1

(a) Aluminum oxide nuggets 6.4 to 38 mm (0.25 to 1.5 in.) or preformed vitrified chips 4.8 by 9.5 to 7.9 by 28.6 mm ($\frac{3}{16}$ by $\frac{3}{8}$ to $\frac{5}{16}$ by $1\frac{1}{8}$ in.).

(b) Dry, mildly alkaline compound.

(c) Mild cleaner with high soap content

In mass finishing of titanium parts, the ratio of medium to parts should be between 10 and 15 to 1, depending on the size of the parts. Proportionately more medium is required as part size increases. Water is used to cover parts and medium. Surface finish is improved when more water is added, but cycle time required to obtain a given finish is increased. The rate of descaling increases directly with barrel speed but is limited by the fragility of the parts being processed. Parts are randomly loaded in the barrel and rotated at relatively low barrel speeds to minimize distortion and nicking. Conditions for mass finishing of titanium parts are also given in Table 4.

Aluminum oxide media are the most satisfactory. They do not contaminate the work and have a long useful life. For oxide removal, small well-worn media produce the highest finish. To avoid possible metallic contamination, the medium used for titanium should not be used in processing other metals. Strong acid-forming compounds should be avoided, principally because they are corrosive and contribute to hydrogen embrittlement. Because of the fire hazard created by fine, dry titanium particles, dry mass finishing of titanium parts is not recommended.

Polishing and Buffing

The polishing and buffing of titanium is accomplished with the same equipment used for other metals. Polishing is frequently done wet, using mineral oil lubricants and coolants. Silicon carbide abrasive cloth belts have been effective. It is common to polish in two or more steps, using a coarser grit initially, such as 60 or 80, to remove gross surface roughness, followed by polishing with 120- or 150-grit to provide a smooth finish. Titanium tends to wear the sharp edges of the abrasive particles and load the belts more rapidly than steel. Frequent belt changes are required for effective cutting. A good flow of coolant improves polishing and extends the life of the abrasives.

Dry polishing is more appropriate than wet for some applications. For these operations, belts or cloth wheels with silicon carbide abrasive may be used. Soaps and proprietary compounds may be applied to the belts to improve polishing and to extend belt life. Abrasive belt materials that incorporate solid stearate lubricants offer improved results for dry polishing operations.

Fine polishing of titanium articles for extremely smooth finishes requires several progressive polishing steps with finer abrasives until pumice or rough types of abrasive are applied. With the softer grades of titanium, such as unalloyed material, fine polishing requires more time and care to prevent scratching. The harder alloy grades can be polished more readily to a surface of high reflectivity. If a matte finish is desired, wet blasting with a fine slurry may be used after initial polishing.

Titanium alloys can be buffed safely. The purpose of buffing is to improve the surface appearance of the metal and produce a smooth tight surface. Buffing is used as a final finishing operation and is particularly adaptable to finishing a localized area of a part. Parts such as joint prostheses, pacemakers, and heart valves require a highly buffed tight surface to prevent entrapment of particles. Close-fitting parts for equipment, such as guidance systems and electronics applications, require highly polished surfaces obtained by buffing. In addition, sheet sizes too large to be processed by other abrasive finishing methods, such as mass finishing or wet blasting, can be economically processed by buffing.

The principal limitations of buffing are distortion, caused by the inducement of localized stress; surface burning, resulting from prolonged dwell of the buff; an inability to process inner or restricted surfaces; and the feathering of holes and edges. Proper care of the buffing wheel is essential. Buffing with insufficient compound or a loaded wheel produces burning or distortion of the part. After buffing, no further cleaning of parts is required except degreasing to remove the buffing compound.

Wire Brushing

Wire brushing of titanium alloys is not recommended when other finishing methods, such as buffing, can accomplish the objective. In one case, wire brushing resulted in serious defects. A stiff-bristled wire brush removed surface scratches and oxide films, but the surface was pitted by the wire tips. To avoid pitting, softer wire bristles were tried, and the surface of the titanium acquired a burnished appearance. When the surface layers were cold worked, the grinding scratches, instead of being removed, were filled with smeared metal. Wire brushing with a silicon carbide abrasive grease has been used successfully to remove burrs, break sharp edges from edge radii, and blend chamfers.

Removal of Grease and Other Soils

Removal of grease, oil, and other shop soils from titanium parts is normally accomplished with the same type of equipment and the same cleaning procedures used for stainless steel and high-temperature alloy components.

Vapor degreasing normally employs either trichloroethylene or perchloroethylene. Under certain conditions, these solvents are known to be a cause of stress-corrosion cracking in titanium alloys. Methylethyl ketone is used as a cleaner in situations where chlorinated solutions are not desired. All titanium parts should be acid pickled after vapor degreasing.

Other cleaning methods use chemicals that, if they are left to dry on the part, may have a harmful effect on the properties of titanium. Among these are soda ash, borates, silicates, and wetting agents commonly used in alkaline cleaners; kerosine and other hydrocarbon solvents used in emulsion cleaners; and mineral spirits employed in hand wiping operations. Residues of all these cleaning agents must be completely removed by thorough rinsing. To ensure that a surface that is free of contaminants, rinsing is frequently followed by acid pickling.

Surface Modification

Ion Implantation

The ion implantation process involves the acceleration of ions to a sufficiently high velocity so that they are able to penetrate the surface of the substrate material being implanted. The mean depth of penetration depends on the energy, the atomic number, the atomic masses of the implanted and the target species, and the angle of incidence. A 1 mA beam takes approximately 16 s to achieve a dose of 1×10^{17} ions over 1 cm^2, assuming perfect implantation. Industrial implanters are typically designed to accelerate the ions to energies of between 50 and 200 keV, resulting in implant layer thicknesses of up to several hundred nanometers. High ion current densities, 30 to 40 $\mu A/cm^{-2}$, reduce the time necessary to reach a required dose, but they significantly increase the workpiece temperature, which is also dependent on the thermal mass of the substrate, which may in turn be influenced by appropriate heat sinking.

Wear resistance of titanium and titanium alloys may be improved by ion implantation. This is the most commercially used aspect of the technology applied to titanium substrates. The most commonly implanted species are nitrogen and carbon, which may be noted from a review of the ion implantation of Ti-6Al-4V (Ref 4). This improvement in wear behavior is effected by the increase in surface hardness that is achieved by ion implantation offsetting a change in wear mechanism from mild oxidative to severe adhesive wear. The surface oxide layer formed on titanium and conventional titanium alloy substrates provides a useful low-friction surface, but when this oxide is removed, rapid adhesive wear occurs against many counterface materials. An increase in near-surface hardness allows the material to resist plastic deformation at higher stresses and hence support the oxide at higher stresses. A threefold increase in microhardness at loads of 1 to 2 g can be achieved in these alloys (Ref 5).

There are three mechanisms from which hardening of ion implanted titanium arises: ion-induced damage, solid solution hardening, and precipitation hardening. Ion-induced damage arises from the creation of a dense network of dislocations similar to that achieved during cold working or in shot peening: improvements in fatigue properties may be achieved through appropriate ion implantation. The strain fields associated with the dense dislocation network require that a higher-energy barrier be overcome to enable the atomic motion required for plastic deformation.

Solid solution hardening may be achieved by either substitutional or interstitial alloying elements. The strain field associated with an "impurity" atom increases the load required to permit dislocation movement.

Precipitation hardening is effected by dislocations being pinned by coherent or incoherent precipitates. For the maximum precipitation hardening effect, a fine distribution of coherent precipitates is required. For very low ion doses, $\sim 10^{15}$ to 10^{16} ions/cm^2, damage-induced hardening effects dominate; for intermediate doses, $\sim 10^{16}$ to 10^{17} ions/cm^2, solid solution hardening becomes dominant; for high doses, $>10^{17}$ ions/cm^2, precipitation hardening dominates. The boundaries obviously depend on the physical properties of the implanting and implanted species and the relevant phase equilibria.

The hardening effect achieved in implantation of nitrogen into Ti-6Al-4V is shown in Fig. 4, the maximum hardness increase being in excess of 170% at a depth of 50 nm below the surface. In this case, the microstructure of nitrogen-implanted Ti-6Al-4V consisted of a fine dispersion of TiN precipitates in a deformed nitrogen-rich matrix. This resulted in a hardening of the surface region and the presence of surface compressive residual stresses. A dose of 1×10^{17} atoms N/cm^2 improved the wear resistance, but no TiN precipitation was observed. The survival of the implanted layer was extended by increasing the ion dose to 4×10^{17} atoms N/cm^2, where the hardness increase levels off. The slower oxidative wear mode was obtained against both ruby and steel in ball-against-disc wear tests.

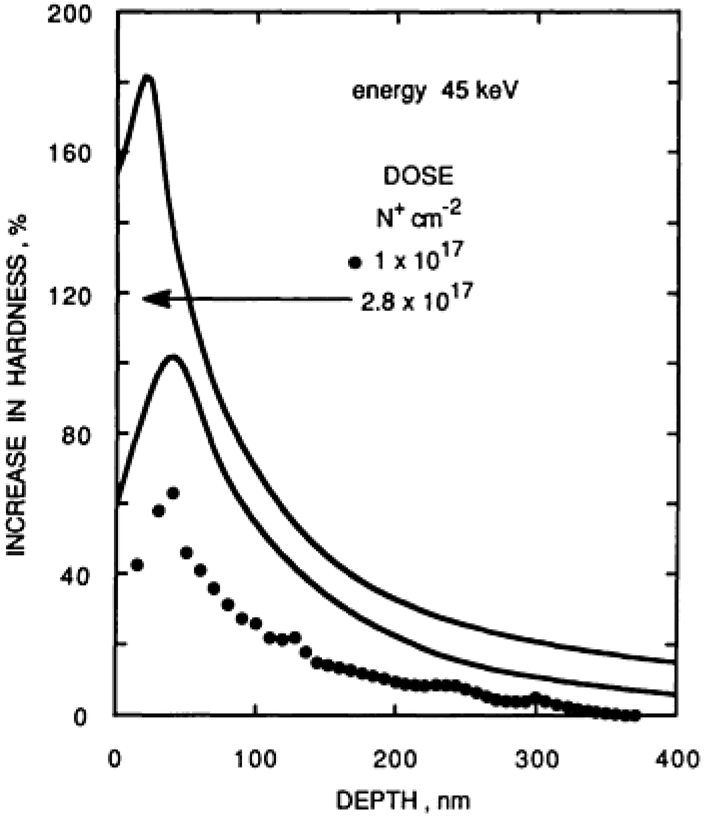

Fig. 4 Percentage increase in hardness with depth into material for N^+ implanted Ti-6Al-4V. Source: Ref 6

In addition to the simple hardening mechanism, ion implantation is thought to supply a reservoir of nitrogen to the oxide layer when it is removed, with the result that the reformed surface layer is possibly an oxynitride. Low wear rates have been maintained to depths two to three times the depth of the implanted layer, which can be explained in terms of physical displacement due to plowing during the wear process. The relative effects on hardness of nitrogen- and carbon-implanted Ti-6Al-4V are shown in Fig. 5. The very low solubility of carbon in α-Ti as compared to that of nitrogen in α-Ti limits the contribution of solid solution strengthening to the hardnesses measured.

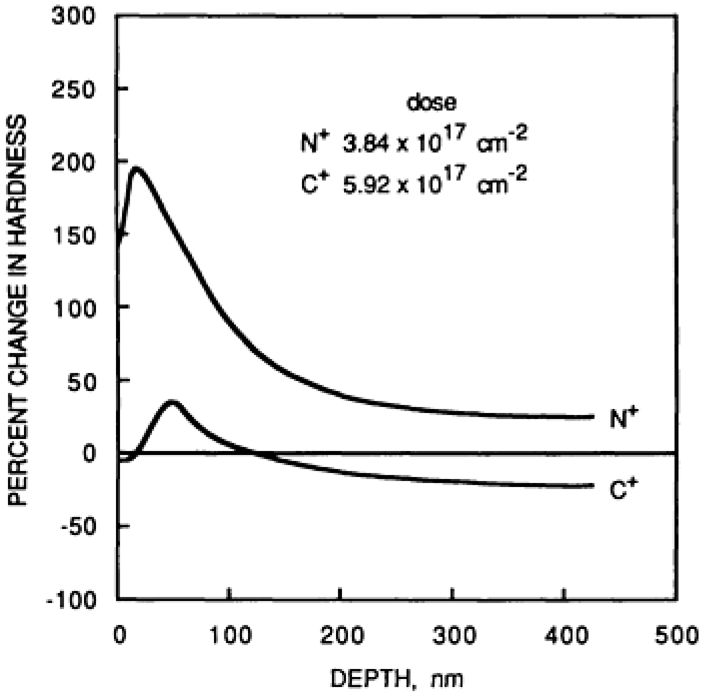

Fig. 5 Percentage change in hardness with depth for N^+ and C^+ implanted Ti-6Al-4V. Source: Ref 7

An example of the application of an ion-implanted titanium alloy is in total joint replacement, where the excellent biocompatibility combined with its specific mechanical properties make the use of Ti-6Al-4V desirable. The combination of this alloy and ultrahigh-molecular-weight polyethylene is unsatisfactory because of unacceptably high levels of wear in the joint. Ion implantation can improve this situation. In α+ β alloys such as Ti-6Al-4V, a hard α-case is produced at the surface because of the high levels of the α-stabilizing element, nitrogen, present. Although significant improvements in wear resistance for ion-implanted femoral heads have been noted in many investigations, wear does occur through a combination of oxidative wear, caused by the loss of the passivating oxide debris. The use of the process in the treatment of biomaterials has reached some degree of commercial maturity (Ref 5). Alloys used in hip, knee, and small quantities of wrist, shoulder, finger, and toe joint replacements are routinely ion implanted. Ion implantation of titanium and titanium alloys for improvements in wear is best summarized by noting that the very small depth to which hardening of the substrate alloy occurs allows these significant improvements to be effective only in moderately mild regimes of wear.

Other areas of application (Ref 5) are found in gas turbines, where discs and blades are implanted. Fretting wear is the problem, which can be significantly reduced by ion implantation. The best results using this process are obtained when one surface is treated with carbon and the other surface is implanted with a different species, such as nitrogen. Titanium gears for a variety of low-load aircraft applications are used because of weight savings, and problems of scuffing can be reduced by nitrogen implantation. Titanium components for use in hydraulic systems are often used because of the corrosion-resistant nature of the metal and its alloys. Ion implantation has been used to reduce galling against both steel and other titanium alloy counterface materials. Titanium ball valves articulating against PEEK valve seats suffer unacceptably high rates of wear, producing leaks after as few as ten open/close cycles. Ion-implanted balls withstand 100 operations with no sign of abrasion.

High cycle fatigue may be influenced by ion implantation with both nitrogen and carbon. Increases in fatigue strength have been measured in rotating beam fatigue tests (Ref 8). The endurance limits have been increased for both implanted species, the largest increase being 20% achieved with carbon implantation. The improvements are attributed to the creation of residual compressive stresses at the surface of the Ti-6Al-4V substrate, though the reasons for the greater improvement achieved with carbon implantation over that achieved with nitrogen implantation are not clear.

Corrosion behavior of titanium and titanium alloys can be modified by appropriate surface alloying using ion implantation. Implantation of molybdenum, tantalum, and molybdenum and tantalum together produces beneficial effects on passivation curves in a sulfuric acid solution (Ref 9). Other implanted species that produce beneficial effects include platinum and palladium. Palladium implantation also improves the resistance of titanium to crevice corrosion and hot chloride solutions (Ref 10).

Oxidation resistance of ion-implanted titanium alloys has been researched using a variety of alloying elements. Oxidation for 50 min in dry oxygen at 600 °C has been reduced by implantation to a level of $\sim 2 \cdot 10^{16}$ ions/cm^2 of species that have either oxides with high negative free energy of formation or large ionic radii for smaller heats of formation (Ref 11). Particularly beneficial effects were obtained from implanting barium, rubidium, cesium, strontium, calcium, ytterbium, and europium. The reduction in oxidation was thought to be caused by implanted impurities obstructing short-circuit diffusion paths or forming Ti + M (implant) mixed oxides. $BaTiO_3$ has been found after barium implantation and oxidation, which improved the fretting fatigue behavior of both titanium and Ti-6Al-4V. Implantation of various elements, including rubidium, cesium, strontium, and calcium, affected the oxidation resistance of titanium (Ref 12). This has been explained in terms of changes in oxidation rate laws, limited solubilities of the implanted elements in the titanium, and the tendency to form ternary oxides with titanium. Implantation of elements in excess of their equilibrium solubility may be necessary for a significant effect on oxidation behavior. Europium, which is one of the less soluble elements in titanium, was shown to produce significant inhibition to oxidation at 600 °C, where the presence of ternary oxides was a prerequisite for a strong inhibitive effect.

Laser and Electron Beam Treatment

Energy beam surface treatment for materials encompasses a wide range of processes, ranging from laser ablation at very high power densities to the transformation hardening of steels and the annealing of metals and alloys at relatively low power densities. The only processes applied to titanium and titanium alloys to any significant extent are surface melting, surface cladding, and surface alloying techniques. These processes all involve the use of the energy beam to melt a surface layer in order to produce a conduction-limited melt profile, as opposed to melting in the "keyhole" regime, which is necessary for deep penetration welding. A conduction-limited melt profile may be close to hemispherical if the beam is a focused spot or something similar, or it may be flat-bottomed if some form of beam scanning across the direction of beam-workpiece relative movement is employed. This molten region may vary in size from <1 μm, where gas alloying is used to mark surfaces, up to >400 μm, where hard surface layers are created for load-bearing, wear-resistant applications. The maximum melt depth is dependent on the absorbed power of the beam by the workpiece, the traverse speed, and the maximum temperature reached in the melt pool before unacceptable surface disruption occurs.

Surface melting using energy beams can homogenize a surface by melting all the microstructural components of the workpiece and allowing the relatively rapid resolidification of the melted region, distributing the phases on a much refined scale, or allowing the phases to solidify as new, metastable phases. In the extreme case, surface melting can be used as a rapid solidification tool by employing very high power densities and very rapid traverse speeds, thus relying on the efficient heat extraction from the melted region by the unheated bulk of the workpiece. In simple terms, the cooling rate, dT/dt, through the solidification range is equal to the product of the temperature gradient, dT/dx, in the melt and the solidification rate, dx/dt, which is the speed of the solidifying interface where T is temperature, t is time, and x is distance. The temperature gradient is related to the power density and the solidification rate is related to the traverse speed or pulse length.

Energy beam surface melting has been carried out using electron beams of powers similar to those commonly used for welding and a variety of lasers, the most useful of which is the carbon dioxide laser, which has output powers ranging from 500 W to multikilowatts. The depth of melting employed is normally between 0.1 and 1 mm, and the beams are usually moved across the workpiece surface at speeds between 5 and 100 mm/s. These parameters result in cooling rates through the solidification range of most alloys, between 10^2 and 10^6 K/s, with the heat being conducted away into the bulk of the workpiece. Mass transport in these melts results from thermal gradients and surface tension gradients.

No significant changes in the overall mechanical properties occur with either commercially pure titanium or Ti-6Al-4V after laser surface melting. For example, columnar beta grains formed upon solidification of Ti-6Al-4V transform to martensite on further cooling (Ref 13). Surface melting has been used to rapidly solidify dispersion-strengthened titanium alloys. For example, titanium plus erbium has been melted with the objective of improving the high-temperature strength of titanium alloys by forming thermally stable dispersoids (Ref 14). Supersaturated solutions containing erbium and oxygen were produced by laser surface melting of experimental alloys, which, after subsequent heat treatment, formed fine dispersions of rare earth oxides, partially coherent with the titanium matrix. Alloys with an excess of oxygen relative to the erbium content for the formation of Er_2O_3 were found to be the most resistant to coarsening of the precipitate.

Energy beam surface alloying is achieved by changing the chemical composition of the substrate material during surface melting. Of the many possible alloying additions, nitrogen is the most widely researched. The object of the process is to harden the surface of the titanium alloy to a depth of 0.1 to 0.5 mm in order to improve its wear resistance. It is usually carried out using a CO_2 laser and incorporates a gas jet blowing nitrogen or nitrogen and argon at the melt pool. By controlling the amount of nitrogen takeup by the melt pool, a range of solidification structures can be obtained that are usually described as predominantly TiN dendrites, nitrogen-rich α-Ti dendrites, or nitrogen-rich basket-weave. In fact, the microstructure most commonly contains TiN dendrites surrounded by nitrogen-rich α-Ti as a result of nonequilibrium solidification through the peritectic of the titanium-nitrogen phase equilibrium system. There is also a series of continuous layers across the surface of the laser-alloyed track that are responsible for the gold color of the surface after the process. The degree of alloying has a direct influence on the hardness of the alloyed volume, which can be simply controlled by changing the interaction time of the nitrogen with the melt pool (i.e., by altering the traverse speed) (Fig. 6) or changing the nitriding potential of the alloying gas (i.e., by diluting the nitrogen with an inert gas such as argon) (Fig. 7).

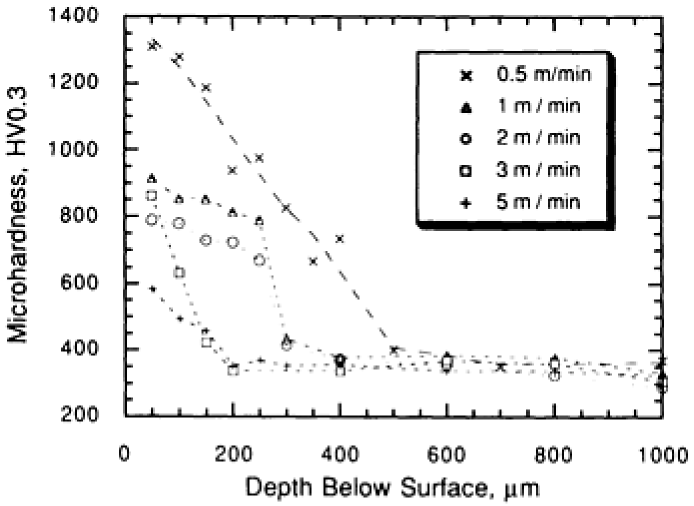

Fig. 6 Influence of feed rate on hardness profile for laser gas nitrided Ti-6Al-4V, 6.6 × 10^4 W/cm^{-2}, 40:60 N2:Ar, 75% track overlap. Source: Ref 15

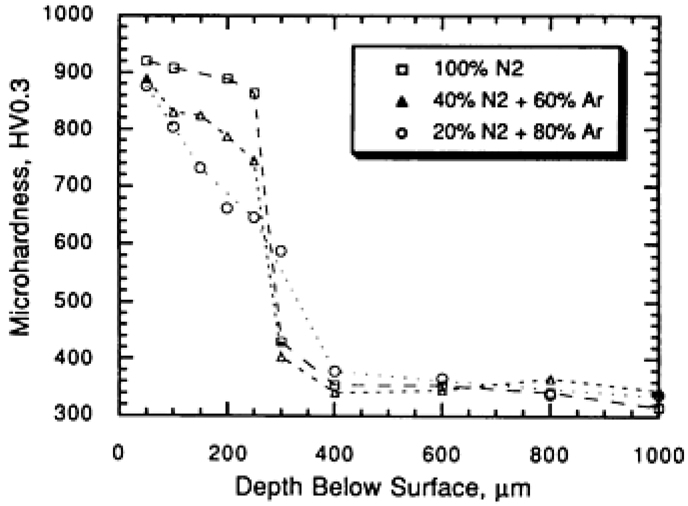

Fig. 7 Influence of gas mixture on hardness profile for laser gas nitrided Ti-6Al-4V, 6.6 × 10^4 W/cm^{-2}, 1 m/min^{-1}, 75% track overlap. Source: Ref 15

The major concerns of this process, and of other energy beam melting processes of all materials, are to avoid cracking, porosity formation, and unacceptably rough surfaces. Cracking is the major problem associated with laser-gas-nitrided titanium; it results from thermal stresses acting on the hard, relatively brittle phases arising from the process. The problem is ameliorated by using a mixture of argon and nitrogen in the treatment gas to produce an alloyed region of less than maximum possible hardness (<650 HV) and by preheating the substrate. With typical processing parameters, if the preheating temperature exceeds 300 °C (570 °F), cracking can be completely eliminated (Ref 15, 16).

Laser gas nitriding has also been used on a much finer scale to produce marking on the surface of, for example, watch cases. Nitrogen is used to produce a gold color, and oxygen may be used to produce a gray color. Carbon dioxide or neodymium yttrium-aluminum-garnet lasers may be used for this process, where melts as shallow as 1 μm are created.

Other systems that have been investigated include carbon and boron alloying. These substances are usually added to titanium alloys by using preplaced graphite or boron powder, although laser gas carburizing of titanium alloys may be achieved using a carbon-bearing gas in a manner similar to that for laser gas nitriding. These two systems produce similar microstructures, which is a reflection of the similarity between the Ti-C and Ti-B equilibrium systems at the relevant compositions. At low alloying additions, a divorced eutectic solidification is predominant where Ti + TiC and Ti + TiB solidify in each system, respectively. At higher interstitial contents, primary TiC and TiB (Ti_2B) solidify as large dendrites, together with the eutectic solidification microstructure. The hardnesses measured in the alloyed regions have been found to be a reflection of the volume fraction of the compounds solidified, because negligible amounts of carbon and boron can be in solution in α- or β-Ti. Laser gas carburizing using methane diluted 1 to 4 with argon produces a maximum hardness of 650 HV for 100 μm, decreasing to the substrate value at a depth of 300 μm below the surface (Ref 17).

More recently, combinations of alloying elements have been used to produce hardness increases and wear performance improvements. The most successful of these is the simultaneous addition of carbon and silicon in the form of silicon carbide (Ref 16). Surface hardnesses of 650 to 750 HV without any cracking are achieved using electron beam surface alloying of a powder slurry of SiC powder and a polyvinyl alcohol binder. The microstructure comprises TiC dendrites surrounded by α-Ti dendrites, which contain some silicon and very fine precipitation of Ti_5Si_3, and a eutectic of α-Ti + Ti_5Si_3. The overall silicon content of the melt was ~6 wt% Si. The advantage of this system is that the α-Ti component of the microstructure is relatively tough compared to that solidified after laser gas nitriding. A typical hardness profile obtained from this process is shown in Fig. 8. Wear performance similar to that of hardened and tempered low-alloy steels, and superior to that of laser nitrided and untreated Ti-6Al-4V, has been measured in unlubricated sliding-rolling wear tests (30% sliding) at contact stresses of up to 750 MPa (applied load 120 kg/F) (Fig. 9).

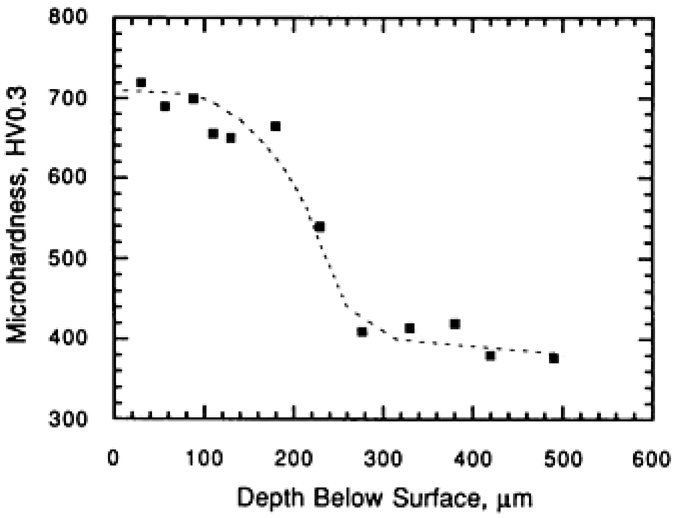

Fig. 8 Hardness profile from electron beam SiC alloyed Ti-6Al-4V after surface grinding to remove rippling. Source: Ref 16

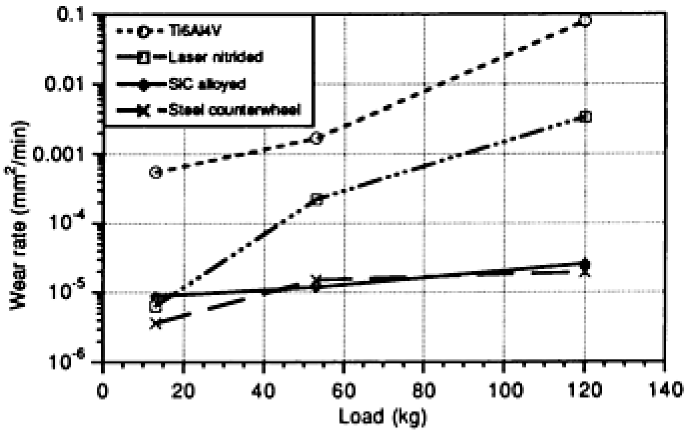

Fig. 9 Wear rates from Amsler sliding-rolling wear tests for high-energy-beam beam surface alloyed Ti-6Al-4V. Source: Ref 16

Other elements that have been electron beam surface alloyed into the surface region of titanium alloys include nickel, chromium, silicon, aluminum, and silicon and aluminum. Surface alloys containing silicon and aluminum (Ref 18) have been subjected to high-temperature oxidation tests, between 750 and 910 °C (1380 and 1670 °F) in air. Beneficial effects of the alloying were measured regarding both oxidation kinetics and the adherence of oxide scale.

Laser particle injection is an energy beam treatment that retains some solid phase during the thermal excursion. It involves the injection of hard particles into a shallow laser melt track. In a Ti-6Al-4V matrix, TiC particles ranging in size from +325-230 to +140-70 mesh have been injected (Ref 19). Partial dissolution of the carbides occurs, but they remain substantially in a particulate form, effectively creating a particulate-reinforced metal matrix composite. Maximum volume fractions of 0.6 included carbide have been created. Improvements in performance by a factor of four, independent of carbide volume fraction for $V_f > 25\%$, were measured for TiC-injected Ti-6Al-4V over untreated materials using dry sand/rubber wheel abrasive wear tests (Ref 20).

Laser cladding involves the addition of a sacrificial layer on the surface of the substrate material, ideally with minimum dilution of the cladding by the substrate but with good adhesion of the clad. A prerequisite for good bonding of the clad to the substrate is similar coefficients of thermal expansion. For erosion resistance in gas turbines, TiC in a β-Ti alloy matrix has been clad on a Ti-6Al-4V substrate, as has TiC in a maraging steel matrix for particularly arduous service (Ref 21).

Diffusion Treatments

Diffusion treatments, as the name suggests, require sufficient time at temperature to allow significant atomic mobility to occur. Because the process temperature usually affects the bulk of the component to be treated, the effects of the thermal cycle on the bulk properties of the material must be considered. If, for example, wrought Ti-6Al-4V bar has been annealed at 700 °C (1300 °F), it is highly likely that a thermal excursion to 800 °C (1470 °F) for 20 h will affect its mechanical properties to a significant degree. For this reason, it is desirable that a diffusion treatment be carried out at as low a temperature as possible if it is the final heat-treatment step for a material and if the workpiece is temperature sensitive.

Nonmetallic Elements

Oxidizing of titanium and titanium alloys can be using to improve their tribological properties. Oxygen in solution in α-Ti produces significant strengthening of the material (Fig. 10).

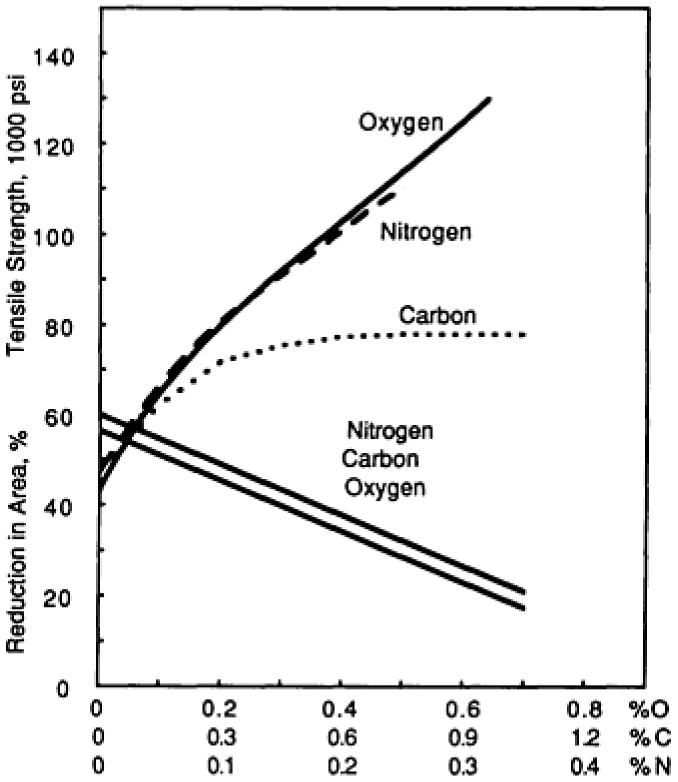

Fig. 10 Effect of interstitial alloying elements on strength and reduction in area of iodide titanium. Source: Ref 22

Over the past 40 years, a great deal of work has been devoted to the study of the oxidation of titanium and its alloys, as described above in this article. By contrast, little attention has been paid to deliberate oxidation as a tribological surface treatment of titanium alloys. Investigations are scattered over many journals over a long period of time. One observed that when chemically pure titanium was heated in the range 850 to 1000 °C (1560 to 1830 °F) in air at a pressure between 10^{-3} and 10^{-2}mm Hg, the surface was effectively hardened (Ref 23). The process was commonly disregarded, however, because at a temperature high enough to achieve an appreciable hardening effect, a considerable amount of scale is also formed (Ref 24). Fatigue strength is also reduced. It was subsequently shown that the friction coefficient of commercial titanium markedly decreases when titanium is heated in air at 350 °C for 17 h (Ref 25) and that the coefficient of friction of the oxidized surface of titanium remains low after removal of the brittle compound layers (Ref 26). These early results led to a number of more detailed studies concerning the oxidizing treatment of titanium for improvements in wear behavior.

In view of the difficulties associated with the severe scaling of titanium alloys when heated in air, controlled oxidizing in molten salts has been attempted. When titanium specimens are heated in lithium carbonate salt baths at temperatures between 600 and 900 °C (1110 and 1650 °F) for 2 to 4 h, satisfactory layers are formed. The technique has been used for production batches of titanium pistons (Ref 27).

The Tifran process has been used to treat Ti-6Al-4V, and in one set of tests, even in the absence of lubricant, seizure was eliminated. Decreases in the wear rate and improvements in the behavior of the lubricating film were observed. The technique is based on diffusion in the gaseous phase, resulting in formation of a layer on the surface of the alloy, which has a titanium oxide base. The effect of Tifran treatment on the wear life and efficiency of annealed Ti-6Al-4V gears has been studied by vacuum testing. Compared with other surface treatments, Tifran-treated gears exhibit the best wear resistance and the lowest power losses (Ref 28).

Oxygen diffusion hardening (ODH) of Ti-6Al-7Nb alloys results in a surface with a gradation in hardness from the surface to a depth of 50 µm. The maximum hardness is 900 HV, compared with 360 HV for the untreated alloy. The corrosion resistance of the ODH-treated titanium alloy is equal to that of commercially pure titanium and untreated Ti-6Al-7Nb alloy (Ref 29).

A wear-resistant surface treatment, based on oxidizing of titanium alloys in air, is used to protect valve spring retainers made of Ti-22V-4Al β-Ti alloy (Ref 30). Better wear resistance was afforded to the component with the oxidation process treatment than with either ion nitriding or gas carburizing. The brittle oxide layer formed on the surface was removed before use. The wear resistance of oxidized (at 850 °C, or 1560 °F, for 30 min) valve spring retainers was better than that of steel retainers, and after shot peening, the fatigue strength of oxygen-surface-hardened Ti-22V-6Al exceeds that of the as-received alloy.

Nitriding of titanium and titanium alloys has been investigated for many years and is used effectively on a small scale for protection against wear. The wear resistance is imparted by a very favorable phase equilibrium relationship between the elements. Nitrogen has a high solid solubility in α-Ti, and the strength increase effected by the interstitial nitrogen is significant, as shown in Fig. 10. Reference to a titanium-nitrogen equilibrium phase diagram shows that above 12.7 wt% N, the compound Ti_2N is formed at temperatures below 1100 °C (2010 °F); it has a tetragonal crystal structure and a hardness of ~1500 HV. At higher nitrogen contents, over a wide range of compositions, TiN with an NaCl-type crystal structure and a hardness of ~3000 HV is formed. Nitriding produces a thin compound layer of TiN at the surface, above a thicker compound layer of Ti_2N, which is above a diffusion zone of nitrogen-strengthened titanium. The surface differs from that achieved through oxidizing in that a useful, hard compound layer structure is created at the surface.

Nitriding cannot be achieved in air because of the tendency of titanium to form TiO_2 in preference to either of the nitrides, but it can be achieved in a nitrogen gas atmosphere. At 1 atm in nitrogen or ammonia, no technologically useful surface is created below 800 °C (1470 °F). However, treatment in ammonia at higher pressures, for example 1.2 MPa, yields thicker compound layers and diffusion zones. In order to remove the hydrogen from parts treated in ammonia, a tempering treatment at a temperature between 300 and 400 °C (570 and 750 °F) at a pressure of 10^{-2} mbar is included in this process. Components treated by this process include surgical instruments, watch cases, racing engine and racing car components, and precision machine parts. The high pressure used in the process allows treatment of narrow, deep, blind holes and intricate details such as fine threads (Ref 31).

It follows that nitriding of titanium alloys may be carried out in hot isostatic pressing equipment, where pressures of up to 100 MPa have been used (Ref 32).

An alternative medium for the introduction of nitrogen and its subsequent diffusion into the surface of titanium and titanium alloys is a plasma. Plasma, ion, or glow discharge nitriding has long been applied to ferrous alloys, but the direct current plasma process is equally applicable to titanium-base materials. Nitrogen, nitrogen-hydrogen, nitrogen-argon, or cracked ammonia may be used as the treatment gas. Nitriding may be achieved at temperatures down to 300 °C (570 °F), but the value of processing at these temperatures is doubtful because of the very thin (1 μm) hardened region produced. More usually, processing is carried out at temperatures in the range of 700 to 900 °C (1300 to 1650 °F). The plasma process uses and exhausts smaller volumes of gas than any gaseous treatment. However, experience is needed to monitor and control the temperature throughout the workpiece. Because all the heat input comes from the plasma, sections of component with significantly different surface area-to-volume ratios may differ in temperature. The thicknesses of compound layers found adjacent to corners also differ from layers on continuous surfaces of workpieces. This effect is attributed to variations in the sputtering rates at these different points. Successfully plasma-nitrided components include racing car steering racks, gears, and ball valves. Components are ready for use directly after treatment and have the characteristic gold color of TiN (Ref 16).

Significant improvements in wear resistance are gained after nitriding titanium-base materials, the sources of the benefits being twofold; the hard surface compound layers of TiN and Ti_2N and the support given by the nitrogen-strengthened diffusion zone beneath them. A typical hardness profile from plasma nitrided Ti-Al-4V is shown in Fig. 11, in which the dashed line represents the hardnesses of the thin TiN and Ti_2N compound layers. The processing conditions used were 850 °C (1560 °F) for 20 h in ammonia. A loss of about 10% of fatigue strength is associated with nitriding, but this can be mitigated against by appropriate design of a component.

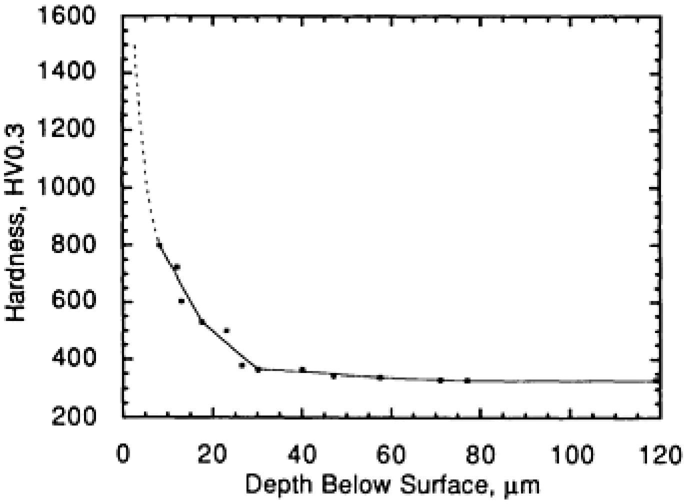

Fig. 11 Hardness profile (Vickers, 0.3 kg load) from plasma-nitrided Ti-6Al-4V. Source: Ref 16

A number of salt bath treatments have been developed for titanium, the oldest of which is probably the Tiduran process (Ref 33). In this process, the titanium component is immersed in a cyanide-based salt bath at 800 °C (1470 °F), usually for 2 h. Carbon and nitrogen, and sometimes small amounts of oxygen, diffuse into the surface to produce a hardened diffusion zone. The maximum hardness achieved in the process is in the range of 750 to 800 HV, falling progressively into the substrate, giving a case depth of about 50 µm. A uniform 10 µm is removed from the surface of the metal during the process. Components can usually be used in the as-coated condition, or they may be given a light pickle to remove the black surface.

Localized heat sources, such as a plasma torch combined with a nitrogen atmosphere, can be used to produce a superficial nitrogen-enriched surface region, but quality control is extremely difficult.

Carburizing of titanium and titanium alloys may be achieved in nonoxidizing, carburizing environments. The phase equilibrium system for Ti-C differs from those for Ti-O and Ti-N in that there is very little solid solubility for carbon in titanium. Hence, compound layer formation of TiC may result, but there is no significant diffusion zone beneath the TiC. Carburizing is accomplished in pack processes using carbonaceous media such as calcium carbonate, or following evacuation and heating to 1050 °C (1920 °F), a carburizing gas is introduced and is used for cooling. Carburizing has been used for the creation of wear-resistant surfaces on components such as engine valves.

Boronizing of titanium-base materials is similar to carburizing in that it results in the formation of an extremely hard compound layer with a negligible diffusion zone. TiB_2 is usually the outermost layer, although other borides are also formed. Wear resistance of boronized titanium has been studied (Ref 34), and in comparison with other surface treatments, it has performed very well in lightly loaded gear tests (Ref 35), compared to similar materials.

Siliconizing of titanium alloys can be achieved, for example, by using an atmosphere of 3 vol% silane in argon mixture at 1100 °C (2010 °F) for 2 h, which produces a 10 µm Ti_3Si_5 compound layer. The objective of this process is to improve oxidation resistance by changing the oxidation product. TiO_2 has been observed after oxidation in both air and oxygen at a range of temperatures. At low temperatures (<875 °C, or 1600 °F), the oxidation product was a dense mixture of TiO_2 and SiO_2, but at temperatures in excess of 900 °C (1650 °F), the outer layer consisted of pure TiO_2 (Ref 36). Titanium silicide surface layers have also been obtained using a pack process, the pack comprising of silicon with aluminum fluoride or sodium fluoride as the activator (Ref 37).

Metallic Elements

Aluminizing has been carried out via pack processes or deposition and diffusion processes to improve the oxidation resistance of titanium alloys. In a pack process, the compound layers formed depend on the processing parameters. For example, at 760 °C (1400 °F) for 20 h, 50 µm of $TiAl_3$ is formed; 900 °C (1650 °F) for 16 h produces $TiAl_3$ at the surface and thinner layers of TiAl and Ti_3Al form sequentially toward the substrate of $TiAl_2$. Cracks through the compound layers are often present, and Kirkendall porosity occurs in some cases. Diminution of the $TiAl_3$ layer by inward diffusion of aluminum at the oxidizing temperature is faster than the consumption of the coating by oxidation. Cracking of the aluminide coating, thought to occur on cooling after the aluminizing process, is a significant problem. Large, deep, open cracks form during the oxidation of pre-existing ruptures. Other pre-existing cracks that remain virtually closed are oxidized to a lesser degree. There are also closed cracks that seem to form during cooling from the oxidation temperature.

Nonetheless, at 900 °C (1650 °F) the weight gain of the aluminized coatings has been found to be 50 times less than for pure titanium, 30 times less than for Ti-6Al-4V, and 5 times less than for a silicide coating. After 10 h, assuming a linear rate, the oxidation of the aluminide coating was 300 times slower than for the pure titanium (Ref 38). Between 850 and 1000 °C (1560-1830 °F) and room temperature, cyclic oxidation of aluminized titanium also allowed the diffusion of aluminum to continue during the oxidation experiments (Ref 39), but at lower temperatures, the beginning of rapid oxidation was delayed. The $TiAl_3$ surface layers provided better oxidation resistance than the TiAl layer. Successful pack aluminizing of Ti-14Al-24Nb has been achieved (Ref 40). Similar pack-aluminized, intermetallic material has been subjected to cyclic oxidation, and excellent protection from cyclic oxidation resistance was measured to 1000 °C (1830 °F). Thicker coatings were found to offer limited resistance to oxidation because of cracking of the coatings after about five cycles; after more cycles, large growths were observed. Optimum coating thicknesses were found to be 40 to 70 μm (Ref 41).

Pack-aluminized layers are considered to be much thicker than is necessary for protection against oxidation. Thinner aluminized coating can be obtained by duplex routes, for example, by electron beam evaporation followed by a diffusion anneal (Ref 42).

Nickel diffusion treatments have been attempted for improvements in tribological behavior. In one case, an electrodeposition process was followed by a diffusion treatment in order to form the compound layers Ti_2Ni (600 HV) and $TiNi_3$ (1000 HV), from which the excess nickel layer was subsequently removed by a chemical process (Ref 43). No particular attention was paid to the potential of the diffusion zone.

Electrodeposited nickel on a titanium alloy substrate that was subsequently diffusion heat treated produced nickel penetration to a depth of ~200 μm (20 h at 850 °C, or 1560 °F). The specimens were then solution treated at 900 °C (1650 °F) and water quenched. Aging at 500 °C (930 °F) for 2 h resulted in hardnesses of ~600 HV in the diffusion zone (Ref 44).

The fact that nickel diffusion into titanium readily occurs implies that the use of overlay coatings based on nickel (or iron or cobalt) are of limited use for oxidation resistance, both because of loss of the coating to the substrate and because some of the reaction products may degrade critical mechanical properties.

Copper diffusion has been achieved by both electroplating and ion plating copper onto the surface of titanium alloys, followed by a diffusion heat treatment. In one case a heat treatment of 800 °C (1470 °F) for 12 h followed by furnace cooling was used, which resulted in an outer compound layer of Ti_2Cu, beneath which there was a Ti_3Cu layer and a diffusion zone. The Ti_2Cu layer has been shown to perform well in wear testing, comparable with plasma-nitrided titanium and physical vapor deposited TiN. No optimization of the diffusion zone was carried out. The maximum diffusion zone hardness was 650 HV at 5 μm below the surface, dropping to a core hardness of 450 HV at 15 μm below the surface (Ref 45). Nickel and copper diffusion treatments involving electroplating followed by heat treatment are relatively low-cost surface engineering systems for wear resistance. The nickel diffusion treatment has been looked at as a possibility for a seal ring and a titanium alloy control rod couple in a nuclear power station; the surface treatment allows a reduction in friction and a longer component lifetime. Titanium alloy valves have been treated by nickel diffusion in the seat area in order to improve the cavitation erosion resistance of the components for use in chemical and power generation plants.

Coatings

Chemical Conversion Coatings

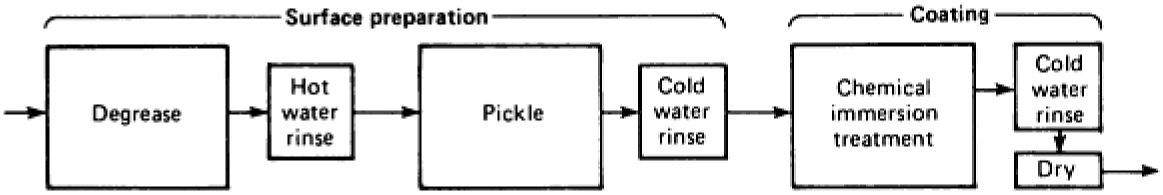
Chemical conversion coatings are used on titanium to improve lubricity by acting as a base for the retention of lubricants. Titanium has a severe tendency to gall, and lack of lubricity creates serious problems in applications involving the contact of moving parts in various forming operations (Ref 1).

Conversion coatings are applied by immersing the material in a tank containing the coating solution. Spraying and brushing are alternate methods of application. One coating bath consists of an aqueous solution of sodium orthophosphate, potassium fluoride, and hydrofluoric acid, which can be used with various constituent amounts, immersion times, and bath temperatures. The resultant coatings are composed primarily of titanium and potassium fluorides and phosphates. Several solutions are listed in Table 5. The flow chart in Fig. 12 indicates a processing sequence for the coating of titanium alloys.

Table 5 Conversion coating solutions for titanium alloys

Bath No.	**Bath solution**	**Composition**	**Amount**		**Temperature**		**pH**	**Immersion time, min**
			g/L	**oz/gal**	**°C**	**°F**		
1	Degreasing solution	$Na_3PO_4 \cdot 12H_2O$	50	6.5	85	185	5.1-5.2	10
		$KF \cdot 2H_2O$	20	2.6				
		HF solution[a]	11.5	1.5				
2	Pickling solution	$Na_3PO_4 \cdot 12H_2O$	50	6.5	27	81	<1.0	1-2
		$KF \cdot 2H_2O$	20	2.6				
		HF solution[a]	26	3.4				
3	Chemical immersion solution	$Na_2B_4O_7 \cdot 10H_2O$	40	5.2	85	185	6.3-6.6	20
		$KF \cdot 2H_2O$	18	2.3				

(a) Hydrofluoric acid, 50.3% by weight



Type of solution	Composition	Operating temperature		Cycle time, s
		°C	°F	
Degreasing	Alkaline cleaner	Boiling point		60-120
Pickling	15% HNO_3, 1% HF in water	23	75	10-60
Chemical immersion	(a)	. . .	. . .	. . .

(a) See Table 5.

Fig. 12 Processing sequence used in the chemical coating of titanium alloys

Cleanliness of the part before immersion is critical, and all preliminary cleaning and handling operations must be closely controlled for good results. Finger marks or residual grease on the surface of a part will interfere seriously with the coating process.

The appearance of the baths varies widely during the coating reaction, ranging from rapid bubbling to relative dormancy. Some coatings rub off when still wet; others are adherent. The various solutions produce coatings of approximately the same dark gray or black color.

The control of pH and immersion time is important. Dissolved titanium and the active fluoride ion make it impossible to use glass electrodes for pH measurements. Indicator paper and colorimetry are the most satisfactory methods for measuring in the degreasing and chemical immersion baths, which are held at 5 to 7 pH. The pickling bath is quite acid, and titrametric analysis offers the most practical method of control. When the bath is in the proper coating range, a 20 mL (0.70 fluid oz) sample in 100 mL (3.4 fluid oz) of water will neutralize 11.8 to 12.0 mL (0.4 to 0.41 fluid oz) of normal sodium hydroxide, using a phenolphthalein indicator.

Coating thickness depends on immersion time. In all three baths, a specific time is reached after which the coating weight remains essentially constant. In the fluoride-phosphate baths, a maximum coating weight is reached at some time before this equilibrium point. The maximum coating weight is obtained in about 2 min in the low-temperature bath and in about 10 min in the two other baths (Fig. 13).

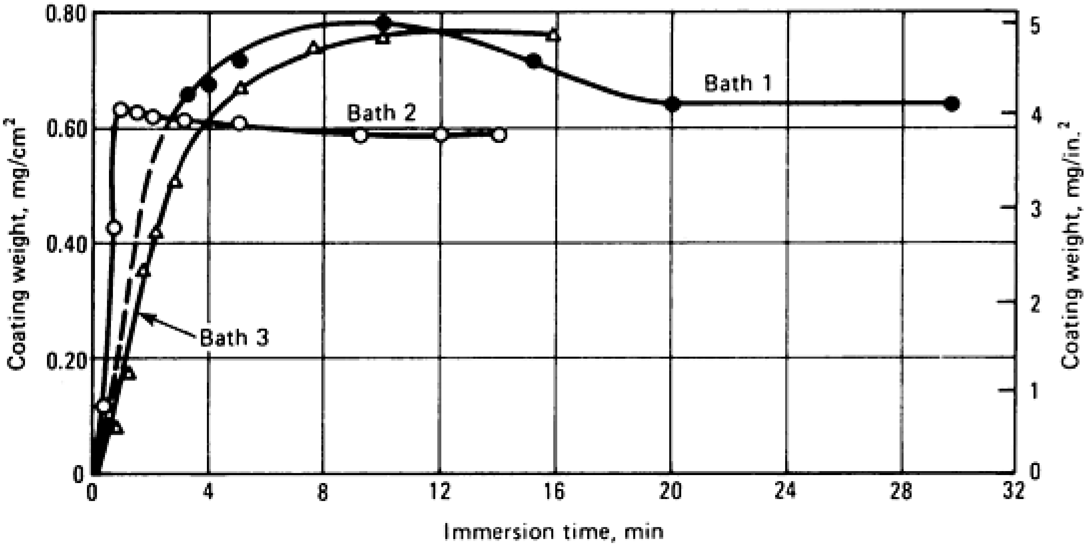


Fig. 13 Weight of conversion coating as a function of immersion time. See Table 5.

Results of extensive wire-drawing experiments (Table 6) illustrate the effectiveness of conversion coatings when used with various lubricants. Reciprocating wear tests showed that conversion coatings and oxidized surfaces provided some improvement in wear characteristics, but when conversion-coated samples were also oxidized, a marked improvement was noted. The conversion coating increases the oxidation rate of titanium at about 425 °C (800 °F) and may increase oxidation rates at temperatures up to 595 °C (1100 °F). The original coating is retained above the titanium oxide layers. High-speed rotary tests have indicated marked improvement in the wear characteristics of the metal after conversion coating and lubricating with one part of molybdenum disulfide and two parts of thermosetting eponphenolic resin.

Table 6 Comparison of conversion coatings used with various lubricants in wiredrawing of titanium

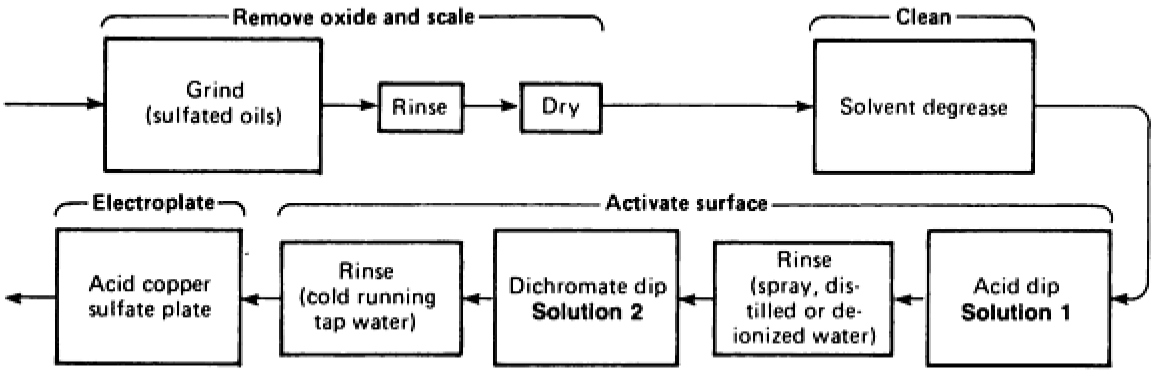
Coating	**Drawing compound**	**Total reduction, %**	**No. of passes**	**No. of coats**	**Final condition**
Bare	Molybdenum disulfide with grease	. . .	0	. . .	Galled
Bare	Soapy wax	. . .	0	. . .	Galled
Degreasing bath	Molybdenum disulfide with grease	85	8	2	Smooth
Pickling bath	Molybdenum disulfide with grease	94	17	7	Smooth
Pickling bath	Soapy wax	68	7	3	Galled
Pickling bath(a)	Molybdenum disulfide with grease	70	7	1	Smooth
Chemical immersion bath	Lacquer molybdenum disulfide	63	8	2	Smooth
Chemical immersion bath	Molybdenum disulfide with grease	63	8	3	Smooth

(a) Coating heated for 1 h at 425 °C (795 °F)

Conversion coatings are easily removable without excessive loss of metal by pickling in an aqueous solution containing 20% nitric acid and 2% hydrofluoric acid by weight.

Plating

Copper Plating. The electrodeposition of copper on titanium and titanium alloys provides a basis for subsequent plating. A flow chart outlining the processing sequence for copper plating titanium is shown in Fig. 14. After cleaning and before plating, the surface of the titanium must be chemically activated by immersion in an acid dip and a dichromate dip to remove the passivating oxide film and obtain adequate adhesion of the plated coating. The compositions and operating temperatures of these activating solutions are shown in the table with Fig. 14.



Solution No.	Type of solution[a]	Composition of solution
1	Acid dip	60% HF, 1 vol, 69% HNO_3, 3 vol
2	Dichromate dip	$Na_2Cr_3O_7 \cdot 2H_2O$, 290 g/L (33 oz/gal), 60% HF, 55 g/L (6.2 oz/gal), H_2O, remainder[c]

Solution No.	Operating temperature		Cycle time, s
	°C	°F	
1	Room temperature		[b]
2	82-100	180-212	20

Fig. 14 Processing sequence for electroplating copper on titanium alloy parts

Water purity is critical for the composition of activating solutions. Chemicals of technical grade are as effective as, and may be substituted for, chemically pure grades. In both the acid and dichromate baths, the hydrofluoric acid content is critical and must be carefully controlled.

After proper activation, titanium may be plated in a standard acid copper sulfate bath. The adhesion of the deposited copper is better than that of 60-40 solder to copper, and the deposit successfully withstands the heat of a soldering iron. The normal thickness of the plated deposit is about 25 μm (1 mil).

Copper-plated titanium wire is available commercially. The outstanding property of this material is the lubricity of its copper-plated surface. The wire can be drawn easily and can be threaded on rolls. Such wire has been used in applications that require electrical surface conductivity.

The titanium wire is plated continuously at a speed of about 60 m/min (200 ft/min) in a copper fluoborate acid bath at a current density of 7.5 to 12.5 A/dm^2 (75 to 125 A/ft^2). The final copper deposit is a thin flash coating. Higher current densities up to 150 A/dm^2 (1500 A/ft^2) have been tried, but if the copper coating is too thick, adhesion is poor.

Platinum Plating. Although titanium is not satisfactory as an anode material because an electrically resistant oxide film forms on its surface, application of a thin film of platinum to titanium results in a material with excellent electrochemical properties. Theoretically, the thinnest possible film is sufficient to give the highly desirable low overvoltage characteristics of platinum; furthermore, the film need not be continuous or free of defects to be effective.

The greatest immediate use for platinum-coated titanium is for anodes in the chlorine-caustic industry. Some horizontal-type chlorine cells use expanded metal anodes. From 1.3 to 2.5 μm (0.05 to 0.1 mil) of platinum is applied to the anode surface. Replating of the anodes may be required after about 2 years, depending on the operating conditions. The attrition rate for platinum appears to be about 0.6 g/tonne (0.5 g/ton) of chlorine.

Several platinum and electrode suppliers have developed reliable methods for platinum plating of titanium; most use proprietary solutions. A platinum diamino nitrite bath has been used successfully to apply platinum to titanium. In this and other procedures, certain precautionary steps are required to achieve adherent, uniform plates. The surface must be cleaned thoroughly and etched in hydrochloric or hydrofluoric acid to produce a roughened surface. Some procedures also involve a surface activating treatment just before plating. Immersion for 4 min in a solution of 895 mL (30 fluid oz) of glacial acetic acid containing 125 mL (4 fluid oz) of 52% hydrofluoric acid, followed by a prompt rinse, appears to be an effective activating treatment if performed immediately before plating. A postplating treatment, consisting of heating to 400 to 540 °C (750 to 1000 °F) for 10 to 60 min, stress relieves the plate and improves adhesion. This treatment can be done in an air atmosphere, and a light oxide film forms on unplated areas.

Coatings for Emissivity. Electrodeposits and sprayed coatings of gold on titanium are used to provide a heat-reflecting surface that reduces the temperature of the base metal. Gold-coated titanium has been used for jet engine components.

The gold coating is applied by spraying a gold-containing liquid on chemically clean titanium sheet. This is followed by a baking treatment. Normal coating thickness is about 25 μm (0.1 mil).

Coatings for Wear Resistance. Plating of hard chromium and electroless nickel are the most widely used on ferrous substrates for wear-resistant applications. However, in wear situations the thin oxide layer present on titanium alloys can make satisfactory adhesion of these coatings to titanium substrates difficult to achieve. Measures taken to overcome this problem include (Ref 46):

- In situ formation of alkali metal halogen complexes that protect from further oxidation and are later dissolved in acid plating solution
- Surface cleaning with an etchant, followed by rinsing in a water solution containing anions of cyanides, tartrate, citrate, and acetate complexing or chelating ions, followed by heat treatment
- Cathodic cleaning of the surface, activation in stannous chloride solution, coating in copper-reducing solution or gold chloride dip, electroplating copper, and copper striking from copper cyanide solution
- Chemical etching, immersion plating in a mixture of hydrofluoric acid, zinc sulfate, and sodium dichromate, followed by rinsing and conventional chromium plating
- Oxide removal in hydrofluoric acid/fluoboric acid solution, then transfer to a fluoborate plating solution to prevent reoxidation
- Immersion in nitric acid and sodium citrate solution; alkaline electroless nickel plate
- As above, abrade in hydrochloric acid, then Woods nickel strike, copper strike, chromium plate

These are some of the many procedures that have been attempted. An additional concern is that contact with acidic solutions allows hydrogen embrittlement of the titanium alloys.

Another approach to activation involves the dissolution of some microstructural constituents prior to plating. These are the aluminum-rich α-Ti phase and in Ti-6Al-4V, precipitated Ti_2Cu in Ti_2Cu and precipitated impurities at the grain boundaries of unalloyed titanium. Postplating heat treatment to 480 °C (895 °F) allows further improvements in adhesive strength, associated with diffusion of nickel into titanium and vice versa (Ref 47).

Heat treatment has been successfully used for enhancement of adhesion of hard chromium plating of titanium alloys. A 700 °C (1290 °F) temperature was used for the heat treatment, which resulted in a loss of hardness of the hard chromium, so a second chromium plating was applied to the initial, adherent, heat-treated chromium surface. Degradation in fatigue properties was ameliorated by the use of shot peening. Components treated using this procedure have included oil seal collars, racing car flywheels, bearing housings, and pistons (Ref 48).

Physical Vapor Deposition

Physical vapor deposition (PVD) is a term that covers several processes (including evaporation, ion plating, and various forms of sputtering) to deposit metals, alloys, compounds, or metastable materials on a wide variety of substrates. The most successful engineering application is the coating of tool material substrates by reactive ion plating or reactive sputtering of TiN and related materials.

The PVD treatment of titanium alloy substrates has found limited application so far, but arc evaporation has been used to deposit 4.5 μm of TiN, and sputter deposition has been used to deposit 0.5 μm of TiN on gears for space mechanisms. The thinner coating suffered from problems of adhesion, whereas the thicker coating eventually failed through galling (Ref 31). Pin-on-disc wear tests have demonstrated reductions in coefficients of friction for TiN and TiC on titanium substrates against 440C stainless steel (Ref 49, 50). Electron beam source and arc source ion plating have been used to produce 1 to 2 μm of TiN on the surface of Ti-6Al-4V.

The failure of conventionally applied TiN coatings on titanium alloy substrates under load-bearing wear situations was evaluated and modifications were made to produce a better PVD TiN process. Initially, a coating produced using an electron beam evaporative source was found to perform significantly better than an arc source coating in lubricated Falex tests against steel jaws. The poor performance of the arc source coating was caused by removal of small splats of titanium from the coating and the introduction of titanium into the wear couple. This problem was negated by lightly polishing the arc source coating before testing. Survival of the electron beam source coating at higher contact stresses was achieved by an improved sputtering process at a higher-than-normal temperature (700 °C vs. 450 °C, or 1290 °F vs. 840 °F) before evaporation of the titanium component of the coating commenced (Ref 51, 52). This process is tradenamed Nitron and is provided by Tecvac UK, Ltd. The improvements in load-bearing wear situations of the modified process is demonstrated by the Falex wear test data shown in Fig. 15. Engineering components routinely coated with TiN include brake pistons and other components for racing cars, aerospace components for which titanium is used because of its strength-to-weight ratio, and pump parts and valve components for oil, chemical, and food industries for which titanium is used because of its corrosion resistance.

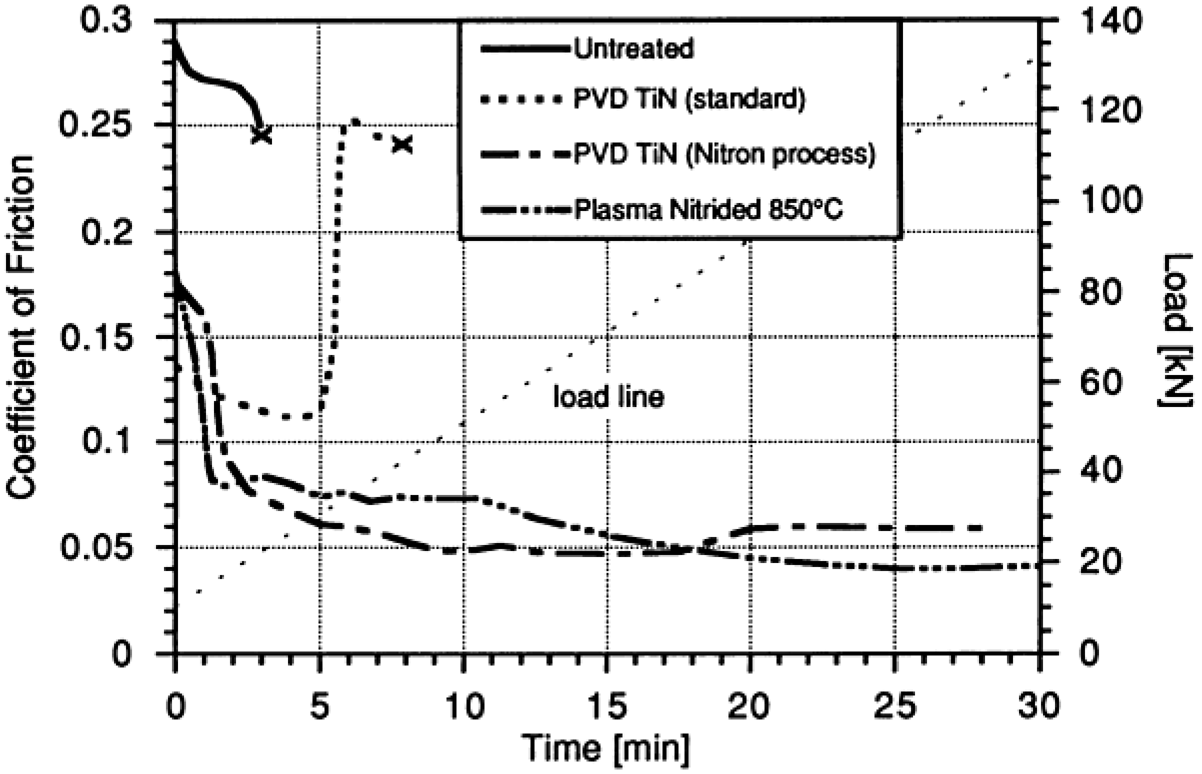

Fig. 15 Results from lubricated Falex wear tests for untreated and plasma-processed Ti-6Al-4V; carbon steel jaws. Source: Ref 16

One very active area of surface engineering research, mentioned above in the discussion of ion implantation, is in the area of surgical implants, where mechanical and chemical properties make titanium a useful material but its tribological properties require improvement. TiN deposition has been widely researched and is routinely employed by commercial coaters. Surface roughness of the component is a critical parameter in this type of wear couple, and polishing is usually required after TiN deposition (Ref 53).

In the same field of application (surface engineering of prosthetics), amorphous diamond-like carbon (DLC or ADLC) is stimulating interest. Optimization of the wide range of properties available from these coatings is essential, and, as in DLC coating of other substrates, adhesion problems must be overcome. The very low coefficients of friction and wear rates exhibited by these coatings are very promising, and the coatings have performed well in reciprocating abrasion wear tests against bone cement in Ringer's solution, as have TiN coating and zirconia (Ref 53) (Table 7).

Table 7 Results of polymethyl methacrylate abrasion tests of various metals and ceramic coatings following 10^6 wear cycles

Material	Coating	Surface hardness, DPH	Initial R_a, µm	Final R_a, µm	Wear track depth, µm
Ti-6Al-4V	. . .	330	0.06	4.15	27.5

Sprayed Coatings

Sprayed coatings may be applied to titanium alloy substrates as they are to many other materials; no special pretreatment is required for titanium-base materials. Sprayed coatings are mainly deposited using plasma spraying, but detonation gun, high-velocity oxyfuel (HVOF), and vacuum plasma spraying are also used. There is a vast range of materials that can be sprayed onto titanium substrates if so desired.

The main function of sprayed coatings on titanium is for wear protection in aerospace engines and other gas turbine applications. In the low-pressure compressor, titanium alloy midspan support faces are sprayed with tungsten carbide-cobalt for protection against fretting wear. Wear protection is also afforded to blade roots, location lugs and fan dampers by means of a "soft" coating (Cu-Ni-In) to protect the titanium components (Ref 54). The coating is very dense, has a very low oxide content, and resists fretting wear. The coating wears at a predetermined rate and the components can be removed and the coating resprayed after an establisher service period. The value of such a soft coating to combat fretting wear of titanium alloys has been demonstrated in laboratory tests in which a copper-base electroplated deposit outperformed many other surface treatments (Ref 55). In the intermediate-pressure compressor, abradable coatings are used for a variety of seals. These coatings, blends of aluminum-silicon and polyester powders, are worn away by, for example, blades. A good seal is maintained by partial wear of the coating and essentially no blade-tip wear occurs. Plasma-sprayed anti-fretting-wear coatings for titanium alloys, usually of tungsten carbide-cobalt, are also widely used.

Another major use of sprayed coatings is in repair of components. Some large, very expensive titanium components undergoing final machining operations are damaged, chiefly due to tool wear. Rather than scrap such components, plasma-sprayed coatings of Ni-Al-Mo are used to rebuild critical volumes. When titanium alloying processing vessels used in the production of dry-cell batteries undergo corrosion, they are repaired using plasma-sprayed tantalum.

Returning to the area of prosthetics, titanium implants are sprayed with hydroxyapatite (HAP). This compound is the ceramic constituent of bone, and when it is deposited with appropriate amounts of porosity and surface roughness, bone growth can occur and cementation between the bone and the HAP coating results. This material is commonly sprayed onto femoral stems, dental implants, knee implants, and acetabular caps (wherever a titanium prosthesis comes into contact with bone). The other widely used sprayed deposit in this area of application is titanium itself. Again, appropriate surface roughness and porosity are important because, although not a constituent of bone, titanium is biocompatible and does not discourage bone growth. Therefore, when a successful implant is carried out, the bone will grow, resulting in mechanical keying of the new bone and the porous titanium.

Other Coatings

Anodizing of titanium and titanium alloys enhances the wear resistance of the material. It produces layers of TiO_2 less than 100 nm thick. Such coatings are unable to withstand more than relatively light loads, but they do produce significant improvements over untreated titanium. The process is frequently used on titanium fasteners and can be considered the basic minimum treatment for any titanium component subjected to a rubbing action. The range of interference colors produced by anodizing at different voltages is also used to obtain decorative effects on titanium jewelry and other items.

Sol-gel coatings on titanium alloys are being studied for use as oxidation protection surface treatments. A range of surface coatings on a Ti_3Al-Nb-based alloy, including sputtered oxides of magnesium, yttrium, zirconium, and hafnium, sputtered fluorides of calcium and yttrium, and 1 μm thick layers of silicon, aluminum, and boron oxides were applied both by sputtering and from sols, and calcium, sodium, and phosphorus oxides were also applied from sols (Ref 56). A reaction barrier undercoat expected to be stable with the titanium alloy was combined with oxidation barrier topcoats. Weight gains for various systems after 1 h at 982 °C (1800 °F) in air are shown in Fig. 16. The measured values for weight gain are indicative of the relative film integrity after exposure; sputtered coatings were often cracked. A sputtered yttria coating was improved by dipping in boric acid, which, during heating, forms boron oxide, which was believed to fill the cracks in the yttria layer, consequently improving the protection achieved.

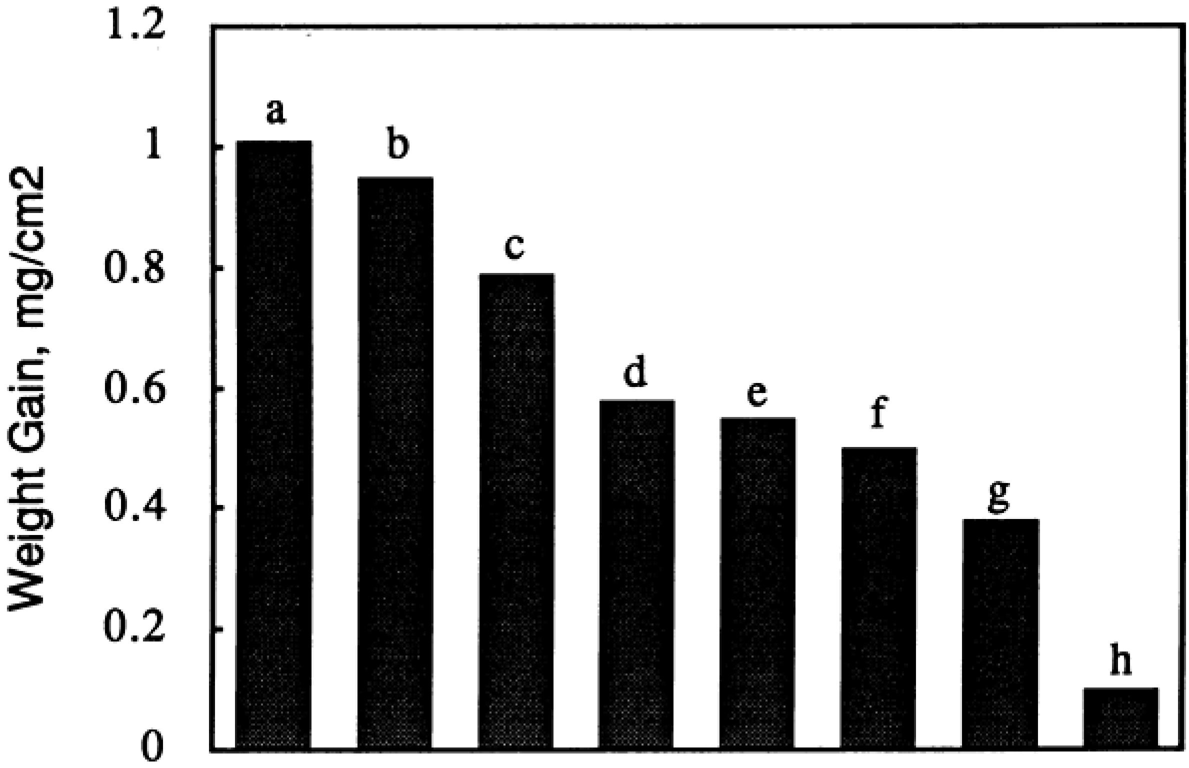

Fig. 16 Weight gain for 1 h at 982 °C (1800 °F) in air for (a) uncoated alloy, (b) sputtered yttria, (c) boron oxide from solution, (d) sodium aluminum borophosphate from solution, (e) calcium phosphate from solution, (f) calcium aluminate from solution, (g) calcium aluminophosphate from solution, and (h) magnesium silicophosphate from sol-gel. Source: Ref 56

A multilayered system involving 1 to 2 μm of reaction barrier coating is applied (either barium titanate or yttrium-stabilized zirconia), over which is a diffusion-barrier coating containing magnesium phosphate and silica glasses. In cyclic oxidation tests to 980 °C (1800 °F), the performance of this coating equaled and exceeded that of other, thicker reaction coatings (Ref 57).

Chemical vapor deposition (CVD) coatings are seldom applied to titanium-base substrates. However, some work has been done, again with the object of improving oxidation resistance (Ref 58). Sputtered silica and CVD silicate layers, both with and without aluminum base coats, have been tested for relatively low temperatures. The best results were obtained from the combined aluminum coating, which diffuses to form $TiAl_3$ and sputtered silica.

Another type of coating for γ-titanium aluminides is based on the Ti-Cr-Al system, within the composition range for which an alumina film is formed on the surface in elevated-temperature oxidation. Methods of application used are slurry fusion, low-pressure plasma spraying, HVOF spraying, and sputtering. Good oxidation behavior has been noted, but significant interdiffusion of the coating and the substrate occurs at the oxidation temperature (Ref 59).

Contemporary Developments

Plasma immersion ion implantation (PI^3) has been developed at the Australian Nuclear Science and Technology Organisation. It is an innovative process that combines and exploits the advantages of the established techniques of both ion implantation and plasma nitriding to produce surface-modified components with optimum performance characteristics. As such, it offers the potential expansion of the surface engineering market to applications that are prohibitively expensive with current ion-beam technology (Ref 60).

Specifically, PI^3 involves surrounding the sample by the ion source, in the form of a radio-frequency generated plasma. This enables a steady-state sheath to form around the target. A series of short, high-voltage, negative pulses are then applied directly to the workpiece, causing ions to be accelerated from the plasma to bombard the target from all sides simultaneously at approximately normal incidence. Therefore the line-of-sight restriction of conventional ion implantation is eased and the sputtering effects are reduced, allowing uniform coverage to be achieved on complex shapes at a lower unit cost.

The technology results in a modified layer of much greater depth than in conventional ion implantation. As well as implanting ions into the first 0.2 μm to obtain a surface layer with unique tribological properties, there is the additional possibility at elevated temperatures of producing a strengthened diffusion-enhanced "tail" of up to 100 μm thickness that supports the implanted layer.

Work on the effects of PI^3 on titanium alloys has so far been limited to studies on the Ti-6Al-4V alloy. Samples have been treated in a nitrogen atmosphere at between 350 °C and 550 °C (660 and 1020 °F), for either 3 or 5 h. Preliminary investigations indicate that under these conditions, considerable increases in surface hardness can be achieved. At temperatures of 500 °C (930 °F) and above, the surface Knoop hardness of Ti-6Al-4V increases by 150 to 170% at 25 g load. Furthermore, samples treated at all temperatures in the range were hardened to some degree.

These findings were reflected in significant improvements in the wear resistance of the alloy. Pin-on-disc wear testing has been carried out at low loads (2 N) and in the presence of ethanol. Samples treated at 350 and 450 °C (660 and 840 °F) showed some decrease in wear volume, compared to the untreated material. However, the Ti-6Al-4V disc that had been treated at 500 °C (1020 °F) for 5 h exhibited no measurable wear after the test had been completed.

One drawback of PI^3 is its effect on the surface roughness of samples during treatment. Unlike conventional ion implantation, the PI^3 process results in significant increases in surface roughness that are greater as temperature and time of treatment are increased.

Plasma source ion implantation (PSII) was developed simultaneously at the University of Wisconsin. Whereas the PI^3 unit has a radio-frequency generated plasma, the PSII process employs a filament discharge (direct current source) that ionizes the gas.

Research using titanium alloy substrates has concentrated on implantation at ambient temperatures (i.e., not greater than 100 °C), with nitrogen implanted at 50 keV to a fluence of 3 × 10^{17} atoms/cm^2, to produce a peak concentration of nitrogen of about 40 to 50% at the surface and a treated depth in the region of 2000 to 3000 Å.

Transmission electron microscopic analyses of the implanted layers show fine precipitates of TiN dispersed throughout the structure. However, in more recent work, comparing x-ray electron dispersive spectra for implanted and unimplanted Ti-6Al-4V, it has been concluded that this is more realistically represented by Ti(V)N, because the vanadium is thought to substitute for the titanium. Pin-on-disc wear testing has been carried out under extremely low loads (0.1 to 0.2 N) in both corrosive and lubricated conditions. Again, significant improvements in wear resistance have been exhibited by the surface-modified Ti-6Al-4V, comparable to those achieved by conventional ion implantation (Ref 61, 62).

Duplex Treatments. Plasma nitriding or modified PVD TiN coating provides a titanium surface with improved resistance to sliding contact under moderately high contact stresses. However, neither process is capable of providing a sufficiently deep case for use in bearings and gears. Deep hardened layers provided by laser or electron beam surface alloying are able to withstand the high stresses encountered in these applications but do not resist sliding motion.

Some work has been carried out to combine deep hardening with a subsequent surface treatment to enable the material to withstand the action of high load in mixed rolling/sliding and, in particular, to resist scuffing failure. Electron beam surface alloying of Ti-6Al-4V with silicon and carbon has been followed by surface grinding and then plasma nitriding.

Samples tested using a minidisc scuffing test with 54% slip (slide-roll ratio of 0.37) and a contact pressure of 1.3 GPa (Ref 16) demonstrated a dramatic improvement in scuffing resistance for the duplex-treated sample over and above that of the electron beam SiC-alloyed material alone. No visible signs of wear, other than a slightly polished appearance, resulted on the duplex-treated sample, whereas there was severe scoring on the surface-alloyed treated sample. The combination of a deep hardened case, able to resist high contact stresses, with a plasma-nitriding treatment to alter the chemical as well as physical and mechanical nature of the surface is capable of providing titanium alloys with a surface treatment of great potential value under severe wear conditions. The improvements to Ti-6Al-4V substrates produced by these surface engineering processes are summarized in Fig. 17.

Surface Engineering of Zirconium and Hafnium

Revised by R. Terrence Webster, Metallurgical Consultant

Introduction

ZIRCONIUM AND HAFNIUM SURFACES may require cleaning and finishing for reasons such as preparation for joining, heat treatment, plating, forming, and producing final surface finishes. Special surface preparation and cleaning is generally not required for corrosion resistance because the naturally formed surface oxide protects the metal regardless of surface condition. They are difficult to electroplate via traditional methods, but plating can be accomplished using special alternative processes.

Surface Soil Removal

Grease, oil, and lubricants used in machine forming and other fabricating operations may be removed by a number of techniques. Alkaline or emulsion cleaners used in simple soak tanks or with ultrasonic cleaning, acetone or trichloroethylene solvent washing, or vapor degreasing and detergents are all widely used. For light soil removal, hand wiping is done with solvents such as acetone, alcohol, trichloroethylene, or various alternatives to trichloroethylene (which is not environmentally attractive). Electrolytic alkaline cleaning is also used. In the electrolytic system, the work can be either anodic or cathodic polarity, provided the voltage and current can be controlled to avoid anodizing or spark discharge, and subsequent pitting. Removing these soils is essential before acid etching to provide uniform acid attack. The soils must be removed before heat treatment and joining to prevent contamination and consequent loss of ductility.

Blast Cleaning

Mechanical descaling methods such as sandblasting, shot blasting, and vapor blasting are used to remove hot work scales and hard lubricants from zirconium and hafnium surfaces. Aluminum oxide, silicon carbide, silica sand, and steel grit are satisfactory media for mechanical descaling. Periodic replacement of used media may be required to avoid excessive working of the surfaces by dull particulates. Roughening of exposed surface areas occurs from grit or shot impingement, depending on the grit size used. Any abrasive or shot blast cleaning may induce residual compressive stresses and warpage in the surface of the material, particularly thin sheet. Warpage also may occur in sections that are subsequently chemical milled or contour machined.

Blast cleaning is not intended to eliminate pickling procedures. Abrasive blasting does not remove surface layers contaminated with interstitial elements such as carbon, oxygen, and nitrogen. Generally blast cleaning is followed by a pickling step to ensure complete removal of surface contamination and cold-worked layer and to produce a smooth, bright finish.

Chemical Descaling

Some scale, as well as forming lubricants, can be removed by proprietary water solutions of strong caustic compounds, or by the use of molten alkaline-based salt baths. The salt baths operate at temperatures of 650 to 705 °C (1200 to 1300 °F) and must be used carefully according to manufacturer instructions. Salt bath descaling is accomplished by a series of cycles through the salt, a water rinse, and a sulfuric acid bath to remove scale before final pickling.

Pickling or Etching

Metal removal by a chemical bath of nitric-hydrofluoric acid is used most commonly, although other baths have been used. The usual bath for zirconium, Zircaloys, and hafnium is composed of 25 to 50% nitric acid, 70 vol%; 2 to 5% hydrofluoric acid, 49 vol%; and the remainder water. The acid bath for zirconium-niobium alloys consists of 28 to 32% sulfuric acid, specific gravity 1.84; 28 to 32% nitric acid; 5 to 10% hydrofluoric acid; and the remainder water.

Bath temperatures should not exceed 65 °C (150 °F) during pickling, to help prevent excessive pickup of the hydrogen that forms during the pickling. Zirconium and hafnium are very sensitive to small amounts of hydrogen, which lowers their fracture toughness markedly.

To help prevent formation of insoluble fluoride surface stain, a stop bath consisting of 70% HNO_3, and 30% H_2O can be used. The article is pickled in the nitric-hydrofluoric acid bath and is immediately dipped in the stop bath. Thorough rinsing in cold water follows the stop bath.

The hydrofluoric acid attacks the zirconium and hafnium, and the nitric acid oxidizes the hydrogen formed by the reaction and prevents its absorption by the metal. The ratio of nitric to hydrofluoric acid should not be less than 10 to 1 normality. Except for the zirconium-niobium alloys, the rate of metal removal is linear with hydrofluoric acid concentration and doubles as the bath temperature rises from 43 to 71 °C (110 to 160 °F).

Material etched in the nitric-hydrofluoric acid bath must be rinsed quickly and completely with flowing water, to prevent an insoluble fluoride surface stain from forming. This stain is extremely detrimental to corrosion resistance in hot water and steam environments of nuclear reactors. Extreme precautions to ensure a rapid and effective rinse are required for this service. A rapid temperature rise during the transfer to the rinse water can lead to redeposition of the etching product.

Anodizing and Autoclaving

Zirconium and hafnium oxidize readily in air and aqueous solution, but the tenacious oxide layer generally protects the metal from further oxidation. Methods to produce a dense oxide layer to serve as a protective coating for zirconium and hafnium are anodizing and autoclaving. Before anodizing, the article should be cleaned in a 50% nitric acid/50% water solution and then in water with the assistance of ultrasonic vibration.

The anodizing solution used for zirconium and hafnium consists of:

- 45.4 vol% absolute ethanol
- 26.5 vol% water
- 15.2 vol% glycerine
- 7.6 vol% lactic acid, 85% concentration
- 3.8 vol% phosphoric acid, 85% concentration
- 1.5 vol% citric acid

Voltage during anodization is raised slowly from about 20 V to 200 to 300 V. A rapid rise in voltage may overload the amperage and/or power capabilities of the equipment. A wide variety of anodization films with different thicknesses and colors can be produced. Voltage governs the thickness of the oxide layer, which determines the color (first gold, then red, green, blue, and black with increasing thickness). This technique can be employed to decoratively color zirconium and hafnium alloys and to enhance metallographically prepared surfaces for light microscope observation. See P.E. Danielson's articles on color metallography and the metallography of zirconium, hafnium, and titanium in Volume 9 of the *ASM Handbook.*

Caution should be exercised during the anodizing process, especially when the high voltage is reached. Operators should wear rubber gloves. Rubber floor mats are also advisable.

Autoclaving is a standard test for zirconium and hafnium for the nuclear industry. Testing is conducted to determine proper processing history and/or surface cleanliness for critical applications. Specific (surface area basis) weight gain and/or visual standards are used to determine compliance. The test for zirconium and Zircaloys is carried out at 400 °C (750 °F) under a steam pressure of 10 MPa (1.5 ksi) for 1 to 14 days. The test for hafnium is carried out at 360 °C (680 °F) under a water pressure of 18.6 MPa (2.7 ksi).

Autoclaving procedure may be used to produce a dense oxide coating for zirconium and hafnium. The water used should have a pH value of 6 to 8, with a resistivity of 1×10^4 Ω· m (1×10^6 Ω· cm) minimum when corrected to 22 °C (72 °F). The autoclave should be constructed of type 300 series stainless steel, and should be fitted with a pressure gage, pressure records, thermocouples, a safety blowout assembly, and a high-pressure venting valve. In preparation for anodizing, the article should be detergent cleaned, followed by solvent cleaning with reagent grade acetone, trichloroethylene, or perchloroethylene. The article should be cleaned further by acid pickling as described in a previous section. Upon completion of the designated pickling time, the article should be immediately and rapidly transferred to the first water rinse tank with a temperature maintained at 27 °C (81 °F) and a flow rate of at least two bath changes per minute. It should then be transferred to the second water rinse tank at the same temperature for at least 15 min. After this, the article should be transferred to the third rinse tank containing water at 80 °C (175 °F) minimum. All rinse water, especially in the third rinse tank, should have a pH of 7 (±1) and a resistivity of 5000 Ω· m (500,000 Ω· cm) minimum. After rinsing, the article should be dried by a method that prevents water marks, stains, or contamination on the surfaces of the article, by wiping with a clean, lint-free cloth, and blowing with dry air. Autoclaved zirconium and its alloys show a dense, shiny black coating of oxide, while hafnium shows a dense, iridescent coating of oxide, the color of which ranges from purple or blue to gold.

Oxide Layer for Low Friction Surfaces. A thick, dense, and adherent oxide layer can be produced on zirconium and hafnium by heat treatment. The resultant oxide layer will have low friction resistance and will resist galling and seizing, while retaining excellent corrosion resistance. For small precision-shaped components, compensation must be made for oxide buildup as well as stress-induced changes (see "Selected References" for citations on oxide growth).

The treatment consists of cleaning the surface, followed by heating for 4 to 6 h at 550 °C (1022 °F) in air. The resultant oxide layer will be approximately 5 μm (0.0002 in.). Thicker oxide films can be produced by heating in a controlled atmosphere of inert gas and oxygen in an air furnace, a fluidized bed furnace, or molten equimolar NaCl and KCl fused salts.

Polishing and Buffing

The polishing and buffing of zirconium is accomplished with the same methods used for titanium. Polishing is frequently done wet, using mineral oil lubricants and coolants. Silicon carbide abrasive cloth belts have been effective. It is common to polish in two or more steps, using a coarser grit initially, such as 60 or 80, to remove gross surface roughness, followed by polishing with 120 or 150 grit to provide a smooth finish. Zirconium and titanium tend to wear the sharp edges of the abrasive particles and to load the belts more rapidly than steel. Frequent belt changes are required for effective cutting. A good flow of coolant improves polishing and extends the life of the abrasives.

Dry polishing is more appropriate than wet for some applications. For these operations, belts or cloth wheels with silicon carbide abrasive may be used. Soaps and proprietary compounds may be applied to the belts to improve polishing and to extend belt life. Abrasive belt materials that incorporate solid stearate lubricants offer improved results for dry polishing operations. *Caution: Accumulation of zirconium and titanium fines can be pyrophoric.*

Fine polishing of zirconium and titanium articles for extremely smooth finishes requires several progressive polishing steps with finer abrasives until pumice or rouge types of abrasive are applied. With the softer grades, such as unalloyed titanium or zirconium material, fine polishing requires more time and care to prevent scratching. Harder grades can be polished more readily to a surface of high reflectivity. If a matte finish is desired, wet blasting with a fine slurry may be used after initial polishing.

The purpose of buffing is to improve the surface appearance of the metal and to produce a smooth, tight surface. Buffing is used as a final finishing operation and is particularly adaptable to finishing a localized area of a part. Parts such as body prostheses, pacemakers, and heart valves require a highly buffed, tight surface to prevent entrapment of particles. Close-fitting parts for equipment, such as the modern guidance systems, and electronics applications require highly polished surfaces obtained by buffing. In addition, sheet sizes too large to be processed by other abrasive finishing methods, such as mass finishing or wet blasting, can be economically processed by buffing.

The principal limitations of buffing are distortion, caused by the inducement of localized stress; surface burning, resulting from prolonged dwell of the buff; an inability to process inner or restricted surfaces; and the feathering of holes and edges. Proper care of the buffing wheel is essential. Buffing with insufficient compound or a loaded wheel produces burning or distortion of the part. After buffing, no further cleaning of parts is required except degreasing to remove the buffing compound. Further information may be found in the Section "Finishing Methods" in this Volume.

Vapor Phase Nitriding

Other surface modification techniques employ reactive gases such as nitrogen to form a surface layer that diffuses into the surface under temperature. The nitrogen must be extremely pure (less than 100 ppm oxygen with a dew point of -45 °C, or -50 °F). The part to be surface treated is heated in nitrogen, which forms a substoichiometric nitride layer on the surface. Depending on temperature and time, the nitride layer will form to a depth of several thousand angstroms. The coating thus produced is a light gold color for zirconium and its alloys. Typical temperatures are in the range of 850 to 1050 °C (1560 to 1920 °F) with times ranging from several minutes to 30 min at temperature. The operation may be performed in a vacuum furnace that is compatible with the introduction of nitrogen.

High-temperature vapor-phase synthesis (HVS) is used to form reactive layers of carbides, nitrides, and carbonitrides on the surface of zirconium, hafnium, tantalum, niobium, and their alloys. The ceramic surfaces of HVS-processed materials provide both wear and corrosion resistance, protecting the unreacted interior of the host material. The properties of the reacted material can be tailored to meet the requirements of a range of applications. In general, however, the materials have relatively high thermal conductivities and, unlike conventional oxide ceramics, are not particularly susceptible to thermal shock.

Metal-refining applications of HVS-processed materials are particularly promising. Most molten metals do not wet these ceramics, and they also resist both abrasion and corrosion. Other potential applications include transfer tubes for routing abrasive or reactive chemicals and gases, at high or low temperatures, and components of high-strength, high-stiffness structures. Property and performance testing are currently in progress.

Electroplating

Hafnium, zirconium, and Zircaloys (zirconium-tin alloys), are difficult to coat with an adherent electroplate because they form a tenacious oxide film in air and aqueous solutions. There are alternative processes for plating nickel on zirconium.

In the first process, the zirconium article is etched in either an ammonium bifluoride sulfuric acid, 45 g/L (6 oz/gal) of ammonium bifluoride + 0.5 mL (0.02 fluid oz) of sulfuric acid aqueous solution for 1 min at 22 °C (72 °F), or an ammonium bifluoride solution, 45 g/L (6 oz/gal) of ammonium bifluoride aqueous solution for 3 min at 22 °C (72 °F). For nickel plating, the electrolyte consists of 81 g/L (11 oz/gal) of nickel as in $Ni(NH_2SO_3)_2$, 1.0 g/L (0.13 oz/gal) of nickel chloride, and 40 g/L (5.2 oz/gal) of boric acid in an aqueous solution, with an ideal surface tension of 0.038 N/m (0.003 lb/ft). The pH value should be kept at 3.8 to 4.0, with the current density of 2.15 A/dm^2 (21.5 A/ft^2), and the temperature at 50 °C (120 °F). Preheating is required to improve bond strength. Carry the treatment at 700 °C (1300 °F) in vacuum for 1 h with the plated article placed in a molybdenum alloy, TZM ring, or constrained case. Because the coefficient of thermal expansion for molybdenum is lower than that of zirconium and nickel, it provides a stress on the plating as the assembly is heated.

In the alternate process, the zirconium article is etched with an aged aqueous activating solution of 10 to 20 g/L (1.3 to 2.6 oz/gal) of ammonium bifluoride and 0.75 to 2.0 g/L (0.1 to 0.26 oz/gal) of sulfuric acid, for about 1 min at ambient temperature. The solution is aged by immersion of a piece of pickled zirconium for at least 10 min at ambient temperature. The next step is to remove any loosely adhering film or smut formed on the article in the activating step. This can be accomplished in one of the following methods:

- Using a chemical solution which is either an aqueous solution of 2 to 10 vol% fluoboric acid or a hydrofluosilic acid of a similar concentration. The solution is maintained at about 25 °C (77 °F), and the article is immersed in the solution for about 1 min
- Submerging the article in water and applying ultrasonic energy of 20,000 to 30,000 cycles/s for 1 to 2 min
- Swabbing the loosely adhering film from the article by rubbing the surface with cotton, paper, or a brush

An optional step of rinsing the article in water can be practiced by using deionized water to free the article of any residual traces of the material used in previous steps.

Preferred metals to be deposited on the article include copper, nickel, and chromium. The chemical compositions and conditions used for the different electrolytes are shown in Table 1. Similar procedures can be used for electroplating metals on hafnium, although information in this respect is sparse. Some work has been done on advanced surface treatments for the purpose of enhanced corrosion resistance, appearance, resistance to hydrogen uptake, texture control, and other features. (See, for example, selected references by Sabol and McDonald.)

Table 1 Electrolyte compositions and conditions for plating on zirconium

Electrolyte	Composition	Amount		Temperature		Current density		Heat treatment$^{(a)}$

Surface Engineering of Refractory Metals and Alloys

Revised by John A. Shields, Jr., Climax Specialty Metals

Introduction

THE REFRACTORY METALS include niobium (also known as columbium), tantalum, molybdenum, tungsten, and rhenium. With the exception of two of the platinum-group metals, osmium and iridium, they have the highest melting temperatures and lowest vapor pressures of all metals. The refractory metals are readily degraded by oxidizing environments at moderately low temperatures, a property that has restricted the applicability of the metals to low-temperature or nonoxidizing high-temperature environments. Protective coating systems have been developed, mostly for niobium alloys, to permit their use in high-temperature oxidizing aerospace applications.

Refractory metals at one time were limited to use in lamp filaments, electron tube grids, heating elements, and electrical contacts; however, they have since found widespread application in the aerospace electronics, nuclear and high-energy physics, and chemical process industries. Each of the refractory metals, with the exception of rhenium, is consumed in quantities exceeding 900 Mg (1000 tons) annually on a worldwide basis.

This article describes surface cleaning, finishing, and coating methods used with molybdenum, tungsten, tantalum, and niobium. Because of similarities in processes and applications, molybdenum and tungsten are discussed together, as are tantalum and niobium.

Surface Engineering of Molybdenum and Tungsten

The surface engineering processes used for molybdenum and tungsten are largely similar to those used for steels and heat-resistant alloys (see the articles "Surface Engineering of Carbon and Low-Alloy Steels" and "Surface Engineering of

Heat-Resistant Alloys" in this Volume). This section describes exceptions, modifications, and special practices for treating molybdenum and tungsten surfaces.

Mechanical Cleaning and Polishing of Molybdenum and Tungsten Surfaces

Abrasive Blasting. The oxides of tungsten and molybdenum become volatile at relatively low temperatures. Oxides formed on the metal surface during hot working are porous. To remove these oxides, abrasive blasting is not generally required. It can be useful, however, to remove surface oxides from large or bulky components such as forgings to prepare them for machining. Grit sizes ranging from 36 to 120 mesh are commonly used.

Caution should be exercised when using this technique for two reasons. It is easy for particles of the abrasive medium to become embedded in the surface of the material, and it is not always possible to remove them if they are ceramic. If "iron" grit is used, embedded particles may be removed with hydrochloric acid, or by the nitric-hydrofluoric acid cleaning process described later in this section. When thinner sections such as sheet or plate are subjected to abrasive blasting on one side for an extended length of time without being turned over, the thermal stress caused by the temperature difference across the thickness of the plate may result in cracking of the metal.

Mechanical Grinding and Finishing. Belt grinding is commonly used to produce uniform surface finishes on both flat and round mill products of molybdenum and tungsten. The choice of equipment and abrasive are dictated in part by the equipment available and in part by the finish required. Wet grinding is preferred to avoid overheating and subsequent cracking. The liquid medium (water or a water-soluble coolant) also serves to minimize airborne dust and to lubricate the cutting medium. Table 1 summarizes recommendations for grinding molybdenum (Ref 1). Grinding wheels and papers should employ aluminum oxide or silicon carbide media. Emery paper is ineffective in grinding molybdenum and tungsten.

Table 1 Grinding recommendations for unalloyed molybdenum

Chemical Cleaning and Polishing of Molybdenum and Tungsten Surfaces

Molten Caustic Process. To remove the heavy oxide scale from tungsten, molybdenum, and their alloys, the molten caustic process is used. The molten caustic bath can be sodium hydroxide ($NaOH$) containing 0.5 to 3% sodium nitrite ($NaNO_2$), or it can be molten potassium hydroxide (KOH) containing 10% $NaNO_2$. Individual plants may use slightly different formulations. The operating temperature ranges from 315 to 400 °C (600 to 750 °F), and the immersion time is from 5 to 20 min or until the bubbling reaction stops. Caution should be taken to avoid any water getting into the bath, or a violent reaction will occur. When the workpiece is removed from the caustic, it is rinsed immediately with a jet of hot water in order to blast off the dissolved material and attached salt.

In the molten salt bath room, a suction hood or other ventilation system should be installed. The operator should use a control in a separate room or be separated from the bath container by a partition. In the vicinity of the bath container, the operator should wear a respirator, a face shield, rubber gloves, and an apron. In case the skin or eyes come in contact with the salt, one should flush the eye or skin area with plenty of water for at least 15 min.

Acid Cleaning and Pickling. When tungsten and molybdenum are slightly oxidized on the surface or after the heavily oxidized workpiece is cleaned with molten caustic, acid cleaning is used. The acid solution consists of 50 to 70 vol% of concentrated HNO_3, 10 to 20% of concentrated HF, and the remainder water. The cleaning solution is best when maintained at temperatures of 50 to 65 °C (120 to 150 °F). The process of acid pickling is twofold. First the nitrogen dioxide generated by nitric acid oxidizes the metal surface. Then the oxide is dissolved in hydrofluoric acid. The nitric-hydrofluoric bath also dissolves iron-containing contaminants that may have become embedded or included in the metal surface during high-temperature processing.

In the pickling area, ventilation and drainage systems should be installed. For the pickling acid, a recycling system to remove the residues and to refresh the acid is recommended. In small operations without recycling, the acid solution should be disposed of in a manner consistent with environmental regulations.

The dangers of hydrofluoric acid cannot be overemphasized. Any personnel working with the material must be adequately protected with rubber gloves and garments. Emergency spill kits should be readily available to neutralize any acid spills and more importantly treat any acid burns. Hydrofluoric acid is a "calcium seeker" that can cause severe and permanent injury to bone, and even death if burns are not treated properly.

Tungsten normally receives no other acid cleaning treatments, but molybdenum is occasionally further acid cleaned in a nitric-sulfuric acid bath. Acid concentrations are normally 750 to 900 g/L (100 to 120 oz/gal) HNO_3 and 100 to 200 g/L (15 to 25 oz/gal) H_2SO_4. The bath is typically operated at ambient temperatures.

Thorough water rinses are necessary after all acid cleaning treatments to remove acid residues and dissolved species. The best approach is to employ clean water sprays; the effluent from all rinse operations must be handled carefully to conform with environmental and safety regulations.

Solvent Cleaning. To remove oil, grease, and other contaminants from the surface of tungsten or molybdenum, a common organic solvent such as trichloroethylene, acetone, or isopropanol may be used. Cleaning is usually performed at room temperature by immersing and soaking the part in the solvent. Ultrasonic vibration is sometimes used to loosen soils from deep recesses. For large parts, spraying or wiping with the solvent may serve the same cleaning purpose. A proper ventilation system should be installed in the room for solvent cleaning.

Electrolytic Cleaning. Two common methods for cleaning molybdenum and tungsten are acid electrolyte (aqueous solution of 5 to 50 vol% concentrated HF, using 5 V, 60 Hz alternating current) and alkaline electrolyte (aqueous solution of 2 to 10 wt% NaOH or KOH with a nickel cathode, using a current density of 230 A/dm^2, or 2300 A/ft^2).

Preparation of Molybdenum and Tungsten for Coating and Joining

Plating is a coating technique that generally requires very clean surfaces, and a number of techniques have been developed to produce such surfaces. Table 2 summarizes operating information for several electrolytic cleaning techniques that have been applied to molybdenum. Table 3 lists nonelectrolytic techniques that are also in use.

Table 2 Etching solutions and conditions for molybdenum

Solution composition	Amount		Anodic current density		Time, min	Temperature	
	g/L	oz/gal	A/dm^2	A/ft^2		°C	°F
Sulfuric acid, H_2SO_4	880	1140	2-10	20-100	2-3	21-32	70-90
Phosphoric acid, H_3PO_4	718	93					
Chromate trioxide, CrO_3	100	153	38	380	2	21-32	70-90
Sodium chromate, Na_2CrO_4	10	1					
Sulfuric acid, H_2SO_4	1180	153	22	220	$\frac{1}{2}$	21-32	70-90

Chromate trioxide, CrO_3	250	33	15.5	155	$\frac{1}{3}$	56	135
Sulfuric acid, H_2SO_4	2.5	0.3					

Table 3 Nonelectrolytic cleaning techniques for molybdenum

Solution	**Temperature**		**Immersion time, min**
	°C	**°F**	
Satisfactory preparation for electroplating			
Aqueous: 300 g/L (40 oz/gal) potassium ferricyanide	RT	RT	1
"Ultra-clean" surfaces for electronic applications			
Aqueous: 80% H_2O_2, 10% HCOOH	RT	RT	5-10
Alternate "ultra-clean" surfaces for electronic applications			
Concentrated H_2SO_4 and 3.5 vol% saturated $Na_2Cr_2O_7 \cdot 2H_2O$	90	195	1

Ion sputtering has been evaluated as a means for preparing molybdenum and tungsten for plating and has not been shown to have an advantage in producing adherent films. However, when sputter cleaning is combined with magnetron deposition of an underlayment coating, the strength of subsequently plated coatings is greatly improved (Ref 2, 3).

Cleaning is also critical to obtaining efficient joints in brazed or welded material. A two-step technique for cleaning molybdenum prior to brazing has been published by one brazing alloy manufacturer, as follows:

Bath No. 1 (wt%)	
Potassium permanganate	5
Sodium hydroxide	10
Water	85
Bath No. 2 (vol%)	

Sulfuric acid (concentrated)	15
Hydrochloric acid (concentrated)	15
Aqueous solution of chromic acid (6-10 wt% CrO_3)	70

Immerse the molybdenum in bath No. 1 for 5 to 10 min at 65 to 80 °C (150 to 180 °F), remove, and spray rinse. This will leave a black smut on the surface. Rinse with cold water, scrubbing off loose smut. Immerse the molybdenum in Bath No. 2 at room temperature for 5 to 10 min, remove, and spray rinse. This cleaning procedure will remove the oxides without attack of the base metal.

Several other processes have been developed for pre-welding cleaning of molybdenum:

Alkaline-Acid Procedure

1. Degrease with acetone.
2. Immerse for 5 to 10 min at 65 to 80 °C (150 to 180 °F) in alkaline solution of 10 wt% NaOH, 5 wt% $KMnO_4$, and 85 wt% distilled water.
3. Rinse with cold water, scrubbing off the loose smut.
4. Immerse for 5 to 10 min at room temperature in a bath of 15 vol% concentrated H_2SO_4, 15 vol% concentrated HCl, 70 vol% distilled water plus 6 to 10 wt% CrO_3.
5. Rinse in flowing cold tap water and allow to drain dry.

The last step has been modified to use distilled water after the flowing tap water rinse and then dried with forced hot air.

Dual-Acid Procedure

1. Degrease with acetone.
2. Immerse 2 to 3 min at room temperature in a solution of 15 vol% hydrochloric acid (37 to 38% HCl), 15 vol% sulfuric acid (95 to 97% H_2SO_4), 15 vol% nitric acid (90% HNO_3), and 55 vol% distilled water.
3. Rinse in flowing tap water.
4. Immerse for 3 to 5 min at room temperature in a solution of 15 vol% sulfuric acid (95 to 97% H_2SO_4) 15 vol% hydrochloric acid (37 to 38% HCl), 70 vol% distilled water, and 6 to 10 wt% chromium trioxide (Cr_2O_3).
5. Rinse in flowing tap water.
6. Rinse in distilled water.
7. Dry with forced hot air.

Cleaning Procedure for Heavy Oxide Films

1. Vapor degrease in trichloroethylene.
2. Virgo (Virgo is a proprietary molten descaling process) descale; 5 to 15 s at 470 ± 15 °C (875 ± 25 °F).
3. Cold water rinse until all Virgo salt is removed.
4. Dry; repeat steps 2 and 3 if oxides are not removed.
5. Cold water rinse, until all Virgo salt is removed.
6. Nitric acid pickle; 20 to 25 vol% of 42 °Bé acid (63 ± 3 °C, or 145 ± 5 °F), until a uniform dark coating is formed.
7. Cold water rinse.
8. Dip in potassium ferricyanide-potassium hydroxide solution:

Potassium ferricyanide, g/L(oz/gal)	300 (40.2)
Potassium hydroxide, g/L (oz/gal)	100 (13.4)
Temperature	Room
Time, s	30-60

9. Cold water rinse.
10. Chromic acid dip; 187 g/L (25 oz/gal) Cr_2O_3, 30 to 45 s, room temperature.
11. Cold water rinse.
12. Alkaline cleaner (90 ± 6 °C, or 190 ± 10 °F), 6 s maximum.
13. Cold water rinse.
14. Hydrochloric acid pickle; 20 to 22 °Bé (63 ± 3 °C, or 145 ± 5 °F),10 s maximum.
15. Cold water rinse.
16. Deionized water rinse containing 0.01 wt% of a chelating material (Sequestrene NA4, NA2, or equivalent material; product of Geigy Chemical Corporation).
17. Repeat step 16 in a second solution.
18. Methyl alcohol--25 vol% acetone rinse.
19. Repeat step 18 in a second solution.
20. Drain dry.
21. Wrap in clean plastic sheeting.

Cleaning Procedure for Nonvisible Oxide Films

1. Vapor degrease in trichloroethylene.
2. Alkaline soak clean:

Sodium hydroxide, g/L (oz/gal)	7.5 (1)
Sodium carbonate, g/L (oz/gal)	30 (4)
Sodium phosphate (Na_3PO_4), g/L (oz/gal)	15 (2)
Temperature, °C (°F)	88±5 (190±10)
Time, min	1-2

3. Cold water rinse.
4. HCl pickle; 20 to 22 °Bé (63 ± 3 °C, or 145 ± 5 °F), 10 to 15 s.

5. Cold water rinse.
6. Rinse in deionized water containing 0.01% by weight of chelating material (same as for above).
7. Repeat step 6 in a second solution.
8. Methyl alcohol--25% acetone rinse.
9. Repeat step 8 in a second solution.
10. Drain dry.
11. Wrap in clean plastic.

After cleaning, the parts are handled with clean, dry gloves until they are welded.

Acid Cleaning Procedure

1. Solution: 95.0 parts H_2SO_4, 4.5 parts HNO_3, 0.05 parts HF, and 18.8 g/L (2.5 oz/gal) Cr_2O_3.
2. Temperature 60 °C (140 °F).
3. Immerse specimens for 30 s.
4. Rinse with hot water.

Electropolishing Procedures for Cleaning Molybdenum Prior to Brazing

1. Solution: 2 parts concentrated H_2SO_4, one part water.
2. Solution temperature 55 °C (130 °F).
3. Current density, 62 to 78 A/dm^2 (4 to 5 A/in.^{2}).
4. Voltage: 10 to 11 V.
5. Polishing time: 2 min.

Plating and Coating of Molybdenum and Tungsten

Electroplating. Molybdenum and tungsten are difficult to plate because the natural oxides formed on the surface of these metals interfere with the adherence of coatings. Chromium has been a favored strike coating because its thermal coefficient of expansion is similar to that of molybdenum. It has good as-plated adherence, and the two metals diffuse to form a solid solution at elevated temperatures. Nickel has also found extensive use as a strike plating because its adherence can be enhanced by a post-plating diffusion anneal. The anodic etching procedure for activation of molybdenum is as follows:

1. Chromium is deposited in a chromic-sulfuric acid bath, 250 g/L (33 oz/gal) Cr_2O_3 and 2.5 g/L (0.3 oz/gal) H_2SO_4, at 90 ± 5 °C (195 ± 9 °F), using a current density of 100 ± 20 A/dm^2 (1000 ± 200 A/ft^2).
2. Nickel is deposited in a Watts-type bath over an acid chloride Wood's nickel strike plate, 240 g/L (31 oz/gal) nickel chloride·hexahydrate, 80 g/L (10 oz/gal) HCl at room temperature, using a current density of 3 to 10 A/dm^2 (30 to 100 A/ft^2), on the chromium-plated molybdenum.
3. Molybdenum plated with 25µm (1 mil) of chromium and 175 µm (7 mils) of nickel is protected in air for 1200 h at 980 °C (1795 °F), and for 100 h at 1200 °C (2190 °F).
4. Chromium-strike plated tungsten is carried out in the same bath as for molybdenum at 50 °C (120 °F), for 1 min with a current density of 5 to 15 A/dm^2 (50 to 150 A/ft^2). Watts nickel can be deposited over an acid sulfate strike on chromium-plated tungsten. This is carried out in a bath containing 240 g/L (31 oz/gal) nickel sulfate·hexahydrate and 40g/L (5 oz/gal) H_2SO_4 at room temperature for 2 to 5 min with a current density of 5 to 10 A/dm^2 (50 to 100 A/ft^2).

Another process intended to produce a hydride film as a basis for nickel plating is as follows:

1. Tungsten is treated cathodically at 1 to 11 A/dm^2 (10 to 110 A/ft^2) in approximately 2% acid or alkali, by weight, for 5 to 15 s.

2. Tungsten is rinsed, and nickel plated for 2 min in a Watts nickel bath, pH 4.0, at 65 °C (150 °F), with a current density of 5 to 11 A/dm^2 (50 to 110 A/ft^2).
3. The nickel-coated tungsten, after heating under vacuum at 450 to 750 °C (840 to 1380 °F) until gas evolution ceases, is cleaned and activated by strike plating in a Wood's nickel bath and then plated as desired.

Recent development shows that gold can also be used as a preplate for the subsequent deposition of other metal coatings. A process for molybdenum is detailed as follows:

1. Alkaline ferricyanide etch for 10 s at room temperature in a solution of 200 to 250 g/L (26 to 33 oz/gal) ferricyanide and 75 to 85 g/L (10 to 11 oz/gal) KOH.
2. Water rinse.
3. Hydrochloric acid, 50 vol%, dip for 10 s at room temperature.
4. Water rinse.
5. Acid gold strike, alkaline gold-cyanide-tartrate bath, 1 to 3 min at 0.1 A/dm^2 (1 A/ft^2), deposit 0.12 to 0.72 mg/cm^2 (0.78 to 4.7 mg/in.^{2}), 0.06 to 0.37 μm (2.4 to 15 μin.).
6. Water rinse and dry.
7. Diffuse in dry hydrogen at 830 °C (1525 °F) for 30 min.
8. Acid gold strike 4 min at 0.1 to 0.2 A/dm^2 (1 to 2 A/ft^2) to deposit additional 0.2 to 0.5μm (8 to 20 μin.).
9. Water rinse and dry. Diffusion in dry hydrogen at 830 °C (1525 °F) for 30 min.
10. Acid gold strike for 45 to 75 s at 0.1 to 0.2 A/dm^2 (1 to 2 A/ft^2).
11. Water rinse.
12. Plate desired metal coating. A thermal treatment in dry hydrogen at 830 °C (1525 °F) reduces the natural oxide to form a metal-metal interface and a diffusion bond.

Tungsten is first plated with about 0.2 to 2.0 μm (8 to 80 μin.) gold, heated at 1200 to 1370 °C (2190 to 2500 °F) under vacuum for 5 min, and then plated with gold or other metals to the desired thickness.

The TZM (0.5% Ti, 0.08% Zr, balance Mo) alloy has good strength properties at high temperature, but is subject to galling in threaded fasteners. Rhodium plating on molybdenum tends to eliminate galling. The process is detailed as follows:

1. Solvent degrease.
2. Alkaline clean at 80 °C (175 °F) for 5 min.
3. Water rinse.
4. Alkaline ferricyanide etch with agitation for 30 s at room temperature.
5. Water rinse.
6. Sulfuric acid, 5 to 10 vol%, dip for 10 s.
7. Rhodium strike at 1 to 2 A/dm^2 (10 to 20 A/ft^2) at 50 °C (120 °F) to deposit a 0.06 to 0.10 mg/cm^2 (0.40 to 0.65 mg/in.^{2}) in an acid rhodium sulfate bath.
8. Water rinse and dry.
9. Diffusion heat treat at 1000 °C (1830 °F) for 30 min, 10^{-4} torr (10^{-2} Pa) maximum, purge with helium.
10. Sulfuric acid dip for 30 s minimum at room temperature.
11. Rhodium plate at 1 to 2 A/dm^2 (10 to 20 A/ft^2) at 50 °C (120 °F) to thickness of 0.5 μm (2.0 μin.).
12. Water rinse and dry.

Application of the rhodium strike directly over the natural oxide to TZM is somewhat difficult to accomplish initially because of the usual high tensile stress in rhodium plate. Reducing this stress is more effective in achieving adherence of the rhodium strike than are efforts to reduce the thickness of the natural oxide on TZM.

Iridium coatings about 12 μm (475 μin.) thick, plated in a fused cyanide bath, over chromium on nickel over gold strike-coated molybdenum, offered oxidation protection for about $\frac{1}{2}$ h in air at 1000 °C (1830 °F).

A typical process for nickel plating is as follows:

1. Degrease.
2. Scrub in detergent.
3. Water rinse.
4. Etch 2 min in potassium ferricyanide.
5. Wipe smut with clean towel and detergent.
6. Cathodically clean in potassium cyanide solution (80 g/L KCN) at 4.65 A/dm^2 (0.30 A/in.^{2}).
7. Cold water rinse 1 $\frac{1}{2}$ min.
8. Strike plate in nickel sulfamate solution for 2 $\frac{1}{2}$ min at 0.78 A/dm^2 (0.05 A/in.^{2}):

$Ni(NH_2SO_3)_2 \cdot H_2O$, g/L (oz/gal)	335 (45)
$NiCl_2$, g/L (oz/gal)	45 (6)
H_3BO_3, g/L (oz/gal)	45 (6)
pH	3.4

9. Water rinse.
10. Hydrogen anneal for 10 min at 875 °C (1605 °F).
11. Water rinse.
12. Repeat step 6.
13. Cold water rinse.
14. Plate in solution of step 8 at 2.3 A/dm^2 (0.15 A/in.^{2}) for 16 min.
15. Water rinse.
16. Repeat steps 12 to 15 until desired thickness is attained.

Anodizing. For the anodizing of tungsten and molybdenum, an acetic-based electrolyte for vanadium may be used. It consists of acetic acid, 0.02 *M* sodium tetraborate-decahydrate, and 1.0 *M* additional water. When the water content is less than 1.0 *M*, the conductivity is reduced to an inconvenient extent. When the content is more than 2*M*, the film formed on molybdenum becomes excessively unstable. In the process, a platinum cathode is preferred, and the temperature is maintained around 25 °C (77 °F), with the presence of air.

The anodic film formed on molybdenum is so unstable that it will change interference colors and eventually disappear when exposed to air. It can be stabilized either by dipping in glacial acetic acid, followed by drying with filter paper, or by using a jet of compressed air immediately after its withdrawal from the electrolyte. Once stabilized, it can be stored in a desiccator almost indefinitely.

High-Temperature Oxidation-Resistant Coatings for Molybdenum. Ductile metallic overlays are among the first materials investigated as coatings for molybdenum. The materials and processes used are summarized in Table 4. The electrodeposition processes have been discussed in the electroplating section. Chromium is the most promising of the metallic coatings for molybdenum. It offers excellent oxidation protection and is compatible with substrate; however, chromium is embrittled by nitrogen and will crack and spall on repeated thermal cycling. A nickel or nickel alloy overlay will protect chromium from nitriding. A duplex coating will give good service for molybdenum up to 1200 °C (2195 °F).

Table 4 Metallic coatings for molybdenum

Process type	Material	Thickness range	
		µm	**µin.**
Electrodeposition	Chromium, nickel, gold, iridium, palladium, platinum, rhodium	12.7-76.2	500-3002
Flame sprayed	Nickel-chromium-boron, nickel-silicon-boron, nickel-chromium, nickel-molybdenum	127-254	5004-10,007
Clad or bonded	Platinum, nickel, nickel-chromium, platinum-rhodium	50.8-508	2002-20,015
Molten bath	Chromium	12.7-25.4	500-1001

Noble metal coatings, such as platinum and iridium, can be used on molybdenum at temperatures to about 1425 °C (2595 °F). They provide a significantly longer useful life at all temperatures than the duplex chromium-nickel coatings.

Coatings based on compounds with aluminum, in initial attempts, were to develop molybdenum parts for aircraft gas turbines. Coatings of aluminum-chromium-silicon, aluminum-silicon, and aluminum-tin systems are indicated in Table 5. The aluminide coatings are applied as thick overlays, using a variety of spray or dip processes. The aluminide coatings provide good oxidation protection to molybdenum at temperatures up to 1540 °C (2805 °F). Life at higher temperatures is very short, less than 1 h, probably as a result of rapid interdiffusion.

Table 5 Aluminide coatings for molybdenum

Type	Compositions	Deposition process	Thickness range	
			µm	**µin.**
Aluminum-chromium	20% Al + 80% (55Cr-40Si-3Fe-1Al)	Thermal spray	178-254	7013-10,008
Aluminum-silicon	88% Al-12% Si	Thermal spray, hot dip	12.7-178	500-7013
Tin-aluminum	90% (Sn-25Al)-10% $MoAl_3$	Slurry dip or spray	50.8-203	2002-7998

Interest in coatings for molybdenum shifted from an aluminide to a silicide base in the mid 1950s. A list of the basic silicide coatings is shown in Table 6. Most of the silicide coatings are deposited by pack-cementation diffusion processes. A major deficiency in the performance of silicide-base coatings appears when the system is used in low-pressure environments. As shown in Fig. 1, silicide coatings that protect TZM substrate for 4 h at 1650 to 1760 °C (3000 to 3200 °F) in air at 1 atm cannot be used above 1480 °C (2695 °F) in air at pressure of 0.1 to 1.0 torr (13 to 130 Pa).

Table 6 Silicide coatings for molybdenum

Type	Deposition process
Molybdenum silicide	Fluidized bed, pack cementation, slip pack, plasma spray, electrophoresis
Molybdenum silicide and chromium	Pack cementation
Molybdenum silicide and chromium, boron	Pack cementation
Molybdenum silicide and chromium, aluminum, boron	Slip pack
Molybdenum silicide and tin-aluminum	Cementation and impregnation

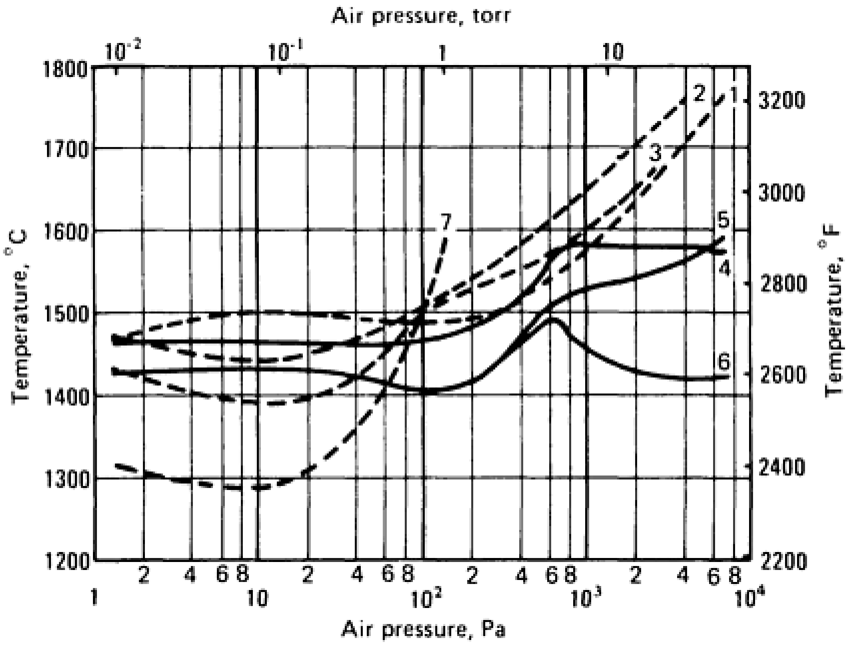

Fig. 1 The effect of air pressure on the maximum temperature for a 4 h life of silicide-coated refractory materials. Alloy/coating: 1, TZM/PFR-6; 2, TZM/Disil; 3, TAM/Durak-B; 4, Cb-752/PFR-32; 5, Cb-752/CrTiSi; 6, B-66/CrTiSi; 7, Ta-10W/Sn-Al

Refractory oxides or ceramics are the only materials suitable for the oxidation protection of molybdenum above 1650 °C (3000 °F) for any length of time. The types of oxide coatings that have been used on molybdenum are summarized in Table 7. Ceramic coatings suffer from one common problem. They crack on thermal cycling and tend to spall from the substrate. For only minutes, during single-cycle uses, such as for rocket motors, ceramic coatings provide useful protection from oxidation to 1930 °C (3505 °F) with Al_2O_3 and to 2200 °C (3990 °F) with ZrO_2.

Table 7 Oxide coatings for molybdenum

Type	Deposition process	Thickness range	
		µm	mils

Zirconium oxide-glass	Frit, enamel	130-760	5-30
Chromium-glass	Frit, enamel	130-250	5-10
Chromium-alumina oxide	Thermal spray over chromium plate	200-380	8-15
Alumina oxide	Thermal spray	25-2500	1-100
Zirconium oxide	Thermal spray	25-2500	1-100
Zirconium oxide	Troweling	2500-7600	100-300

High-Temperature Protective Coatings for Tungsten. A more restrictive situation exists with tungsten. Silicide coatings are protective for a short time to 1925 °C (3500 °F). In the 1090 to 1650 °C (1995 to 3000 °F) range, lives of 10 to 50 h are attained.

Modifying the silicides with tungsten, zirconium, and titanium may be a more successful approach. A tungsten-modified silicide pack coating with HfB_2 additives is available commercially. A multi-element umbrella type, consisting of iridium electrodeposited from a fused salt bath, followed by a plasma-sprayed ZrO_2 layer prevents volatilization losses during very high-temperature oxidation. This may be serviceable at 1800 °C (3270 °F) for several hours. In the ceramic approach, a coating of ThO_2 over a tungsten wire mesh can be used at 2925 °C (5300 °F), and a coating of HfO_2 at 2700 °C (4890 °F).

Surface Engineering of Tantalum and Niobium

The processes and equipment for surface cleaning, finishing, and coating of tantalum and niobium, like those for molybdenum and tungsten, are similar to the processes and equipment used for steels and heat-resistant alloys. Important exceptions and special procedures are noted in this section.

Mechanical Cleaning and Polishing of Tantalum and Niobium Surfaces

Abrasive Blasting. To remove intermediate thickness of the oxide scale of tantalum or niobium, abrasive blasting is applied. The abrasives to be used are usually silicon carbide of grit sizes ranging from 36 to 120 mesh. A good ventilation system is required in the abrasive blasting room, and the operator should wear a mask during working.

Mechanical Grinding and Finishing. Although commercially pure tantalum or niobium is worked at room temperature, their alloys are usually worked at elevated temperatures. Heavy oxide scale is formed. To remove such heavy oxide scale, mechanical grinding is the most effective method. For coarse grinding, a vitrified-bond grinding wheel having a 46 to 60 mesh of aluminum oxide is used. For finishing, a finer grit, vitrified or resinoid-bond grinding wheel 60 to 120 mesh of silicon carbide is used. For the cutting of tantalum or niobium, an abrasive wheel is also preferred. The grinding operation usually is performed dry, but the abrasive cutting is used with water cooling.

A good ventilation system should be installed in a grinding or polishing room. The operator should wear a face shield, mask, and gloves during working. Emery cloth and paper are ineffective for polishing tantalum and niobium. They are seldom used for finishing the product of these metals.

Cleaning and Polishing of Tantalum and Niobium

Alkaline Cleaning. When oxide scale is combined with grease, graphite, molybdenum disulfide, and other lubricants on the workpieces of tantalum and niobium, an alkaline cleaning process is usually used. The starting product for the solution is a solid alkaline material that usually consists of 50 to 80% NaOH, with the remainder being sodium metasilicate and sodium carbonate. The solids are dissolved in water at a concentration of 0.6 to 1.2 kg/L (5 to 10 lb/gal), and the solution is kept at 65 to 80 °C (150 to 180 °F). The soaking time for the workpiece ranges from a few minutes to a few hours. After soaking, the workpiece should be immediately rinsed with a jet of water in order to blast off the loosened scale and attached salt. The operator should wear a face shield, rubber gloves, and an apron during working.

Acid Cleaning and Pickling. After mechanical grinding, abrasive blasting, or alkaline cleaning, tantalum and niobium are cleaned further with an acid solution. This consists of 40 to 60 vol% of concentrated HNO_3 to 10 to 30% of concentrated HF, and the remainder water. The cleaning solution is best when maintained at temperatures of 50 to 65 °C (120 to 150 °F). After acid pickling, the workpiece should be washed with water or rinsed thoroughly with a jet of water to remove any trace of acids.

Good ventilation and drainage systems should be installed in the acid pickling room. A recycling system to remove the residues and to refresh the acid is preferred both for economical and ecological reasons. For small operations without recycling, the acid solution should be disposed of in a manner consistent with environmental regulations.

The dangers of hydrofluoric acid cannot be overemphasized. Any personnel working with the material must be adequately protected with rubber gloves and garments. Emergency spill kits should be readily available to neutralize any acid spills and more importantly treat any acid burns. Hydrofluoric acid is a "calcium seeker" that can cause severe and permanent injury to bone, and even death if burns are not treated properly.

Solvent Cleaning. To remove oil, grease, and other contaminants from the surface of tantalum or niobium, a common organic solvent, such as trichloroethylene, acetone, or isopropanol can be used. Cleaning is performed at room temperature by immersing workpieces in solvent. Ultrasonic vibration is sometimes used to loosen soils from deep recesses. For large parts, spraying or wiping with the solvent may serve the same purpose. A proper ventilation system should be installed in the room for solvent cleaning.

Electrolytic Cleaning. Electrolytic etching may be used for the preparation and activation of tantalum and niobium before electroplating. The electrolytes usually used are as follows:

- For niobium, a concentrated hydrofluoric acid, 49% solution, with alternating current at 1 to 5 V and a current density of 22 to 108 A/dm^2 (220 to 1080 A/ft^2) for 1 to 3 min at room temperature is used.
- For tantalum, a solution consisting of 90% concentrated H_2SO_4 and 10% concentrated HF, used in the 25 to 40 °C (75 to 105 °F) range with a platinum cathode at a current density of 10 to 50 A/dm^2 (100 to 500 A/ft^2), gives excellent results.

Preparation of Tantalum and Niobium for Coating and Joining

Before electroplating, the substrate to be plated should be electrolytically cleaned or activated. The electrolytic cleaning processes for niobium and tantalum have been mentioned in a previous section. After this, the article may be dipped in an aqueous solution of 50% concentrated HNO_3 and 2% concentrated HF, at 20 to 30 °C (68 to 86 °F).

Plating and Coating of Tantalum and Niobium

Electroplating. Copper, chromium, gold, iron, nickel, and platinum are plated on niobium or tantalum. Conditions and solutions for these are given in Table 8.

Table 8 Solutions for plating niobium or tantalum

Solution	Constituent	Amount of constituent		Current density		Temperature	
		g/L	oz/gal	A/dm^2	A/ft^2	°C	°F
Copper	$CuSO_4\cdot 5H_2O$	210	27	1.69	26.9	25	77
	H_2SO_4	80	10				
	Molasses	2.5	0.3				
Chromium	CrO_3	400	52	5.38	53.8	75	165
	H_2SO_4	4	0.5				
Gold	$KAu(CN)_2$	44	5.7	2.15	21.5	54	130
	$K_2C_4H_4O_5$	48	6.2				
	KOH	3	0.9				
	K_2CO_3	10	1.3				
	KCN(a)	30	4				
Iron	$Fe_2SO_4\cdot 7H_2O$	300	39	3.23	32.3	60	140
	$FeCl_2\cdot 4H_2O$	42	5.5				
	$(NH_4)_2SO_4$	15	2				
	NaCOOH	15	2				
	H_3BO_3	30	4				
	Wetting agent	1	0.13				
Nickel	$NiSO_4\cdot 7H_2O$	300	39	1(b)	10	60	140
	$NiCl_2\cdot 6H_2O$	50	6.5				

	H_3BO_3	30	4				
	Wetting agent	1	0.13				
Platinum	Bakers platinum solution No. 209	(c)	(c)	8.07	80.7	88	190

(a) pH, 12.1.

(b) 4.31 A/dm^2 (43.1 A/ft^2).

(c) Diluted to 4 g/L (0.52 oz/gal) of contained platinum made slightly ammoniacal

Iron and nickel deposits are fairly adherent. Other deposits easily peel off the niobium. The presence of a hydride layer between the plate and the niobium limits the strength of the bond, and heat treating is required to decompose the hydride. This involves heating in a vacuum for 1 h at 700 to 1100 °C (1290 to 2010 °F). Improved adhesion of the coating can also be obtained if the surface to be plated is first shot blasted and the flash coated with an undercoat of copper, deposited by chemical displacement from a specified electrolyte.

For plating gold on tantalum, heat treatment before and after the electrolytic plating will enhance the bonding. The temperature for preheating is 1955 °C (3550 °F), and the after-treatment is carried out at 1100 °C (2010 °F). Both treatments occur under vacuum.

For plating nickel, cathodic treatment at 2 A/dm^2 (20 A/ft^2) for 20 to 30 min in a solution of 2.5 vol% of 48% HF, 2.5 vol% of HCl, sp gr 1.16, and 95% absolute methanol at 40 to 50 °C (105 to 120 °F), gives a more uniform surface texture on tantalum. After this treatment, 0.3 μm (12 μin.) of nickel is deposited in a Watts bath, pH 4.0, vacuum heat treated at 500 to 600 °C (930 to 1110 °F), then nickel plated to 10 μm (390 μin.) thick, and again heat treated at 450 °C (840 °F).

Another procedure intended to produce a hydride film as a basis for electroplating with nickel on tantalum or niobium is as follows:

1. The metal is treated cathodically at 1 to 11 A/dm^2 (10 to 110 A/ft^2) in 2%, by weight, acid or alkali for 5 to 15 s.
2. The metal is then rinsed and nickel plated for 2 min in a Watts nickel bath, pH 4.0, at 65 °C (150 °F), with a current density of 5 to 11 A/dm^2 (50 to 110 A/ft^2).
3. After vacuum heating at 450 to 750 °C (840 to 1380 °F) until gas evolution ceases, the nickel-coated article is cleaned and activated by strike plating in Wood's nickel bath, and then plated as desired.

Anodizing is a process in which a current passes through an electrolyte from an inert cathode to the anode, on which a thin layer of the oxide forms during the process. The thin but dense oxide layer thus formed usually protects the metal from further oxidation in air and from abrasion. Anodic oxidation for tantalum and niobium is carried out at constant current density, about 1 to 15 A/dm^2 (10 to 150 A/ft^2), at room temperature either in 0.5 to 2 wt% ammonium citrate or in 0.5 wt% ammonium borate solution, with the pH kept at 9 by adding ammonium hydroxide.

Oxidation-Resistant Coatings for Niobium. The use of refractory metals at elevated temperatures is being pursued intensively by the aerospace industry. One of the major limitations to progress in this field is the need for coatings to protect the alloys from rapid oxidation and embrittlement at elevated temperatures. These coatings may be classified as intermetallic compounds, including silicides and aluminides that form compact or glassy oxide layers; alloys that form compact oxide layers; noble metals that resist oxidation; and stable oxides that provide a physical barrier to the penetration of oxygen.

Many techniques have been used to form protective coatings on niobium alloys. They are as described below.

Pack Cementation. Immersion of the material to be coated in a pack consisting of inert filler, metal coating elements, and halide activator. Heat treatment is conducted in hydrogen or an inert atmosphere. Coating is formed by vapor transport and diffusion.

Vacuum Pack. Immersion of material to be coated in an all-metal pack of coating elements plus halide activator. Heat treatment is performed in dynamic vacuum or under a partial atmosphere of inert gas. Coating is formed by vapor transport and diffusion.

Slip Pack. Similar to the two processes above, substitution of thin disposable bisque for massive pack. Bisque is sprayed, dipped, or applied to the substrate surface in other ways.

High-Pressure Pack Cementation. Similar to pack cementation and vacuum pack, with utilization of inert gas pressure in excess of 1 atm (100 kPa).

Fused Slurry. Uniform application of a metal or alloy slurry to the substrate surface, followed by fusion of the slurry in an inert gas or vacuum environment. Coating forms by liquid-solid diffusion.

Slurry-Sinter. Spray or dip application of metal particles plus binder to substrate surface, followed by solid- or liquid-phase sintering in vacuum or inert environment.

Fused Salt. Electrolytic or nonelectrolytic deposition of metal ions from a fused metal salt solution, such as fluorides, chlorides, and bromides, on the substrate material. Pure or alloy coatings are formed.

Electrophoresis. Deposition of charged metal particles from a liquid suspension onto a substrate surface of opposite electrical potential. Synthesis of particulate deposit generally involves isostatic compaction followed by vacuum or inert atmosphere sintering.

Aqueous Electroplating. Electroplating of metal ions from aqeuous solution. Process can involve suspension of particulate materials in electrolyte and occlusion of these particles in metal deposit.

Fugitive Vehicle. Involves spray or dip application of metal slurry onto the substrate surface, followed by vacuum heat treatment. Slurry contains coating elements and fugitive vehicle that is molten at the firing temperature. Fugitive vehicle has high solubility for coating elements and very low solubility for substrate. Coating forms by transfer of elements from the liquid solution to the substrate surface, with subsequent diffusion growth of the coating phase. Fugitive vehicle is eventually removed by evaporation.

Fluidized Bed. Immersion of the material to be coated in a heated fluidized bed of coating elements, using as the fluidizing gases mixtures of reactive halogen gases and hydrogen or argon. Coating forms by disproportionation of gaseous metal halides on substrate surface, followed by diffusion alloying.

Chemical Vapor Deposition (CVD). Entirely gaseous process. Metal halide gases, plus argon or hydrogen, pass over surface of metal to be coated. Coating forms by hydrogen reduction or thermal decomposition of metal halide at substrate surface, followed by diffusion-controlled coating growth.

Vacuum Vapor Deposition. Evaporation of a metal or alloy from a filament, liquid bath, or other source, followed by condensation of the metal vapor onto a cold or hot substrate surface. Post diffusion treatment is optional.

Hot Dipping. Immersion of material to be coated in a hot liquid bath of the molten coating elements. Coating forms by liquid-solid diffusion.

Hydride and Oxide Reduction. Spray or dip application of metal hydrides or oxides on substrate surface, followed by vacuum or hydrogen reduction, respectively.

Plasma Arc. Spray deposition of particulate metal or oxide particles using conventional plasma arc facility.

Detonation Gun. Patented gun detonation metal spraying process.

Gun Metallizing. Utilization of conventional wire or powder metallizing equipment.

Cladding. Bonding of thin sheet metal cladding to substrate surface by diffusion bonding, forging, rolling, extrusion, and other methods.

Coating systems and processes for niobium are shown in Table 9.

Table 9 Oxidation-resistant coating systems for niobium

System concept	Composition	Process
Silicide coatings		
Complex silicide multilayered	Cr, Ti, Si	Vacuum pack and vacuum slip-pack, fused slurry and pack, fluidized bed, electrophoresis, chemical vapor deposition, electrolytic fused salt
Modified silicide	Si + V, Cr, Ti	Fluidized bed
Modified silicide	Si	Pack cementation, iodine
Modified silicide	Si-B-Cr	Pack cementation, multicycle
Modified silicide	Si-Cr-Al	Pack cementation, multicycle
Modified silicide	Si + additives	Pack cementation, single cycle
Modified silicide	Si + Cr, Al, B	Pack cementation, single cycle
Silicide	Si	Chemical vapor deposition
Molybdenum disilicide	Si + Mo	MoO_3 reduction and chemical vapor deposition
Modified silicide	Si + additives	Pack cementation, fluidized bed, fused salt, slurry dip
Modified silicide	Si + additives	Pack cementation, single cycle
Liquid phase-solid matrix	Se, Sn, Al	Porous silicide applied by pack or CVD-impregnated with Sn-Al
Multilayered complex silicide	40Mo-40Si, 10CrB-10Al	Plasma spray-diffuse

Modified silicide	Si + additives	Pack cementation
Complex silicide	Si-20Fe-20Cr	Fused silicides
Complex silicide	Si-20Cr-5Ti	Fusion of eutectic mixtures
Complex silicide	Si + (Cr, Ti, V, Al, Mo, W, B, Fe, Mn)	. . .
Complex silicide	V-Cr-Ti-Si	Vacuum and high-pressure pack
Complex silicide	Mo-Cr-Ti-Si, V-Cr-Ti-Si, V-Al-Cr-Ti-Si, Mo-Cr-Si	Multicycle vacuum pack
Glass-sealed silicide	Si + glass	Silicide by pack cementation or CVD + glass slip overcoat
Multilayered	Mo, Ti + Si and glass	Slurry sinter application of Mo + Ti powder, pack silicide, glass slurry seal
Aluminide coatings		
Modified aluminide	Al + B	Pack cementation
Modified aluminide	88Al-10Cr-2Si	Fused slurry
Modified aluminide	Al-Si-Cr	Fused slurry
Modified aluminide	Al-Si-Cr, Ag-Si-Al	Hot dip
Multilayered systems	Fe, Cr, Al, Ni, Mo, Si, VSi_2, $TiCr_2$, $CrSi_2$, B + Al	Powder metallize + aluminum hot dip
Simple aluminide	Al	Pack cementation
Multilayered systems	Cr, FeB, NiB, Si, Al_2O_3, SiO_2, ThO_2 + Al	Electroplate dispersions in Ni + Al hot dip
Modified aluminide	Al + (Si, Ag, Cr)	Silver plate + Al, Cr, Si hot dip
Multilayered systems	Al_2O_3 + Ti + Al	(Al_2O_3 + TiH), Spray-sinter + Al hot dip
Oxide-metal composite	Al_2O_3 + Al	Slurry fusion of Al_2O_3-Al mixture

Aluminide	Al + additives	Fused slurry
Modified aluminide	Al + Sn	Hot dip
Zinc coating		
Self-healing intermetallic	Zn and Zn + Al, Ti, Co, Cu, Cr, Fe, Zr, Cu, Si	Vacuum distillation and hot dip
Oxide coating		
Glass-sealed oxide	Al_2O_3 + glass (baria, alumina, silica)	Flame spray Al_2O_3 + glass slurry
Nickel-chromium coating		
Oxidation-resistant alloy	Ni-Cr	Flame spray, detonation gun, plasma arc
Chromium carbide coating		
Carbide	Cr-C	Plasma spray
Noble metal coatings		
Clad	Pt, Rh	Roll bonding and hermetic sealing
Barrier-layer-clad	Pt, Rh + Re, Be, Al_2O_3, W, ZrO_2, MgO, SiC, Hf	Noble metal clad over barrier layer-diffusion couple study
Pure metal	Ir	Fused-salt deposition

Oxidation-Resistant Coatings for Tantalum. Much of the work on tantalum alloys is the outgrowth of approaches taken with niobium alloys. The development of coatings has come generally in the 1970s. Most of the emphasis is on the diffusional growth of intermetallic layers. A few commercial or semicommercial coatings are as follows:

- A series of tin-aluminum-molybdenum-base coatings are used by slurry process. These are limited primarily by poor resistance to reduced pressure and erosion at very high temperatures.
- Electrophoretical deposition of binary disilicides combined with a molybdenum-vanadium system shows no pest phenomenon during service. This process can be considered commercial for small parts.
- A fluidized-bed, three-step silicon-vanadium-silicon process may be used for niobium as well as Ta-10W.
- Complex titanium, molybdenum, tungsten, and vanadium modified silicide coatings can be applied by a two-step method: a slurry plus high-temperature sinter of an alloy layer followed by a straight silicide pack. Protection for hundreds of hours at 870 °C (1600 °F) and 1320 °C (2410 °F) in furnace tests has

been obtained.

- A fused-silicide coating system, particularly Si-20Ti-10Mo, appears practical for coating large, complex aerospace sheet metal components.
- A duplex coating consisting of a sintered hafnium boride-molybdenum silicide layer overlaid with a hafnium-tantalum slurry is serviceable at 1820 to 1870 °C (3310 to 3400 °F).

Surface Engineering of Nickel and Nickel Alloys

Revised by Russell C. Buckley, Nordam Propulsion Systems Division

---

Introduction

NICKEL is a versatile element and will alloy with most metals. Complete solid solubility exists between nickel and copper; wide solubility ranges between iron, chromium, and nickel make possible many alloy combinations. The face-centered cubic structure of the nickel matrix (γ) can be strengthened by solid-solution hardening, carbide precipitation, or precipitation hardening. Nickel alloys are used for a wide variety of applications, the majority of which are designed to take advantage of the corrosion resistance and/or heat resistance properties of these alloys. The classification, physical metallurgy, and applications of nickel and nickel alloys are described in Volume 2 of *ASM Handbook;* information on heat-resistant nickel alloys and stainless steels is provided in Volume 1 of *ASM Handbook.* This article describes cleaning and finishing of nickel alloys; additional and related information is available in the articles "Diffusion Coatings," "Surface Engineering of Heat-Resistant Alloys," and "Surface Engineering of Stainless Steels" in this Volume.

Nickel alloys do not require special techniques or precautions for the removal of shop soils such as soap, drawing compound, oil, grease, cutting fluid, and polishing compound. Oxide, scale, tarnish, or discoloration can be removed from nickel and nickel alloys by mechanical methods, such as grinding or abrasive blasting, or by chemical methods, such as pickling. Conventional methods of cleaning with alkaline compounds, emulsions, or solvents or vapor degreasing may be employed. These processes are described in the articles "Alkaline Cleaning," "Emulsion Cleaning," "Solvent Cold Cleaning and Vapor Degreasing," and "Mechanical Cleaning Systems" in this Volume.

Pickling

Pickling is a standard method for producing bright, clean surfaces on nickel alloys, either as an intermediate step during fabrication or as a last step on finished parts. Procedures used for pickling nickel alloys are governed by both material composition and prior thermal treatment. The necessity of pickling can be avoided by using bright-heating practices, that is, the use of a protective inert and/or vacuum furnace atmosphere to prevent oxidation. Pickling should not be used to overhaul material by dissolving away appreciable amounts of metal. This practice can cause severe, irreversible damage such as pitting and intergranular attack. Significant material dimensional loss can readily occur if process parameters (e.g., continued maintenance of bath chemistry, temperatures, and immersion time) are ignored. Caution should be observed when pickling bimetallic items, weldments, and components with platings or coated surfaces, because selective, localized attack may occur, depending on system dynamics.

Oxidizing furnace atmospheres, high-sulfur-content fuels, and air leakage in furnaces during high-temperature operations can cause heavy scale to form on unprotected nickel alloys. Securely oxidized nickel alloys have a dull, spongy appearance. Hairline cracks are sometimes present, and patches of scale may break away from the surface. In such cases, the rough underlying metal will not allow an attractive finish to be attained by any pickling method. Table 1 provides selected formulas for pickling nickel alloys, and the table below will aid in preparing these formulas:

Acid	°Bé	Specific gravity	Concentration, wt%

HNO_3	42	1.41	67
H_2SO_4	66	1.84	93
HCl	20	1.16	32
HF	30	1.26	70

Table 1 Formulas for pickling nickel alloys

Formula No.	**Reagents**	**Weight, %**	**Amount**		**Temperature**	
			mL	**oz**	**°C**	**°F**
1	Nitric acid (HNO_3) 1.41 sp gr	20	300	10	70	160

	Water		1000	34		
16	Agar-agar	1	10 g	0.3	20-65	70-150
	Potassium ferricyanide ($K_3Fe(CN)_6$)	0.1	1 g	0.03		
	Sodium chloride (NaCl)	0.1	1 g	0.03		
	Water		1000	34		

(a) An addition of at least 40 g of nickel per liter to Formula 2 will prevent overpickling of chromium-bearing alloys.

(b) Volume %

The best methods for removing heavy scale are mechanical removal techniques such as abrasive blasting or grinding, usually with aluminum oxide or silicon carbide, followed by flash pickling. Abrasive blasting requires a relatively low capital investment compared to pickling, considering the extensive equipment needed for pickling and the cost of complying with environmental regulations. Abrasive blasting also eliminates the need to use and dispose of acids and the need to treat the rinse water. However, the removed scale and spent media may be considered a solid waste for disposal purposes. An alternative method is to soak the oxidized material in hydrochloric acid pickle (Formula 11, Table 1), followed by flash pickling if brightening is required.

Precautions must be taken in handling pickling solutions, because noxious and sometimes toxic fumes are liberated. Positive ventilation, either the use of a ventilating hood over the bath or provision of a controlled draft, is required to remove the fumes. Pickling acids must be handled with care, particularly hydrofluoric acid. Protective clothing, face shields, and rubber gloves must be used at all times. When solutions are prepared, acid should always be added to the water. This is especially important when sulfuric acid is diluted. In preparing the solutions shown in Table 1, the ingredients should be added to the water in the order listed.

Bath Life. Pickling baths should be analyzed regularly to determine acidity. Only total acidity can be determined in baths composed of more than one acid; it is impossible to distinguish acidity contributed by one acid source from that contributed by another. However, when the acidity of a bath is being maintained, the ingredients should be added in the proportions used for the original solution. Bath analysis should be performed by a qualified individual, by either wet chemistry or another acceptable means, on an established schedule. Subsequent additions should be made to maintain the bath at the initial acidity level.

With the exception of flash pickling solutions, bath solution should be disposed of when the total metallic content reaches 150 g/L (20 oz/gal). If the bath is used for only one type of alloy, only one element needs to be determined in the analysis. The remaining metallic elements can be determined from the percentage of each in the composition of the alloy. For example, in analyzing baths used for pickling nickel-chromium alloys, the nickel content determines whether the total metallic content is within the 150 g/L limitation.

Flash pickling solutions continue to perform satisfactorily even when nearly saturated with metal salts. Fresh solution should be made up only when salts begin to crystallize on the side of the bath container.

Alloy Groups

For the purpose of discussing pickling procedures, the nickel alloys can be divided into four groups:

- *High-nickel alloys* such as Nickel 200, Nickel 201, Nickel 270, and Duranickel alloy 301
- *Nickel-copper alloys* such as Monel alloys 400 and K-500
- *Nickel-chromium alloys* such as Inconel alloys 600, 625, 718, and X-750
- *Nickel-iron-chromium alloys* such as Incoloy alloys 800 and 825

All alloys within any one group have virtually the same pickling characteristics. However, the pickling procedures for alloys within a group must be varied to suit the surface condition of the metal.

Surface Conditions

Alloys within each composition group that have similar surface conditions are pickled in the same solutions using the same procedures. Three different surface conditions are generally encountered, primarily depending on the method of prior heating:

- *Bright annealed white surface* requiring removal of tarnish by flash pickling
- *Bright annealed oxidized surface* requiring removal of a layer of reduced oxide, sometimes followed by a flash pickle to brighten
- *Black or dark-colored surface* requiring removal of adherent oxide film or scale

Tarnish and dullness from bright annealed metal can be removed by flash pickling or bright dipping. Bright annealed white surfaces are generally found on drawn and spun shapes, cold-headed rivets, cold-drawn wire, and other cold-worked products. The white surface is a result of annealing in a reducing, sulfur-free atmosphere and cooling either out of contact with oxygen or by quenching in a 2 vol% alcohol solution.

Flash pickling solutions act rapidly, and care must be exercised to prevent overpickling and etching. These solutions are used at room temperature. If the bath is cold, it should be warmed slightly to prevent unduly slow action. Best results with flash pickling are obtained by warming the parts by dipping them in hot water, placing them in the acid for a few seconds, and rinsing them again with hot water. A second dip in acid may be used if necessary. Badly tarnished metal may require a total of 3 min in acid, but the material should be withdrawn frequently from the bath and inspected to prevent overpickling.

Reduced-oxide surfaces occur when hot-worked products, such as forged and hot-rolled material, are heated after hot working in a reducing, sulfur-free atmosphere and are cooled out of contact with air or quenched in an alcohol solution. On such products, pickling produces a clean surface for further processing by cold forming, or it produces the finished surface necessary for items such as rivets.

At annealing temperatures in reducing atmospheres, oxides formed on the high-nickel alloys, except those containing chromium, are readily converted to a spongy, tightly adherent layer. On nickel alloys, the layer consists of metallic nickel.

On Monel alloys the layer is a mixture of metallic nickel and copper. The oxide film formed on nickel-chromium alloys and nickel-iron-chromium alloys does not undergo complete reduction in reducing atmospheres, which makes pickling more difficult. The oxide on these alloys is selectively reduced to a mixture of metallic nickel and chromic oxide. The surface color ranges from the characteristic chrome green of chromic oxide to dark brown.

Oxidized or scaled surfaces are present on all hot-worked products and heat-treated material cooled in air. This type of surface also occurs on the nickel-chromium and nickel-iron-chromium alloys in all conditions except bright heated. The oxide film forms on properly heated nickel and nickel-copper alloys during contact with air after the work is withdrawn from the furnace. The nickel-chromium and nickel-iron-chromium alloys form oxide films even when heated and cooled in atmospheres that keep other alloys bright. Thus, the usual pickling procedure for Inconel and Incoloy alloys is designed to remove oxide and scale.

Nickel-Copper Alloys

Depending on the methods of prior heating and cooling, nickel-copper alloys can have any of the surface conditions discussed previously. Accordingly, the appropriate pickling procedure depends on the surface condition of the material.

Tarnish is best removed from bright annealed nickel-copper alloys by pickling in two solutions in sequence. First, the metal should be pickled thoroughly in Formula 2 (Table 1) in brief exposures and rinsed in water at 80 °C (180 °F). After rinsing, the metal should be dipped in Formula 1. The second dip should be followed by rapid rinsing of the workpiece and neutralization in a 1 to 2 vol% solution of ammonia (Formula 14). To dry, small workpieces should be dipped in boiling water and rubbed in sawdust or with a clean, dry cloth.

Reduced-Oxide Surfaces. Formula 8 is recommended for reduced-oxide surfaces on nickel-copper alloys if pickling is done on a large scale. This acid mixture is more destructive to tanks and racks than solutions used for steel or copper. Steel tanks lined with 4.8 mm ($\frac{3}{16}$ in.) thick natural rubber and a double layer of yellow acid bricks have proven to be the best and most economical containers for this corrosive solution. After pickling in Formula 8, the metal should be rinsed in hot water and neutralized in a 1 to 2 vol% ammonia solution. The Formula 8 pickling solution works best after a short period of use. Therefore, when new solutions are prepared, about 2 vol% of spent solution should be added to the fresh mixture to improve its action.

When a pickling room is not regularly operated, the time required for complete pickling of small lots in Formula 8 is usually a disadvantage. Adequate results in most cases can be obtained by using flash pickling solutions (Formulas 1 and 2). However, Formula 8 may be used for occasional small jobs if ceramic vessels or wooden barrels are used as containers. The solution can be heated and agitated by injecting live steam, either through a rubber hose or through a carbon pipe that has a perforated carbon-block end.

Oxidized or Scaled Surfaces. Oxidized nickel-copper alloys having a thin to moderately thick oxide are pickled by immersion in Formula 11, followed by brightening in Formula 6. After treatment in the first bath, the work should be rinsed in hot water before it is transferred to the brightening dip. The second dip in Formula 6 should be followed by rinsing the work in cold water and neutralizing it in a 1 to 2 vol% ammonia solution (Formula 14).

High-Nickel Alloys

Nickel 200, Nickel 201, Nickel 270, Duranickel alloy 301, and similar alloys can have any of the three types of surface conditions. With the exception of flash pickling, high-nickel alloys are pickled in the same solutions used for Monel alloys. However, maintaining separate baths for the two groups of alloys is usually advisable.

Tarnish. Only one dip, Formula 9, is required to remove tarnish from bright annealed high-nickel alloys. The metal should first be dipped in hot water to warm it. Immersion in the acid bath for 5 to 20 s is usually sufficient to produce bright, clean surfaces. After the metal is removed from the pickling solution, it should be rinsed in hot or cold water and neutralized in a dilute ammonia solution.

The pickling action of Formula 9 can be retarded, if necessary, by decreasing the amount of acid to as little as one-third the volume that is added to the standard formula [e.g., as low as 400 mL (13.5 oz) of sulfuric acid or 620 mL (21 oz) of nitric acid]. Normally, however, the formula gives the best results in the proportions given in Table 1.

Reduced-Oxide Surface. The solution used to pickle reduced-oxide surfaces on nickel-copper alloys, Formula 8, is also used for high-nickel alloys. The procedure is the same as the procedure for reduced-oxide surfaces, described in the section "Nickel-Copper Alloys" in this article. If both groups of alloys are being pickled, separate baths should be maintained. Formula 8 may be used for occasional small lots, but suitable results can usually be obtained in less time by flash pickling in Formula 9.

Oxidized or scaled surfaces on high-nickel alloys can be pickled with the hydrochloric acid/cupric chloride solution (Formula 11) used for nickel-copper alloys. A longer time is required, however. Immersion from 1 to 2 h is necessary to obtain a good pickle on high-nickel alloys. After removal from the pickling bath, the work should be rinsed with hot water and dipped for a few seconds in Formula 9, if brightening is required. The brightening dip should be followed with a cold-water rinse and neutralization in a dilute ammonia solution.

Nickel-Chromium and Nickel-Iron-Chromium Alloys

Tarnished or reduced-oxide surfaces are usually not encountered on nickel-chromium or nickel-iron-chromium alloys. These alloys can only be bright annealed in very dry hydrogen or in a vacuum. Oxides formed on their surfaces in other atmospheres do not undergo complete reduction. Oxide or scale is the usual surface pickled on nickel-chromium and nickel-iron-chromium alloys.

Pretreating in a fused-salt bath is strongly recommended to facilitate pickling of oxidized or scaled surfaces. However, if the metal has been properly heated and cooled, it will usually have a surface suitable for direct pickling in Formula 3. If a fused-salt bath is used for pretreating, the following procedure should be used for pickling nickel-chromium and nickel-iron-chromium alloys:

1. Treat in fused-salt bath.
2. Quench in and spray with water.
3. Immerse in Formula 4.
4. Withdraw from bath and rinse with water.
5. Immerse in Formula 1.
6. Withdraw from bath and rinse with water.
7. Pickle in Formula 3 as required.

As with the nickel-copper alloys and high-nickel alloys, an alternative procedure employing a salt bath and Formula 8, with 10 g/L (1 oz/gal) of ferric chloride added to the formula, effectively removes oxide from hot-rolled or annealed Inconel alloys 601 and 671, and from Incoloy alloys 804 and 903. The procedure for the use of a salt bath is described in the section "Nickel-Copper Alloys" in this article.

If the oxide film cannot be readily removed by pickling directly in Formula 3, or if a fused-salt bath is not available, Formula 13 is a useful pretreatment. The work should be soaked for 1 to 2 h in Formula 13, removed, rinsed to remove all of the caustic solution, and pickled in Formula 3. On highly refractory oxides, it is sometimes necessary to repeat the cycle. Adding 7 to 10 g/L (0.9 to 1 oz/gal) of iron to Formula 3 decreases the danger of overpickling. This can be done conveniently by adding the proper weight of scrap iron to the bath when it is prepared.

The nitric acid/hydrofluoric acid bath (Formula 3) must be used with care. Nickel-chromium and nickel-iron-chromium alloys are subject to intergranular attack in this solution if they have been sensitized by heating in, or slowly cooling through, the 540 to 760 °C (1000 to 1400 °F) temperature range. Time in the bath should be kept to a minimum, and bath temperature must not exceed 50 °C (125 °F). Stress-relieved and age-hardened material can also be sensitive to intergranular attack if the heat treatment involved exposure to sensitizing temperatures.

Salt Baths

Pretreatment baths of fused salts aid in the pickling of many alloys. They are particularly effective in pickling nickel-chromium and nickel-iron-chromium alloys. Several proprietary baths are commercially available; information on their use can be obtained from manufacturers.

Precautions must be taken in handling salt baths. Protective clothing, face shields, and suitable gloves should be used. Room-temperature solution, or powder residue, may cause severe chemical burns. Extreme temperatures of working salt baths exacerbate the need for constant vigilance. Operators should avoid mixing salt bath constituents with those of pickling baths. Typically, rinse water should be used after salt bath processing and prior to pickling. Tank carryout should be minimized by sufficient draining. *Caution: Operators should not dispose of salt bath and pickling bath materials in the same container without approval from a qualified supervisor.*

Bath Life. Salt baths are basically alkaline and not acid in constitution. Bath maintenance should be in accordance with the supplier's instructions. Bath monitoring and control will be similar to that described in the section "Pickling" in this article.

Salt baths are of three types: reducing, oxidizing, and electrolytic. Oxidizing baths are usually the least expensive to operate and the easiest to control, whereas reducing baths are no longer in common use. Electrolytic baths, although more expensive to install and operate, are quite effective for nickel alloys.

Oxidizing salt baths have a base of either sodium hydroxide or potassium hydroxide. Other salts, such as sodium nitrate and sodium chloride, are added to provide controlled oxidizing properties. The sodium hydroxide bath is operated at temperatures of 425 to 540 °C (800 to 1000 °F); a temperature of 480 °C (900 °F) is preferred for descaling nickel alloys. The potassium hydroxide bath operates at lower temperatures, usually 200 to 260 °C (400 to 500 °F). Treatment time in oxidizing baths is usually 5 to 20 min. In the operation of continuous strand pickling lines, the time may be as short as 15 to 60 s.

The salt bath oxidizes the lower oxides on the surface of the work to form soluble salts and water. Quenching after treatment removes part of the scale and loosens the remainder so that it is easily removed by appropriate acid dips. Oxidizing salt baths are also effective cleaners. They remove oil, grease, organic materials, and some inorganic substances from metal surfaces.

Electrolytic salt baths have a sodium hydroxide base and contain other salts, such as sodium chloride and sodium carbonate, that form reducing agents at the cathode and oxidizing agents at the anode when electrically activated. Baths are usually operated at about 480 °C (900 °F), and although electrolytic salt baths can be used as a batch process, they are more suitable for continuous operations such as descaling of strip. Two tanks are normally used for continuous processes. The work is made anodic in the first tank and cathodic in the second.

Specialized Pickling Operations

Although pickling is most often used to remove the oxide or scale formed during heating, it is also used to remove foreign metals and other substances. Several procedures specifically designed for such purposes are applicable to nickel alloys.

Removal of Lead and Zinc. Lead and zinc embrittle high-nickel alloys at elevated temperatures. Consequently, when the alloys are formed in dies made of materials containing lead and zinc, all traces of the die material picked up during forming should be removed. When parts will be given intermediate anneals for processing, or when they will be exposed to high temperatures during service, removal of lead and zinc becomes especially important.

Formula 10 is used to remove lead and zinc from nickel and nickel-copper alloys. For nickel-chromium and nickel-iron-chromium alloys, a bath of nitric acid similar to Formula 1 (but with the concentration of nitric acid increased to 30%) is used. After being immersed in the appropriate bath for 15 min, the work is removed, rinsed in water, and dried.

Detection and Removal of Embedded Iron. During mechanical operations such as rolling to shape or hot pressing, small particles of iron may become so firmly embedded in the surfaces of nickel alloys that they cannot be removed by the cleaning methods normally used for dissolving grease or cutting compounds. Under certain corrosive conditions, such iron particles can initiate local attack. For that reason, it is often necessary to test for iron traces and remove them.

For large-scale testing, a solution of about 1% sodium chloride is effective. A chemically pure grade of salt should be used to prevent false results from iron that might be present in less pure grades. When compressed air is available, it is usually less expensive to keep the tank full of salt spray with an atomizer than to fill it with the solution. After 12 to 24 h in the dilute salt solution, any iron particles in the nickel alloy will appear as rust deposits.

The ferroxyl test works well for small-scale testing. A potassium ferricyanide solution, made up in approximately the proportions shown in Formula 16, is applied to the surface of the material. The ingredients are mixed in earthenware, glass, or ceramic vessels and then boiled until all of the agar-agar is dissolved and a clear liquor is formed. Chemically pure sodium chloride should be used to prevent iron contamination of the test solution. The warm solution is applied to the surface to be tested and allowed to remain for at least 1 h. The solution gels as it cools, and the presence of iron on the metal surface is indicated by blue spots in the gel.

The ferroxyl test is sensitive enough that minute particles of iron that collect on the surface in the form of shop dust will appear as small blue spots in the gel. Because the iron dust will be washed off with the gel, the small spots should be distinguished from the larger ones caused by embedded iron. If spots of relatively major proportions develop, large iron particles are probably present.

A solution of hydrochloric acid and ferric chloride, Formula 12, is used to remove embedded iron. This solution should be used cold and should remain in contact with the metal for only the minimum time required for iron removal, not exceeding 1 h. After the work is removed from the solution, it should be rinsed thoroughly in cold water, then rinsed again in warm water. The detection tests should be repeated to verify the removal of the iron.

Prevention and Removal of Copper Flash. Copper flash sometimes forms on the surface of nickel alloys during pickling. For copper deposits to form, copper ions in the solution must be in the cuprous state, or they must pass from the cupric to the cuprous state during the cementing process. Consequently, any agents in the pickling bath that tend to maintain the cupric state will help prevent coppering.

Oxidizing agents such as nitric acid and sodium nitrate promote the action of pickling solutions but become depleted with use. As the pickling bath ages, the concentration of copper ions increases while the concentration of oxidizing agents decreases. Thus, aging the bath facilitates coppering on areas where the reducing effect of the metal exceeds the oxidizing power of the bath.

When coppering occurs on Monel alloy 400 and other high-nickel alloys containing an appreciable amount of copper, the bath can be restored by adding small amounts of nitric acid or sodium nitrate. Nickel has greater reducing capacity than Monel alloy 400 and requires a greater concentration of oxidizing agents to prevent coppering in solutions containing copper salts. For this reason, Nickel 200 and similar alloys must not be pickled in solutions that have been used for nickel-copper alloys.

Patches of copper will plate out on nickel-copper alloys if steel contacts the alloys while they are wet with acid. Steel tongs or other devices used to handle the work are the usual sources of kippered areas. Coppering is prevented by using handling devices made of Nickel 200 or Monel alloy 400.

Copper flash is readily removed by immersing the alloy in an aerated, 4 to 5% ammonia solution at room temperature. The solution composition should be approximately 125 mL of ammonia to 1 L of water, or 1 pint of commercial aqua ammonia to 1 gal of water. The work should be immersed for about 1 min only, then rinsed in water.

Electrolytic Pickling. Light oxide films on any of the nickel alloys can be removed by electrolytic pickling in Formula 7. The work should be made anodic by using a current density of 5.4 to 10.75 A/dm^2 (50 to 100 A/ft^2). Electrolytic pickling is also useful for etching ground material to obtain a surface suitable for inspection.

Electropolishing of high-nickel alloys smooths the surface by removing metal through a controlled electrochemical process that is similar to, but essentially the reverse of, electroplating. When the alloy is immersed into an electrolyte and maintained anodic, metal is electrochemically removed ion by ion. This simultaneously deburrs the alloy, maximizes tarnish protection, and reduces surface fouling while producing a uniformly bright and smooth surface luster. Properly electropolished surfaces are microscopically featureless, non-contaminating, non-particulating, and effectively stress relieved. Such high-performance and high-purity metal surface finish properties are unattainable by more traditional mechanical finishing techniques.

High-quality electropolishing of the high-nickel alloys produces brilliant lustered reflectivity. Best results are obtained from metals with fine grain boundaries that are free of nonmetallic inclusions and seams. Electropolished surfaces should not exhibit frosting, shadows, streaks, stains, pitted areas, or an "orange peel" or pebbly appearance.

Important factors in final finish quality are proper electrolyte selection, bath temperature, and bath maintenance (specific gravity, acid concentration, and metals content) and direct current from a ripple-free source applied at optimum voltage and current density. More complex configurations require adequate cathode design for effective polishing in inaccessible areas, inside corners, and in other areas of low current density. Agitation of either the electrolyte or the metal may be necessary to prevent gas entrapment, gassing streaks, flow marks, or similar undesirable markings.

Cleaning of Springs. In general, cleaning of springs made of a high-nickel alloy is not recommended after heat treating. The oxide on heat-treated springs usually aids in resisting corrosion at high temperatures. When the oxide is removed, resistance to relaxation is often lowered. If cleaning is necessary for inspection of the springs, they should be treated in a salt bath, quenched in water, and rinsed to produce a good surface. Table 2 shows the effect of the cleaning method on resistance to relaxation of Inconel alloy X-750 springs that were age hardened at 730 °C (1350 °F) for 16 h.

Table 2 Effect of cleaning method on relaxation of Inconel alloy X-750 springs(a)

Cleaning method	Relaxation(b), %
No cleaning, as age hardened	10.0
Oxidizing salt bath plus Formula 3	11.5
Tumbling in sand and oil	12.8
Abrasive blasting (120 grit with water)	13.3
Shot peening	13.5
Abrasive blasting (standard sand, dry)	14.6

(a) Cold drawn (No. 1 temper) and age hardened at 730 °C (1350 °F) for 16 h.

(b) Relaxation after 250 h at 415 MPa (60 ksi) and 540 °C (1000 °F)

Cleaning for Welding. Before maintenance welding is done on high-nickel alloys that have been in service, products of corrosion and other foreign materials must be removed from the area to be welded. Clean, bright base metal should extend 50 to 75 mm (2 to 3 in.) from the joint on both sides of the material to prevent the corrosion products from embrittling at welding temperatures.

Cleaning can be done mechanically (by grinding with a fine wheel or disk) or chemically (by pickling). Mechanical cleaning methods usually use an abrasive medium containing either aluminum oxide or silicon carbide grit. Care must be taken to avoid embedding abrasive grit into the weldment surface. Sometimes wire brushing with an austenitic stainless steel brush and/or local macroetching with a Schantz etch, or similar flash pickling, is an appropriate procedure immediately prior to welding.

Flash pickling solutions are effective in cleaning before welding. The solutions can be applied by swabbing, brushing, or dipping, if the parts are easily handled. A single dip in Formula 2 is adequate for the nickel-copper alloys. Formula 1 is used for nickel alloys, and Formula 3 is useful for nickel-chromium and nickel-iron-chromium alloys.

Reactive Gas Ion Thermal Processing

Reactive gas ion thermal processing is high-temperature processing that introduces certain extremely reactive gases disassociated into ions, specifically hydrogen and fluorine. It has been shown to be effective in reducing tenacious oxides of aluminum and titanium and scale found on high-nickel alloy surfaces.

Although hydrogen, considered an industrial gas, is generally readily available, the source of the fluoride ion is a commercially available system: chromous fluoride (CrF_2,) polytetrafluoroethylene (PTFE), or hydrogen fluoride gas (HF). The process uses a heated reaction vessel, generally a retort, and the work and its holding fixtures are placed inside. Reaction temperatures for high-nickel alloys are typically around 1100 °C (2000 °F), although times and temperatures will depend on specific processing requirements. Forethought must be given to safety and environmental concerns.

Example: Repair of Gas Turbine Engine.

For acceptable repair of an aircraft gas turbine engine that had some high-nickel alloy components, it was necessary to use high-purity, dry hydrogen gas, introduced into a retort during an elevated-temperature run, to reduce most surface oxides. Subsequent establishment of next-generation braze repair technologies was possible on these alloys only after successful incorporation of fluoride ion processing. The significantly more reactive fluoride ion and its innate, aggressive reduction of oxides achieved surface, and even subsurface, cleaning with complete subsurface oxide/scale conversions in cracks as fine as 0.013 mm (0.0005 in.).

Results. Process parameter definition ensures repeatable oxide reduction without unacceptable substrate damage. Positive results are removal of surface oxide from exposed internal/external surfaces; effective cleaning prior to coating, welding, or brazing; removal of mill scale; and stripping of aluminide coating. Negative results are slight alloy depletion, typically of aluminum, molybdenum, and titanium constituents, on exposed surfaces; and slight intergranular attack on exposed surfaces.

Finishing

Nickel alloys can be ground, polished, buffed, or brushed by all methods commonly used for other metals. For high-nickel alloys, a series of operations is required to produce a satisfactory finish. The number and type of operations required depend on the initial finish of the material, the desired final finish, and the type of equipment used. The pressures and speeds of the finishing equipment must be closely controlled. The high-nickel alloys, particularly nickel-chromium and nickel-iron-chromium alloys, do not conduct heat away as rapidly as copper and aluminum. Excessive heat will destroy the true color of the metal and may warp flat, thin articles.

Some general recommendations for finishing operations are given in Table 3. Table 4 lists spindle speeds and corresponding surface speeds for various wheel diameters.

Table 3 Recommended finishing procedures

Operation	Wheel	Grit No.	Compound	Speed	
				m/s	sfm
Grinding	Rubber bond	24 or 36	None	40-45	8000-9000
	Vitrified bond	24 or 36	None	25-30	5000-6000
Roughing	Cotton fabric, sewn sections	60 or 80	None	30-40	6000-7500
Dry fining	Cotton fabric, sewn sections	100 or	None	30-	6000-

		120		40	7500
Greasing	64-68 unbleached sheeting, spirally sewn sections	150 or 180	Polishing tallow or No. 180 emergy grease cake	30-40	6000-7500
Grease coloring	88-88 unbleached sheeting, spirally sewn or loose disk; or quilted sheepskin	200 or 220	Polishing tallow or "F" emery grease cake	30-40	6000-7500
Bobbing and sanding	Leather wheel for two bobbing operations, second with medium-density felt wheel	. . .	Grout	25	5000
Cutting down	88 unbleached sheeting, loose spirally sewn sections or loose-disk wheel	. . .	Tripoli	40-45	8000-9000
Coloring					
Bright finish	88-88 unbleached sheeting, loose spirally sewn sections or loose-disk wheel	. . .	White aluminum oxide	50	10,000
Mirror finish	Loose-disk, 88-88 unbleached sheeting or Canton flannel	. . .	Green chromium oxide	50	10,000
Brushing	Tampico	. . .	"F" emery grease cake or grout	5-15	1200-3000

Table 4 Spindle speed for various surface speeds and wheel diameters

Surface speed		**Spindle speed, rev/min, for indicated wheel diameter**						
m/s	**sfm**	**150 mm (6 in.)**	**200 mm (8 in.)**	**250 mm (10 in.)**	**300 mm (12 in.)**	**360 mm (14 in.)**	**410 mm (16 in.)**	**460 mm (18 in.)**
15	3,000	1930	1450	1150	950	820	710	640
20	4,000	2550	1900	1500	1300	1100	950	850
25	5,000	3200	2400	1900	1600	1375	1200	1050
28	5,500	3500	2600	2100	1750	1500	1300	1175
30	6,000	3800	2850	2300	1900	1650	1425	1275
38	7,500	4800	3550	2850	2400	2100	1800	1600
40	8,000	5100	3800	3100	2550	2200	1900	1700

45	9,000	5750	4300	3450	2850	2450	2150	1900
50	10,000	6400	4750	3800	3200	2750	2400	2100

Grinding, often the first operation in a finishing sequence, is used to remove large surface imperfections and to rough-down welds prior to polishing and buffing. Rubber-bond grinding wheels are used for nickel and Monel nickel-copper alloys for their cutting effectiveness and for their relative softness, which reduces the heat generated. Rubber-bond wheels should be operated at a surface speed of 40 to 45 m/s (8000 to 9000 sfm). Vitrified-bond wheels are preferred for grinding harder alloys such as the Inconel and Incoloy alloys. These wheels should be operated at a surface speed of 25 to 30 m/s (5000 to 6000 sfm). Light welds can be ground efficiently with a No. 36 grit wheel, whereas a No. 24 grit is more practical for heavy welds.

Polishing. The first polishing operation should be done with very fine grit to remove all surface defects and give a base upon which to build the final finish. Wheels of No. 60 to 80 grit are usually required to remove heavy oxide or deep defects.

The first operation should be done dry. After the initial roughing, tallow should be used on all roll-head wheels of No. 150 grit or finer. Tallow clogs the wheel, giving a smoother finish and reducing the amount of heat generated.

When flat work is polished, each subsequent operation should be done with a grit 30 to 40 numbers finer than the previous one, until the surface is ready for the brushing or bobbing operations needed to prepare for buffing.

When possible, the scratches produced by the abrasive should cross the scratches left by the preceding operation. When polishing is done in only one direction, the finer abrasive will follow in the grooves made by the coarser abrasive, and the efficiency of the polishing wheels will be impaired.

Wheels for roughing and dry finishing should be made of tightly woven, unbleached cotton fabric. To prevent chattering, the wheels should be perfectly balanced and should have a soft or cushioned face. Fine grit wheels require more cushions than coarse wheels.

A more resilient and flexible wheel should be used for greasing operations. Greasing wheels should be made of 64- to 68-count unbleached sheeting and should have more cushion than the wheels used for coarser polishing. Grease coloring may be done on a full-disk, quilted sheepskin wheel or on a spirally sewn wheel made of fine-count (88-88) heavy sheeting. Compounds of artificial abrasives are preferred for roughing and dry finishing. Turkish emery is usually used for greasing and grease coloring.

Bobbing done with emery grout is more like burnishing than polishing, and if it is performed in one operation, it is best done with leather wheels. If it is done in two operations, the second should be done with a medium-density felt wheel, because felt wheels require less pressure. The best results are obtained from emery roll-head wheels at surface speeds of 33 to 38 m/s (6500 to 7500 sfm). The metal drags at slower speeds, and at excessive speeds, the wheel tends to pull up the surface of the metal.

Buffing. For good results in buffing, a high-quality wheel of the proper construction and material is essential. Wheels should be of sturdy, closely woven, high-count sheeting. The close weave gives good cutting, and the heavy threads provide good coloring.

Buffing is usually done in two operations. The first, the cutting-down operation, is done with a sewn buffing wheel operating at a surface speed of 40 to 45 m/s (8000 to 9000 sfm). The second, the coloring operation, is done with a loose-disk wheel operating at a surface speed of approximately 50 m/s (10,000 sfm). A loose disk, Canton-flannel wheel is best for buffing to a mirror finish. The high speeds used in buffing create a high heat. Consequently, less pressure is necessary than for polishing.

The cutting-down operation is normally performed with tripoli compound, which leaves a haze on high-nickel alloys. Buffing compound with less grease should be used to promote deep color. White aluminum oxide and green chromium oxide compounds can be used for the final coloring. Chromium oxide compounds produce less friction and give a truer color.

Brushing. A tampico or wire wheel produces a brushed finish on the high-nickel alloys. Tampico wheels usually produce a better finish and higher luster, and because of their flexibility, they are better for irregular shapes. A tampico wheel is used with emery paste or grout to produce a satin finish, or with pumice and water or pumice and oil to produce a better finish. For wet brushing, tampico wheels should have wooden hubs.

Wire brushes can be used to produce a satin finish on sheet metal articles. Brushes should have a wire diameter of 0.10 to 0.20 mm (0.004 to 0.008 in.). They should not be made of steel or brass wire, because small particles from the brush are always embedded in the metal during the process. Steel particles rust, and brass particles discolor the nickel alloys.

Brushing is done at slower speeds than those used for polishing. Brushing speeds are normally 5 to 15 m/s (1200 to 3000 sfm), depending on the final finish desired. Higher speeds, 20 to 30 m/s (4000 to 6000 sfm), are required to produce a bright wire brush finish. Wire brushes operated at too slow a speed produce coarse, undesirable scratches.

Blasting. Abrasive media blasting has the ability to produce a cosmetically appealing, uniform, matte gray appearance that varies from dull to a high-sheen luster. The appearance depends on the medium chosen (aluminum oxide, silicon carbide, glass bead, steel shot, crushed plastic, etc.); particle size (No. 24 grit for rough finishes vs. No. 220 for smooth finishes); and particle shape (angular grit or cut shot for a dull appearance vs. crushed plastic, round glass beads, or cast steel shot for luster and sheen).

Nondestructive Inspection

Care must be taken in finishing high-nickel alloys when subsequent inspection will be performed with an ultrahigh-sensitivity, fluorescent penetrant nondestructive method. Under certain conditions, finishing operations using plastics, such as plastic blasting media, plastic brushes, or buffing pads with embedded grit, leave a residue of thin, smeared plastic on the surface that introduces high background fluorescence during fluorescent penetrant inspection. Similarly, coarse abrasive blasting may hamper the detection of surface flaws by penetrant methods. On the other hand, fine grit blasting (No. 60 or finer) has been successfully used to enhance detection of surface flaws, such as investment casting defects.

Surface Engineering of Zinc Alloys

Revised by Thomas P. Groeneveld, Battelle Columbus Operations

---

Introduction

THE PRIMARY PRODUCT FORMS of zinc and zinc alloys requiring surface engineering prior to coating or use are die castings, wrought zinc alloys, and zinc-coated steels. The vast majority of die castings are nominally Zn-4Al alloys covered by ASTM B 86 (Ref 1). These alloys are known commonly as alloys 3, 5, and 7. However, during the 1980s, applications increased for zinc die castings containing higher aluminum contents, nominally 8, 12, or 27% (Ref 2). In addition to the increased use of electrogalvanized zinc-coated steel by the automotive industry, there has been a significant increase in other applications that use painted or powder-coated galvanized steel, particularly in the appliance industry (Ref 3, 4).

Because of their inherent corrosion resistance, zinc and zinc alloys can be used satisfactorily in many applications without subsequent finishing. However, a variety of finishes are used for improved corrosion protection or appearance: conversion coatings, such as chromate, phosphate, and anodize; organic paint of various types; and metallic coatings, including electroplating, electroless plating, and vacuum metallizing. The normal sequence of preparation steps prior to painting or electroplating of zinc alloy die castings includes:

- Mechanical finishing to smooth parting lines and rough or defective surfaces, plus buffing, if necessary
- Solvent degreasing or aqueous-based solution degreasing followed by rinsing
- Soak alkaline cleaning and/or alkaline electrocleaning followed by rinsing
- Acid dipping followed by rinsing

Guidelines for preparing zinc die castings for electroplating are contained in ASTM B 252 (Ref 5). If die cast parts are to be painted, they are often given a chromate or phosphate conversion coating treatment following alkaline cleaning to improve corrosion resistance and coating adherence. Wash primers also are used for those purposes.

Wrought zinc products are subjected to solvent cleaning, soak alkaline cleaning, and electrolytic alkaline cleaning prior to electroplating (Ref 6). Zinc-coated steel products (hot dip or electrogalvanized) typically are solvent cleaned to remove stamping and forming lubricants and general handling soils, then are alkaline cleaned and are given either a phosphate or chromate treatment prior to coating, to improve corrosion resistance and coating adherence.

Surface preparation and cleaning prior to plating or painting is considered by many to be the most important aspect of the finishing process. If surfaces are not properly prepared, defects in the base metal will show through the finished coating, and if the parts are not properly cleaned, coating adherence will be reduced and premature corrosion often results.

For die castings, proper runner and gating design and proper control of the die casting process, particularly die temperature control, can produce castings in which surface defects are minimized. Thus, preplating or prepainting surface preparation processes can be reduced with substantial savings in finishing costs. Similarly, proper trim die design and maintenance can reduce the amount of effort spent smoothing parting lines.

Mechanical Finishing

Finishing of Parting Lines. Of the various product forms of zinc alloys, die castings require the most extensive mechanical finishing prior to electroplating or painting. This situation results because the castings must be trimmed to remove gates and runners, overflows, vents, and flash. Grinding and polishing of the parting lines is the first step after the castings have been trimmed. Finishing of the parting lines is done on set-up wheels or abrasive belts, by tumbling with abrasive media, or by vibratory finishing. Wheels or belts with coarse grit (60- to 120-mesh) are used for heavy metal removal, if necessary (Ref 2). The parting line regions typically are finished with 220- to 300-grit abrasive wheels or belts (Ref 5, 6). A lubricant, such as paraffin, may be used to produce a finer finish. Set-up wheels are typically operated at peripheral speeds ranging from 1800 to 2400 m/min (6000 to 8000 ft/min). Abrasive belts should not be operated at speeds greater than 2100 m/min (7000 ft/min); speeds ranging from 1080 to 1200 m/min (3500 to 4000 ft/min) often are used (Ref 5, 6).

Tumbling in barrels loaded with abrasive media such as limestone, preformed and fused alumina, ceramic shapes, or abrasive-loaded plastic chips can be used to remove parting line burrs. A lubricant such as soap or detergent solution (alkaline cleaner) often is used during barrel tumbling. Tumbling cycle times to remove parting line burrs range from 4 to 12 h.

Vibratory finishing also is used to finish the parting line regions (Ref 7, 8, 9, 10, 11). Abrasive-loaded plastic chips usually are used for zinc die castings because they do not mar the casting surface. Ceramic media and steel media can be used, but these media, because they have greater densities than plastic media, will indent the casting surface, leaving an "orange peel" type of surface. Coarse grit abrasives (80-grit) can remove burrs in minutes during vibratory finishing.

Resin-bonded abrasive chips remove burrs in times ranging from 1 to 4 h. The speed of finishing in vibratory finishing is controlled by the frequency and amplitude of vibration. Frequencies from 700 to 2100 vibrations/min and amplitudes from 0.8 to 6.4 mm ($\frac{1}{32}$ to $\frac{1}{4}$ in.) are used to deburr zinc die castings. Traditionally, neutral to alkaline cleaners (lubricants) have been used during vibratory finishing of zinc die castings. Acidic solutions with pH from 2.5 to 4.5 also have been used to increase the speed of metal removal and thus shorten the process cycle time (Ref 7). If tumbling or vibratory deburring is used without a cleaner, the media must be cleaned periodically to remove contamination (Ref 9). If not maintained properly, the media will contaminate, rather than clean, the castings.

Surface Polishing. Many die castings have sufficiently smooth surfaces that require only buffing prior to the chemical treatments used in preparation for electroplating or painting. However, others may require spot or overall polishing to remove surface defects or roughness. Spot or surface polishing is done with set-up wheels or abrasive belts with 220-mesh or finer abrasive, run at the same speeds as those used for preparing the parting lines. The abrasive surface should be lubricated. The surface finish produced by abrasive wheels or belts typically ranges from 0.2 to 0.4 μm (8 to 16 μin.).

Polishing of the casting surfaces also can be accomplished by tumbling or vibratory finishing under the conditions described previously. Generally, vibratory finishing concentrates the finishing action on the casting corners and edges, although all surfaces receive some finishing action (Ref 8). Abrasive-loaded plastic media are used for die cast zinc because they do not mar the surface. Ceramic media, which are heavier than plastic media, also are used for surface finishing; however, they may produce a slight orange peel texture. Steel media, which are significantly heavier, result in burnishing of the surface to a high luster, but they are suitable for applications for which the surface finish is secondary (Ref 8). To produce a fine, smooth finish, abrasives with 400-mesh are used with commensurate increases in finishing time. The sizes of the media vary significantly, ranging from 1.5 to 50 mm (0.06 to 2 in.) in diameter (Ref 10). Generally, the larger the diameter of the media, the rougher the surface. With proper control of the media, vibratory finishing parameters, and cycle times, buffing prior to plating with a leveling electroplate often can be eliminated. Because of its higher hardness, Alloy 27 may require a longer vibratory finishing time to receive a finish comparable to those on the lower-aluminum-content alloys (Ref 2).

The surfaces of zinc die castings can be polished smooth in centrifugal barrel finishing equipment (Ref 5, 6, 8). The drums are rotated with a peripheral speed of about 600 m/min (1970 ft/min) in an abrasive material such as ground corn cobs or nut shells mixed with a lubricant. Finishing times typically range from 5 to 10 min, and the resulting surface finish is 0.1 to 0.2 μm (4 to 8 μin.), depending on the abrasive used (Ref 6).

Brushing with wheel-mounted filament or fiber strands, run dry or lubricated, also is used to polish casting surfaces, particularly functional castings (Ref 7). Brushing removes sharp edges and burrs and generates fine radii. It does not result in the heavy stock removal, as does abrasive belt polishing, because it does not abrade the surface; however, it reaches internal recesses to deburr, descale, and clean.

Controlled shot peening can be used to smooth rough or defective castings and to remove fins, burrs, and flash from the surface (Ref 5). This process plastically deforms and densifies the casting surface and near-surface layers. That action can seal surface pores, which can create problems in subsequent electroplating and conversion coating. The shot-peening process is described in MIL-S-13165C (Ref 12), which should be consulted for selection of the peening media, shot size, peening intensity, and coverage. Those selections are based on the casting configuration, the smallest-size radii and wall thickness, and the required surface finish and contamination limits, as detailed in the specification.

Buffing of zinc die castings is used to smooth rough areas, eliminate polishing scratches, and produce a mirror-like finish prior to plating with conventional solutions when good leveling plating solutions are not available. If the castings have good surface finish or can be uniformly polished to a finish of 0.25 μm (10 μin.), buffing can be omitted if solutions with good leveling power are used for plating copper and nickel (Ref 5, 6).

Buffing is accomplished on cloth wheels rotated at peripheral speeds up to 2150 m/min (7000 ft/min). Slower speeds, from 1000 to 1600 m/min (3500 to 5000 ft/min), are used for smaller die castings (Ref 4, 5). Buffing wheels (buffs) usually are made of cloth (muslin or canvas) with 34 to 37 threads/cm (86 to 93 threads/in.) (Ref 5, 6). The buffs should be sewn to provide a mushing action from 6.4 to 13 mm (0.25 to 0.5 in.) while remaining rigid through the remaining depth of the buff (Ref 7, 13). The typical buffing compound used for zinc is tripoli (amorphous silica) or lime mixed with 25 to 30 wt% tallow or stearic acid to form a bar. The lubricant used should be readily saponified or emulsified to aid in removal during subsequent cleaning. In addition, only as much lubricant as is necessary should be used to facilitate subsequent cleaning. The compound is applied manually or automatically to the buffing wheels. With automated buffing systems, water slurries of fine abrasive particles and lubricants are applied to the wheels by dripping through controlled-flow tubes or by spraying. With these automated systems the castings advance through a series of buffs with varying diameters and widths, which smooth different areas of the casting surface. After buffing, the casting surfaces should be cleaned by passing them over a relatively clean, dry buffing wheel. Buffing produces surface finishes ranging from 0.025 to 0.05 μm (1 to 2 μin.) (Ref 5, 6, 14).

Buffed castings are more difficult to clean than vibratory-finished parts, especially when the buffing compounds packed in holes, grooves, and other recesses are not removed within a few hours of buffing. It is strongly recommended that the initial removal of the buffing compound and other soils in a precleaning operation be done as soon as possible after polishing and buffing. Most buffing compounds become substantially more difficult to remove after aging several days (Ref 5).

Solvent Cleaning

Following the mechanical finishing of die castings or the forming of wrought zinc or zinc-coated steel, the parts are cleaned to remove finishing compounds, forming lubricants, and general shop and handling soils. Traditionally, the first step in the cleaning process is solvent degreasing, vapor degreasing, or emulsion cleaning. Solvent degreasing typically is done in chlorinated hydrocarbons, such as methylene chloride, 1,1,1-trichloroethane, trichloroethylene, and perchloroethylene. Many of the commonly used solvents are being banned from use, and exposure to their vapors is being strictly regulated for health, safety, and environmental reasons (Ref 5, 15, 16). Thus, before the solvent degreasing process is considered, federal, state, and local safety and environmental laws and regulations should be consulted. In addition, current safe exposure levels for various solvents should be determined prior to their use.

Cold solvents, such as mineral spirits, methylene chloride, trichloroethylene, perchloroethylene, and 1,1,1-trichloroethane, are used with brushing to loosen packed buffing compounds. Simple dipping in cold solvents often is ineffective in removing soil; consequently, vapor degreasing with trichloroethylene or perchloroethylene is still widely practiced. Often buffed die castings are sprayed with, or dipped in, the hot solvent and then subjected to vapor degreasing to remove the last traces of grease and compound. This method is effective provided that adequate measures are taken to remove the fine abrasive and metallic particles from the parts (Ref 5).

Emulsion Cleaning

Emulsion cleaners can be used to soften and remove, to some extent, buffing compounds and other oils and greases (Ref 5, 6). Emulsion soak cleaners usually are made from a hydrocarbon base such as kerosene and a water solution that contains soaps, emulsifiers, and an inhibitor to prevent etching of the zinc and zinc alloy surfaces (Ref 14). They typically are used hot, at 80 °C (180 °F), and with agitation or brushing. The soak time varies from 2 to 5 min (Ref 5). A water-spray rinse should follow emulsion cleaning. The pH of emulsion cleaners should be kept between 7 and 10 to avoid attack of the zinc alloy surfaces.

The compounds not removed by an emulsion cleaner usually are sufficiently softened that they are easily removed in the alkaline spray wash that normally follows. The principal disadvantage of emulsion cleaners is the danger of carryover of hydrocarbon solvent into plating baths (Ref 5). Consequently, it is extremely important that proper alkaline cleaning and rinsing follow emulsion cleaning to ensure solvent removal from recesses and blind holes.

Aqueous Detergent Cleaning (Alkaline Cleaning)

Because of the increasing restrictions on the use of chlorinated hydrocarbon solvents for cleaning, water-based alkaline detergent cleaning systems are being used in place of, rather than in addition to, solvent cleaning systems (Ref 16, 17). No other solvents or cleaners match the desired characteristics of the chlorinated hydrocarbon solvents for degreasing, so much effort is being expended to develop suitable alternative cleaners.

For zinc and zinc alloy parts, a number of alkaline cleaning solutions are available and have been used after solvent cleaning processes. The aqueous-based detergents mix emulsifiers and surfactants (wetting agents) with mild alkaline phosphates, borates, or silicates to optimize properties such as oil emulsion, saponification, dirt suspension and dispersion, water softening, and rinsability. These cleaners are used as soak cleaners, often with ultrasonic agitation, or as power-spray cleaners. Some cycles employ a 2 to 3 min soak treatment followed by spray washing with the alkaline cleaner. The solution temperatures usually range from 70 to 80 °C (160 to 180 °F), but slightly lower temperatures may be more suitable for automated cleaning cycles that include more than 30 s of anodic cleaning (Ref 6). Alkaline cleaning solutions for zinc and zinc alloys are listed in Table 1. Proprietary alkaline cleaners also are available. The alkaline cleaners must have controlled pH and contain inhibitors to prevent attack of the zinc.

Table 1 Alkaline cleaning solutions for zinc die castings

Chemical	**Soak cleaning**	**Power-spray cleaning**	**Anodic cleaning**
Sodium hydroxide, g/L	. . .	1.5	0.5-2[a]
Sodium carbonate, g/L	. . .	3.5	18
Sodium triphosphate, g/L	35	1.0	5
Sodium metasilicate, g/L	. . .	4.0	30[b]
Wetting agent, g/L[c]	0.5	. . .	0.5
Temperature, °C	82	77	71-82
Current density, A/dm^2	. . .	. . .	1.4-2.3
Time, min	1 or 2	1 or 2	0.5

(a) Solutions with a higher concentration of sodium hydroxide or a pH>12 might cause etching and the formation of a loose smut difficult to remove by rinsing.

(b) Solutions containing silicates may be more difficult to rinse than nonsilicated cleaners.

(c) Usually an alkyl sulfonate, alkyl aryl ether alcohol, and/or sodium resinate

A typical alkaline precleaning cycle may include a 1 to 2 min washing period followed by a 0.5 to 1 min draining period, a 0.5 to 1 min spray-rinse period, and a final 0.5 to 1 min draining period (Ref 5). If a spray alkaline cleaning step does not follow the soak cleaning treatment, the soak treatment should be followed by a spray rinse with warm water before electrocleaning.

Following alkaline cleaning and rinsing, parts that will be painted are often given a chromate or phosphate conversion treatment in preparation for painting.

Electrocleaning

The final cleaning step for zinc alloy or zinc-coated parts prior to electroplating is electrolytic, usually anodic, and is conducted in an alkaline bath (see Table 1). Electrocleaning is necessary to complete the removal of oil, grease, and soil and to ensure good electroplate adhesion (Ref 5, 6). Anodic cleaning of zinc alloys is preferred to cathodic cleaning, because the dissolution of the metal prevents the formation of nonadherent metal films resulting from impurities in the cleaning solution (Ref 6). Anodic electrocleaning also helps to remove metallic smut.

The anodic alkaline electrocleaning baths are operated at temperatures from 70 to 82 °C (160 to 180 °F) with a low direct-current voltage of 3 to 6 V and current densities of 1.4 to 3.2 A/dm^2 (15 to 30 A/ft^2) (Ref 6). The cleaning time varies from 25 to 45 s. Lower bath temperatures may be required if the cleaning time exceeds 45 s or if the transfer time to the first rinse is greater than 30 s. Operating an anodic electrocleaner at too dilute a concentration may overetch the zinc (Ref 6).

Rinsing following anodic electrocleaning should include a warm-water rinse, a cold-water rinse, and a water-spray rinse. The rinses should be agitated with air to aid in removal of the cleaner solution from holes, grooves, and other surface irregularities. Alkaline solution trapped in those features can result in process blisters following plating or painting. Rinse waters containing high concentrations of dissolved minerals should be avoided.

Electrocleaning may not be required as a pretreatment for the application of conversion coatings.

Acid Dipping

Prior to electroplating, the surfaces of zinc alloy parts are activated by acid dipping. This process removes oxides that formed during anodic cleaning and trace amounts of alkaline compounds that were carried over from the cleaning operations due to inadequate rinsing. Dilute sulfuric acid, 0.25 to 0.75 wt%, is most often used; the immersion time ranges from 25 to 45 s with the solution at room temperature (Ref 5, 6). Similar solutions of hydrofluoric acid or a mixture of sulfuric or hydrofluoric acids also are effective. For very mild acid dipping, citric acid can be used. All traces of black films or loosely adherent smut must be removed by the acid treatment. For die castings prone to smut, including alloys containing more than 0.25% Cu, ultrasonic agitation effectively prevents smut formation (Ref 6).

Thorough rinsing must follow acid dipping to remove all traces of acid from surface fissures, porous areas, or holes to prevent blistering of the parts at those locations after plating (Ref 5, 6, 17). A succession of two air-agitated rinses and a water-spray rinse is recommended after acid dipping. A final water-spray rinse should use deionized water that can be recycled for use in an initial rinsing stage.

Following cleaning, acid dipping, and rinsing, no water breaks should occur on the surfaces of the zinc alloy castings, wrought zinc, or zinc-coated parts (Ref 6). If water breaks occur, the parts should be recycled through the alkaline and/or electrocleaning steps after those processes have been checked for proper solution composition and temperature. Tests for cleanliness should be made routinely during production (e.g., wiping with a clean white cloth or paper should result in no soil or smut on the cloth). More sophisticated tests are available to determine the effectiveness of cleaning processes (Ref 18), but they typically are not suitable for assessing cleanliness on the line during production. Most are research tools that are used to assess new cleaning processes or modifications to cleaning solution formulations.

Conversion Coating Treatments

Zinc die castings that will be painted with organic coatings must be given a suitable phosphate or chromate conversion coating (Ref 19). Similarly, zinc-coated (galvanized) steel surfaces must be prepared for painting by phosphate or chromate conversion treatments, application of wash primers, annealing treatments, complex oxide treatments, or anodizing (Ref 3, 19, 20). Sometimes the zinc alloy or zinc-coated parts are used after chromating or anodizing without painting. Prior to the various conversion treatments, the zinc alloy or zinc-coated parts are degreased by solvents, alkaline cleaned, and acid dipped using the procedures described previously.

Two types of phosphate treatments are used for zinc alloy or zinc-coated parts: iron phosphate and zinc phosphate. The baths for the iron phosphate, which is applied to steel and sometimes to aluminum and zinc, are proprietary alkali metal phosphate solutions (Ref 3). The baths are operated at temperatures from 16 to 71 °C (60 to 160 °F). The phosphate coating formed is a mixture of oxides and phosphates of the base metal. Technically, there is little or no iron phosphate present on zinc alloys after treatment, but the generic name is commonly used to describe the process on all three metals. The coating weights range from 1.9 to 4.6 mg/m^2 (20 to 50 mg/ft^2). The baths are relatively simple to control, and the films that form improve the corrosion resistance and adhesion of paints and powder coatings.

Zinc phosphates are more commonly used on galvanized coatings and zinc die castings (Ref 3, 20, 21). The baths contain zinc oxide or phosphate and phosphoric acid in combination with accelerators, refining agents, and other proprietary ingredients. They produce heavier crystalline deposits than do the iron phosphate solutions. The best paint or powder coating adhesion is achieved when the coating weight is kept low, in the range from 9 to 28 mg/m^2 (100 to 300 mg/ft^2) (Ref 3).

Chromate treatments consist of a dip or spray in a dilute solution of chromium trioxide and other acids, with the proper accelerator for 5 to 30 s (Ref 20). The baths are operated at temperatures from room temperature to 54 °C (130 °F). The process produces a thin, amorphous chromate coating that increases corrosion resistance and paint adhesion.

Aqueous chromic-organic treatments, applied by dipping or roller coating, are solutions of certain water-soluble resins, properly formulated with chromium compounds (Ref 20). The film is cured or baked after application, whichever is required by the paint system to be applied.

A vinyl wash primer also is used to prepare the surfaces of galvanized parts for painting. It involves the application of an acid-bound resinous film 8 to 13 μm (0.3 to 0.5 mil) thick. The treatment is based on three primary components: a hydroxyl-containing resin, a pigment capable of reacting with the resin and an acid, and an acid capable of insolubilizing the resin by reacting with the resin, the pigment, and the zinc surface. This film usually is applied by spraying, but it may be applied by brushing, dipping, or roller coating. Under normal conditions it will dry sufficiently for recoating within 30 min, and within 8 h of application it will not be softened by organic solvents commonly used in paint coatings. It has good adhesion to the metal substrate and promotes good adhesion of most organic coatings.

Hot-dipped galvanized coatings may be given an annealing treatment under controlled conditions to alloy the coating with the base metal and to change the surface character of the zinc coating and make it more receptive to paint (Ref 20). Annealing treatments usually are performed in the mill shortly after galvanizing coils of steel. The surface produced by annealing can further be treated to enhance paint adhesion by the conversion treatment methods described previously.

The amorphous complex-oxide treatment consists of reacting to the zinc surface in an alkaline solution containing heavy metal ions for times between 5 and 30 s at 45 to 70 °C (115 to 160 °F) (Ref 20). The surface of the zinc is converted to a nonmetallic, amorphous, complex-oxide coating that inhibits corrosion and increases the adhesion and durability of paint finishes. This treatment can be carried out by immersion or spray.

Zinc die castings also can be anodized prior to use or prior to painting (Ref 21). Zinc anodizing produces an unusual fritted coating (Ref 22). Anodizing is conducted in a solution of chromic acid, phosphoric acid, and hydrofluoric acid. Alternating current is preferred, although direct current can be used (Ref 21). The anodizing process is conducted at a current density of 4.3 A/dm^2 (40 A/ft^2) and a bath temperature in the range from 66 to 82 °C (150 to 180 °F). The coating forms during an anodic spark discharge that starts at about 70 V (Ref 22). Because the anodized coating is dielectric, the voltage increases to about 200 V in order to maintain the current density as the fritted coating forms. When the power reaches 200 V (5 to 7 min), the process is terminated. The coating formed is matte green. This coating has very unusual corrosion- and abrasion-resisting properties and can be readily painted.

Following the application of a conversion coating, most commonly zinc phosphate, the treated parts can be coated with most of the organic and water-based systems available. The choice of coating will depend on the service requirements of the coated part.

Introduction

VITREOUS CERAMIC COATINGS are applied over substrates for a number of reasons (Ref 1). These coatings may be applied to a substrate surface to render the surface:

- Chemically more inert
- Impervious to liquids and gases
- More readily cleanable
- Smoother and more resistant to abrasion and scratching
- Mechanically stronger
- Decorative
- Aesthetically pleasing

Vitreous coatings are thin layers of glass fused onto the surface of the substrate. When the substrate is a ceramic, the coating is called a glaze. When the substrate is a metal, the coating is called a porcelain enamel. When the substrate is a glass, the coating is called a glass enamel. This article focuses on ceramic coatings for ceramic and glass substrates. Porcelain enameling is discussed in a separate article in the Section "Dip, Barrier, and Chemical Conversion Coatings," in this Volume.

The first requirement is for a strong bond between the coating and the substrate (Ref 2). The composition must fuse to a homogeneous viscous glass (or ceramic) at a temperature that is either coincident with the temperature at which the body matures or at a temperature sufficiently lower to prevent distortion of the substrate during glost firing.

During and after fusion of the coating materials, they must react with the substrate to form an intermediate bonding layer of proper thickness. If the bonding layer or interface is too thin, the coating will flake off after application and subsequent firing. If the bonding layer is too thick, the composition of the body or the coating may be degraded. The coating must also have a coefficient of thermal expansion that coincides or fits the substrate (Ref 3). When the fired ware is cooled, the coated substrate contracts. If the coefficients of thermal expansion of the coating and the substrate are not matched, stresses that lead to spalling or crazing of the coating will be introduced. The coating materials should have a low surface tension to minimize the crawling of the coating away from the edges or any holes present during firing.

The second group of properties are those associated with the use of the product, such as appearance, smoothness, porosity, and corrosion resistance to various liquids and gases. Almost all vitreous coatings are expected to be homogeneous, smooth, and hard and also to resist abrasion and scratching. Such a surface is also more apt to be impervious to liquids and gases and hence more readily cleanable. The sole exception to the desire for a smooth surface is the textured coating in which a pattern is applied for aesthetic purposes.

In many applications, chemical durability in severe service conditions is a principal reason for the selection of a ceramic coating (Ref 4). Vitreous coatings are formulated to be resistant to a variety of reagents ranging from acids, to hot water, to alkalis, to essentially all organic media. The only important exception is hydrofluoric acid, which readily attacks all silicate glasses.

For some applications, the finished ware is to be subjected to elevated temperatures while in service. This is a prime reason for the selection of ceramic coatings for cookware applications and for industrial and military applications.

The optical and appearance properties of any surface coating material are major considerations in determining which coating will be applied. Various possibilities exist for meeting the requirements of a particular application. Because vitreous coatings can be transparent or opaque; high gloss, satin, or matte; smooth, patterned, or textured; and monochrome or multicolored, the combination of requirements that meets each particular application is extensive.

Glazes

A ceramic glaze is a vitreous coating applied to a ceramic substrate (usually a whiteware). A great variety of formulations are used as glazes (Ref 1). Ceramic ware is fired over a wide range of temperatures from 800 to >1400 °C (1470 to >2550 °F). No single glaze composition would be satisfactory over such a wide range of temperatures. A glaze that melts at low temperature will run off the substrate, react with the substrate, or volatilize if fired at a high temperature. A given glaze composition is generally useful over a temperature range of only 30 °C (55 °F). Typical firing temperatures for glazes based on application can be summarized as follows (Ref 5):

- Electronic substrates, ≈600 to 900 °C (≈1110 to 1650 °F)
- Artware glazes, ≈900 to 1050 °C (≈1650 to 1920 °F)
- Dinnerware and tile glazes, ≈1000 to 1150 °C (≈1830 to 2100 °F)
- Structural clay and sanitaryware glazes, ≈1180 to 1250 °C (≈2155 to 2280 °F)
- Porcelain glazes, ≥1300 °C (≥2370 °F)

Because of the toxicity of lead, glazes are often classified on the basis of the presence or the absence of litharge (PbO). Safe working practices require unfired glazes containing litharge to be handled carefully and to have an acceptable level of acid resistance in raw powdered form in the work environment. Finished tableware coated with a lead glaze must also possess an acceptable level of resistance to chemical attack.

Another way to classify a glaze is according to the way it is constituted. Raw glazes are prepared from mineral powders (usually oxides or carbonates) and are chemically limited to elements that can be obtained in materials having low water solubility. Frits are prepared to allow the use of water-soluble materials, which are first melted to an insoluble glass, and then quenched and broken up. For a partially fritted glaze, only the soluble materials and sufficient network former to make an insoluble glass are fritted. In an all fritted glaze, all components are melted into the frit except for necessary suspending agents.

Markets for Glazed Ceramics

The total whitewares market in the United States was reported to be $3.459 billion in 1989 (Ref 6). A breakdown of the U.S. market for products using glazes is shown in the chart of Fig. 1.

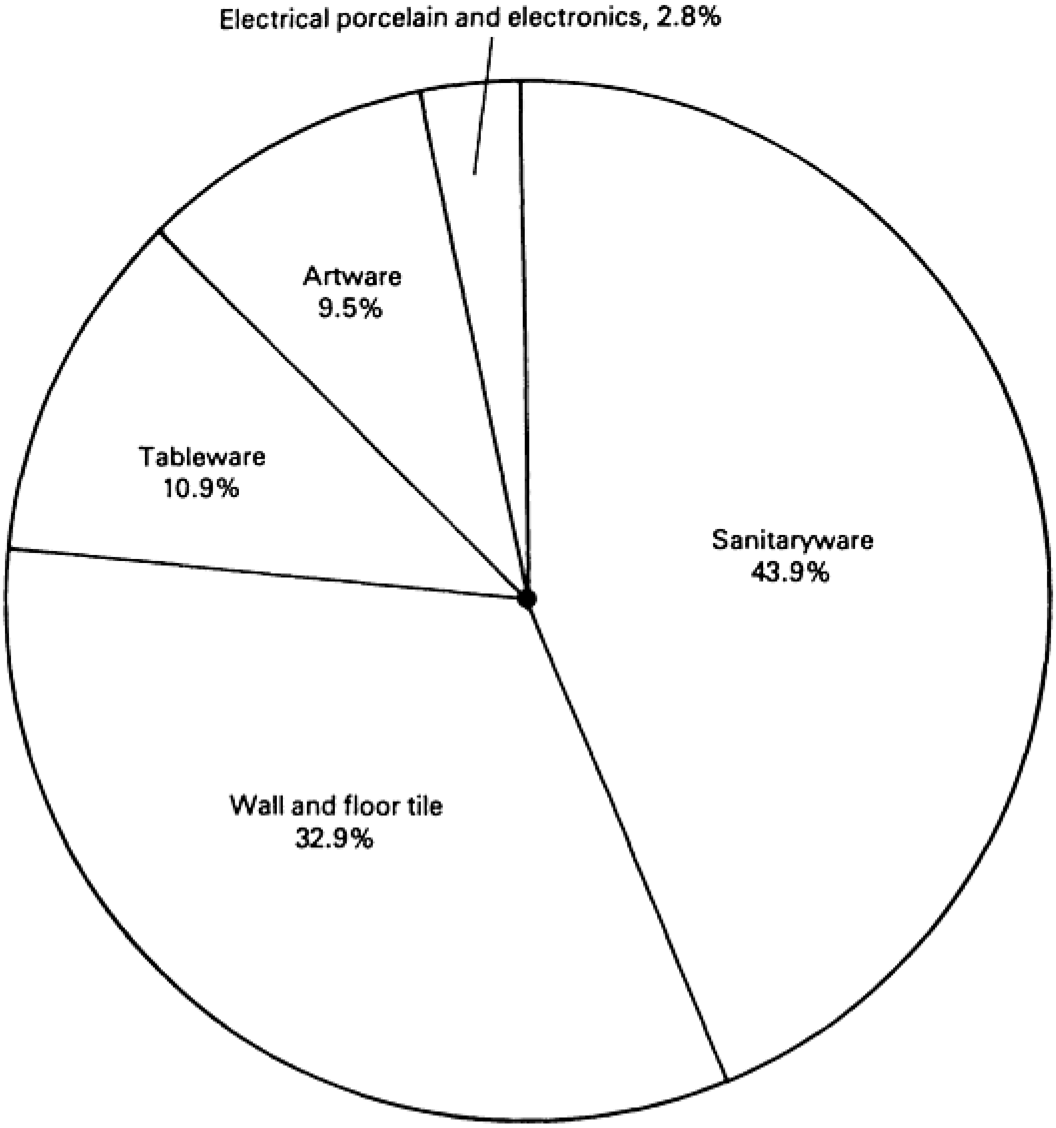

Fig. 1 Breakdown of key segments of the $3.46 billion glaze market in the United States (1989 data)

A ceramic coating typically makes up 10 to 15% of the total manufacturing cost of a ceramic product. The value of the properties provided by the coating usually far outweighs this cost. The protective, functional, and decorative surface that is obtained often serves as a primary selling feature of the end product.

Ceramic glazes find their way into a wide range of applications ranging from coffee mugs to automotive sparkplugs. The major markets for ceramic coatings have different requirements, but one common theme is corrosion resistance and cleanability.

Rarely sold in a ready-to-use form, ceramic glazes are usually formulated and processed for application by the end user.

Role of Specific Oxides in Glazes

The commonly used oxides in glazes are SiO_2, ZrO_2, Al_2O_3, B_2O_3, CaO, SrO, BaO, MgO, ZnO, PbO, Li_2O, Na_2O, and K_2O (Ref 7). Small amounts of fluorine are sometimes used as a partial substitution for oxygen.

Silicon Dioxide. Most glazes contain more silica than all the other constituents combined. Silica promotes low expansion, high durability, and abrasion resistance. Its only serious deficiency is its high melting point, T_m, of 1723 °C (3133 °F).

Alkali Oxides. The foremost reason for adding other oxides is to reduce the maturing temperature. The alkalis are powerful fluxes at all maturing temperatures, and their use is limited by the high thermal expansion they impart to a glaze.

Alkaline Earths. The alkaline earths and magnesia are effective fluxes only at >1100 °C (>2010 °F).

Zinc oxide is effective at >1000 °C (>1830 °F) and in modest amounts it improves the effectiveness of other fluxes.

Lead monoxide is a powerful flux from the lowest temperatures to ≈1150 °C (≈2100 °F), above which volatilization becomes excessive.

Boric oxide is effective at all temperatures. As a network former, it can be used with other oxides to get a high fluxing level. Above 15% B_2O_3 concentration, however, it seriously degrades the durability of the glaze.

Alumina contributes to the working properties of a glaze, improves acid durability, and suppresses phase separation and crystallization of the glaze.

Zirconia is added to a glaze to improve the alkaline durability, and, in higher concentrations, as an opacifier.

Leadless Glazes

Tables 1 and 2 give the formulas of a number of commercial ceramic coatings. The first eight of these are leadless glazes. In these glazes, the alkali and alkaline earth oxides, together with MgO, ZnO, and B_2O_3, are used to provide the fluxing action.

Table 1 Compositions of selected glazes based on mole ratio (Seger formula)

Hard Porcelain Glaze. Glaze 1 is a feldspathic glaze suitable for use only on the highest firing hard paste porcelains (Ref 3).

Soft Porcelain Glaze. For porcelains fired at lower temperatures, such as soft paste porcelain or hard stoneware, glaze 2 would be satisfactory (Ref 8). This glaze is typical of that used on medieval Chinese porcelains.

Sanitaryware Glaze. Glaze 3 is a sanitaryware glaze (Ref 5). It is derived from the soft paste porcelain glaze by the addition of ZnO in large quantities.

Bristol glaze (glaze 4) is used to produce an opaque white coating on stoneware and other dark-colored bodies.

Fast-fire wall tile glazes are derived from the Bristol glaze by increasing the amount of fluxes to increase the melting rate (Ref 9). Glaze 5 is a typical example.

Semivitreous Dinnerware Glaze. The development of glazes for dinnerware is more difficult because of the lower expansion of the bodies. Glaze 6 is an example of a glaze for semivitreous dinnerware (Ref 10). Several alkaline earths are used to improve the melting and surface properties.

Hotel China Glaze. Leadless glazes for vitreous hotel china (such as glaze 7) are a very recent development (Ref 11).

Low Expansion Glaze. Zircon and cordierite bodies are even lower in expansion, requiring a semicrystalline glaze, such as glaze 8 (Ref 12).

Lead-Containing Glazes

Litharge is used in glazes for several reasons (Ref 20). The strong fluxing action of PbO allows the formulation of glazes that mature at temperatures lower than their leadless counterparts, thus leading to greater flexibility in the formulation of the glaze to obtain low expansion, smooth surface, and maturing of the glaze over a wider firing range. Litharge imparts low surface tension for a smooth surface and a high index of refraction that results in a brilliant appearance. Glazes containing litharge heal over defects in the glaze surface more readily and are usually more corrosion resistant. This combination of desirable properties is difficult to achieve in leadless glazes on a production scale.

However, litharge also has disadvantages as a glaze constituent. Lead glazed ware must be fired in a strongly oxidizing atmosphere because lead is readily reduced. Lead oxide cannot be used above 1150 °C (2100 °F) due to volatility. Most importantly, litharge is highly toxic. Moreover, lead poisoning is very difficult to diagnose because its symptoms are similar to other ailments. Therefore, every possible precaution must be taken when preparing lead glazes to avoid poisoning, and ware intended for food contact should be tested as noted below to ensure consumer protection.

Cone 4 Dinnerware Glaze. Glaze 9 in Tables 1 and 2 is an example of a lead-containing dinnerware glaze for cone 4 (1100 °C, or 2010 °F) (Ref 13). (*Cone* refers to pyrometric cones, which are a traditional means of measuring time/temperature thermal cycles, and are still one on the most accurate methods for recording the amount of thermal "work" applied to a kiln of ware. Pyrometric cones are small, triangular pyramids prepared from carefully formulated ceramic compounds designed to soften and melt under precise conditions of temperature and time. A series of cones, which are given numbers corresponding to temperatures at which they soften, are placed in the kiln with the ware. The cones are observed during firing to assist in temperature control, and are examined after the fire to indicate and record the degree of firing achieved.)

Cone 06 Artware Glaze. Glaze 10 is an example of a clear glaze suitable for use on artware and hobbyware bodies at cone 06 (1000 °C, or 1830 °F) (Ref 14).

Electronic Glaze. The glazes used on alumina packages for integrated circuits (ICs) to seal the package represent the lowest firing lead-containing glazes. Glaze 11 is an example of such a glaze, which can be fired as low as 550 °C (1020 °F) (Ref 15).

Heavy-Metal Release

If lead-containing glazes are not properly formulated, they may be less resistant to acid attack, which results in the release of lead. If such glazes are used in contact with food or drink, lead poisoning of the user may result. Cadmium oxide, which is considerably more toxic than lead oxide (Ref 21), is only used in ceramic coatings in connection with the use of cadmium sulfoselenide pigments, which already contain large amounts of cadmium.

To control this problem under production conditions, standard tests have been developed for determining the lead and cadmium content released from glazed surfaces (Table 3). A sample is exposed to a 4% acetic acid solution for 24 h at room temperature while covered. The concentration in ppm of lead and cadmium in the solution is then determined.

Table 3 Standard test methods for determining the lead and cadmium content released from glazed and enamel surfaces used for food preparation when exposed to attack by acetic acid

ASTM standard	Test method	Ref
C 738	Lead and cadmium extracted from glazed ceramic surfaces	22
C 872	Lead and cadmium release from porcelain enamel surfaces	23
C 895	Lead and cadmium extracted from glazed ceramic tile	22
C 927	Lead and cadmium extracted from the lip and rim area of glass tumblers externally decorated with ceramic glass enamels	22
C 1034	Lead and cadmium extracted from glazed ceramic cookware	22

FDA Guidelines. The current United States Food and Drug Administration (FDA) standard limits for lead released are 7 ppm average for six samples of flatware, 5 ppm maximum of six samples of small holloware, and 2.5 ppm maximum of six samples of large holloware (Ref 24). The standard limits for Cd are $\frac{1}{2}$ ppm average for six samples of flatware, $\frac{1}{2}$ ppm maximum of six samples of small holloware, and $\frac{1}{4}$ ppm maximum of six samples of large holloware. These limits are currently under review, and lower levels may possibly be applicable by the time this article is published (Ref 25). Because of statistical fluctuations in the measurements, operating standards must be less than half these guideline values (Ref 26).

In the FDA test, lead-containing commercial dinnerware glazes usually release $\frac{1}{2}$ to 2 ppm (Ref 20). Properly designed commercial artware will be somewhat higher. In contrast, ware implicated in health cases have all released in excess of 50 ppm Pb.

Most glazes have no added cadmium oxide. Those that do contain cadmium will release 0.1 to 0.2 ppm even when properly formulated (Ref 21). For this reason, it is best if CdS-Se colors are not used as surface decorations on glass surfaces that will come in contact with food or drink.

The issue of lead and cadmium release from glassware decorated with glass enamels has also been addressed through a voluntary quality-control program adopted by the ceramic industry (Ref 27). The lip and rim area (that is, the top 20 mm, or $\frac{25}{32}$ in.) of the decorated glass must not leach greater than 50 ppm Pb or 3.5 ppm Cd when analyzed by a modification of the existing ceramic ware test (see Table 3). Failure of one glass in a sample of six is cause for rejection.

Numerous factors must be considered in formulating and processing a glaze to achieve low lead and cadmium release:

- Total glaze composition
- Thermal history during processing
- Glaze application techniques
- Glaze-body solution at the interface during firing
- Atmospheric conditions that exist during firing

Of all these parameters, the most important is the glaze composition.

Heavy-Metal Release Performance Rating. A figure of merit (FM) has been developed to predict the heavy-metal release or acid resistance of a glaze from its composition (Ref 14). Silica, alumina, zirconia, and similar ions such as titania and tin oxide are effective in lowering the lead release (LR) of a glaze:

$$LR_A = 2[Al_2O_3 + [SiO_2] + [TiO_2] + [ZrO_2] + [SnO_2] \qquad \textbf{(Eq 1)}$$

The concentrations given in Eq 1 are expressed in molar ratio. The factor 2 arises from the fact that there are 2 equivalents of aluminum ions per equivalent of Al_2O_3.

It has also been shown that alkalis, alkaline earths, B_2O_3, fluoride, phosphate, ZnO, CdO, and PbO are all more or less detrimental to the lead release in a glaze:

$$LR_B = ([Li_2O] + [Na_2O] + [K_2O] + [B_2O_3] + [P_2O_5]) + [MgO] + [CaO] + [SrO] + [BaO] + [F] + [ZnO] + [PbO] \qquad \textbf{(Eq 2)}$$

Combining these terms gives the figure of merit:

$$FM = LR_A/(LR_B)^{1/2} \qquad \textbf{(Eq 3)}$$

When the figure of merit is >2.05, the lead release is below the standard. When it is <1.80, some measurements are always greater than the standard. This figure of merit applies to all single-phase glazes. In a glass-crystal-line system, the formulation of the least durable component must be used in the calculation.

Opaque Glazes

In opaque glazes, the transmittance of the glaze has been reduced to hide the body. Opacity is introduced into ceramic coatings by the addition of a substance that will disperse in the coating as discrete particles to scatter and reflect the incident light (Ref 5). This dispersed substance must have a refractive index that differs from that of the clear ceramic coating.

The refractive index, n_D, of most glasses is 1.5 to 1.6. Typical opacifiers include SnO_2 (n_D = 2.04), ZrO_2 (n_D = 2.40), $ZrSiO_4$ (n_D = 1.85), and TiO_2 (n_D = 2.5 for anatase and 2.7 for rutile). Opacified glaze (glaze 12) in Tables 1 and 2 is an example of a glaze fired at >1000 °C (>1830 °F) where zircon is the opacifier of choice (Ref 16).

In coatings fired at <1000 °C (<1830 °F), titania in the anatase phase is the best opacifier because of its high refractive index. The temperature limit is the point at which anatase inverts to rutile. Rutile crystals are unsuitable because they grow too large in glass for opacification and then have a yellow color.

Satin and Matte Glazes

Satin and matte effects are also due to dispersed crystals in the glaze (Ref 5). The crystals must be very small and evenly dispersed if the glaze is to have a smooth velvet appearance. Matte glazes are always somewhat opaque. The amount of opacity depends on the difference in refractive index between glaze and crystal and can be fairly small. Glaze 13 in Tables 1 and 2 is an example of a zinc matte glaze where the crystal is willemite (Zn_2SiO_4) (Ref 2). Glaze 14 is a lime matte glaze with a wollastonite ($CaSiO_3$) crystal.

Glass Enamels

Glass enamels are applied to glass for decorative purposes and not to improve chemical durability or cleanability. Because these coatings are matured at temperatures below the deformation point of the glass substrate (540 to 650 °C, or 1000 to 1200 °F) and require larger quantities of fluxing elements, corrosion resistance can be difficult to obtain.

Glass enamels are produced in ready-to-use form (for example, paste, thermoplastics, spray media, and ultraviolet curable media) by a few select manufacturers. These enamels are rarely compounded by the end user and represent a specialty product that is more akin to organic paints than to other ceramic coatings.

The markets for this specialty product are categorized as tableware, glass containers, architectural, lighting, and automotive. There are no published figures on the value of the specific portion of the glass market that is decorated with glass enamels.

As supplied to the user, glass enamels are mechanical mixtures of pigments (see the section "Ceramic Decoration" in this article), fluxes, and organic suspending media. The requirement for low maturing temperatures necessitates the use of very high lead-oxide containing borosilicates for the flux. The industry relies on in-house control tests to ensure acceptable levels of lead release from decorated areas that might come in contact with food or drink (see the section on "Heavy-Metal Release" in this article).

The organic suspending media for glass enamels are similar to materials used to make organic paints.

Ceramic Decoration

Techniques for Coloring Vitreous Coatings. There are a number of ways to obtain color in a ceramic coating (Ref 28). In one method, certain transition metal ions can be melted into a glass when it is made. While suitable for bulk glass, this method is rarely used for coatings because adequate tinting strength and the purity of color cannot be obtained by this process.

A second method to obtain color is to induce the precipitation of a colored crystal in a transparent matrix. Certain materials dissolve to some extent in a vitreous material at high temperature. When the temperature is reduced, the solubility is also reduced and precipitation occurs. This method is used for opacification (that is, the production of an opaque white color). Normally, some or all of the opacifier added to the coating dissolves during the firing process and recrystallizes upon cooling. For oxide colors other than white, however, this method lacks the necessary control for reproducible results and is seldom used.

The third method to obtain color in a vitreous matrix is to disperse in that matrix one or more insoluble crystals that are colored. The color of the crystal is then imparted to the transparent matrix. This method is the one most commonly used to introduce color to vitreous coatings.

Pigment Systems. To be suitable as a ceramic pigment, a material must have a high tinting strength, a high refractive index, and be free of grayness. It must also possess stability under the high temperatures and corrosive environments encountered in the firing of glazes (Ref 29). Most ceramic pigments are complex oxides (see Table 4) with the lone exception being the cadmium sulfoselenide red pigments.

Table 4 Inorganic pigments to impart colors to ceramic coatings

Pigment system	CAS registry number[(a)]	Chemical formula	DCMA number[(b)]
Pink and purple			
Chrome-alumina-pink spinel	68201-65-0	$Zn(Al,Cr)_2O_4$	13-32-5

Iron-titanium brown spinel	68187-02-0	Fe_2TiO_4	13-34-7
Nickel-ferrite brown spinel	68187-10-0	$NiFe_2O_4$	13-35-7
Zinc-ferrite brown spinel	68187-51-9	$(Zn,Fe)Fe_2O_4$	13-36-7
Iron brown hematite	68187-35-9	Fe_2O_3	3-06-7
Chrome-iron-manganese brown spinel	68555-06-6	$(Fe,Mn)(Fe,Cr,Mn)_2O_4$	13-48-7

Chromium-manganese-zinc brown spinel	71750-83-9	$(Zn,Mn)Cr_2O_4$	13-51-7
Yellow			
Zirconium-vanadium yellow baddeleyite	68187-01-9	$(Zr,V)O_2$	1-01-4
Tin-vanadium yellow cassiterite	68186-93-6	$(Sn,V)O_2$	11-22-4
Zirconium-praseodymium yellow zircon	68187-15-5	$(Zr,Pr)SiO_4$	14-43-4
Lead-antimonate yellow pyrochlore	68187-20-2	$Pb_2Sb_2O_7$	10-14-4
Nickel-antimony-titanium yellow rutile	71077-18-4	$(Ti,Ni,Sb)O_2$	11-15-4
Nickel-niobium-titanium yellow rutile	68611-43-8	$(Ti,Ni,Nb)O_2$	11-16-4
Chrome-antimony-titanium buff rutile	68186-90-3	$(Ti,Cr,Sb)O_2$	11-17-6
Chrome-niobium-titanium buff rutile	68611-42-7	$(Ti,Cr,Nb)O_2$	11-18-6
Chrome-tungsten-titanium buff rutile	68186-92-5	$(Ti,Cr,W)O_2$	11-19-6
Manganese-antimony-titanium buff rutile	68412-38-4	$(Ti,Mn,Sb)O_2$	11-20-6
Green			
Chromium-green hematite	68909-79-5	$(Cr,Fe)_2O_3$	3-05-3
Cobalt-chromite blue-green spinel	68187-11-1	$Co(Al_2Cr)_2O_4$	13-29-2
Cobalt-chromite green spinel	68187-49-5	$CoCr_2O_4$	13-30-3
Cobalt-titanate green spinel	68186-85-6	Co_2TiO_4	13-31-3
Victoria green garnet	68553-01-5	$3CaOCr_2O_3 3SiO_2$	4-07-3
Nickel-silicate green olivine	68515-84-4	Ni_2SiO_4	5-45-3
Blue			
Cobalt-aluminate blue spinel	68186-86-7	$CoAl_2O_4$	13-26-2

Cobalt-zinc-aluminate blue spinel	68186-87-8	$(Co,Zn)Al_2O_4$	13-28-2
Cobalt-silicate blue olivine	68187-40-6	Co_2SiO_4	5-08-2
Cobalt-zinc-silicate blue phenacite	68412-74-8	$(Co,Zn)_2SiO_4$	7-10-2
Cobalt-tin blue-gray spinel	68187-05-3	Co_2SnO_2	13-27-2
Cobalt-tin-alumina blue spinel	68608-09-3	$CoAl_2O_4/Co_2SnO_4$	13-49-2
Zirconium-vanadium blue zircon	68186-95-8	$(Zr,V)SiO_4$	14-42-2
Black			
Iron-cobalt black spinel	68187-50-8	$(Fe,Co)Fe_2O_4$	13-39-9
Iron-cobalt-chromite black spinel	68186-97-0	$(Co,Fe)(Fe,Cr)_2O_4$	13-40-9
Manganese-ferrite black spinel	68186-94-7	$(Fe,Mn)(Fe,Mn)_2O_4$	13-41-9
Copper-chromite black spinel	68186-91-4	$CuCr_2O_4$	13-38-9
Chromium black hematite	68909-79-5	$(Cr,Fe)_2O_3$	3-05-3
Chromium-iron-nickel black spinel	71631-15-7	$(Ni,Fe)(Cr,Fe)_2O_4$	13-50-9
Gray			
Cobalt-nickel gray periclase	68186-89-0	$(Co,Ni)O$	6-09-8
Titanium-vanadium-antimony gray rutile	68187-00-8	$(Ti,V,Sb)O_2$	11-21-8
Tin-antimony gray cassiterite	68187-54-2	$(Sn,Sb)O_2$	11-24-8

Red Pigments. Orange, red, and dark red colors are obtained only by the use of the cadmium sulfoselenide pigments (Ref 21, 31). Because cadmium compounds are highly toxic (Ref 32), the cadmium sulfoselenide pigments should not be used in applications that will come in contact with food and drink. Moreover, these pigments must also be handled with great care to avoid the possibility of ingestion.

Pink and Purple Pigments. Chrome alumina pinks (Ref 33) impart pink shades in glazes suitably formulated. The manganese alumina pink is a very pure clean pink, but it is difficult to manufacture. The most stable pink pigment is the iron-doped zircon system (Ref 34) in which the shades of color extend from pink to coral. The chrome-tin system is the only family that can produce purple and maroon shades as well as a pink shade (Ref 35).

Brown Pigments. The zinc-iron-chromite spinels (Ref 36) produce a wide palette of tan and brown shades. The other browns are variations of this system for specific applications.

Yellow Pigments. Zirconia vanadia yellows are economical pigments for use with coatings fired at >1000 °C (>1830 °F) when high tinting strength is not required (Ref 37). Tin vanadium yellows are a strong yellow color but are very costly to produce (Ref 38). The praseodymium zircon pigments have excellent tinting strength in coatings fired to as high as cone 10 (Ref 34). For lower-temperature applications, the tinting strength of the lead antimonate pigment is unsurpassed with the exception of the cadmium sulfoselenides. The rutile pigments yield yellow, orange yellow, or maple shades useful in porcelain enamels and glass enamels.

Green Pigments. Green Cr_2O_3 may be used in a few applications (Ref 39). The zinc-alumina-chromite blue-green pigments give shades from blue to blue-green when used in strong masstones. The Victoria green gives a transparent bright green color. Because of difficulties inherent in the use of chromium-containing pigments, many green ceramic glazes are now made with zircon pigments (Ref 34). Stable greens are obtained with a blend of about 2 parts of the praseodymium zircon yellow to 1 part of the vanadium zircon blue.

Blue Pigments. Cobalt blues, both the spinel ($CoAl_2O_4$) and the silicate (Co_2SiO_4) forms, are the highest tinting strength colors used in ceramics (Ref 40). At the higher firing temperatures used for ceramic glazes, they often cause a bleeding defect. At these specific temperatures, the vanadium-doped zircon blue is used (Ref 34).

Black Pigments. Black ceramic pigments are formed by mixtures of several oxides to form the spinel structure (Ref 41). The one exception is the chromium black hematite, an inexpensive pigment suitable for use in zinc-free coatings (Ref 42).

Gray Pigments. The cobalt-nickel gray periclase uses zirconia or zircon as a carrier for various ingredients of blacks such as cobalt, nickel, iron, and chromium oxides. The titanium-vanadium rutile can be used in porcelain enamels.

Pigment Application in Coatings. When selecting pigments for a specific coating application, consideration must be given to the following parameters (Ref 43):

- Processing stability requirements
- Pigment uniformity and reproducibility
- Particle size distribution
- Compatibility of all materials to be used

An engobe or body stain must be stable to the bisque fire. (*Engobe* is a slip coating applied to a ceramic body for imparting color, opacity, or other characteristics.) An underglaze color or a colored glaze must be stable to the glost fire and to corrosion by the molten glaze ingredients. An overglaze or glass enamel must only be stable to the decorating fire and to corrosion by the molten flux used in the application.

For most ceramic pigments, uniform and reproducible manufacture requires great care. To avoid specking in a blend, no component should be <10% of the mix.

Most calcined ceramic pigments are in the 1 to 10 μm (40 to 400 μin.) range in mean particle size, with no residue on a 325 mesh (44 μm) screen. The optimum particle size for an application is the largest size that gives uniform dispersion and adequate strength in opacified coatings.

A ceramic pigment must function as a component in a glaze or porcelain enamel system. Thus, it must be compatible with the other components (that is, the glaze itself, the opacifier(s), and the other additives).

Pigment Cost Factors Availability. Owing to the limited market and the variety and complexity of the products, ceramic pigments are manufactured by specialty firms and not by the users. In 1991, the cost of ceramic pigments ranged from $9 to $50/kg ($4 to $20/lb) or even higher, depending on the elemental composition and the processing required.

Surface Engineering for Chemical Activity

Michel Deeba and Jennifer S. Feeley, Engelhard Corporation

Introduction

A CATALYST is a substance that accelerates the rate of a chemical reaction toward equilibrium without becoming consumed in the process. The process is cyclic, in that an active catalytic site first forms a complex with adsorbing reactants, and then forms products that desorb, restoring the original site. Catalysts are available in many physical forms, including particulates (tablets, microspheres, etc.), powders for slurry-phase reactions, and washcoated honeycombs or monoliths for fixed-bed reactors. The form that is selected strongly depends on the process being catalyzed.

A catalyst must be designed to have high activity and selectivity. (The *activity* of a catalyst refers to the rate at which it causes the reaction to proceed to chemical equilibrium. *Selectivity* is a measure of the extent to which a catalyst accelerates the reaction to form one or more of the desired products.)

The chemical process being catalyzed should have a high productivity within a specified reactor volume, with high reaction rates for the desired reactions and low rates for undesired reaction pathways. A catalyst also must have sufficient durability, that is, a certain lifetime will be required of it, depending on the process in which it is used. Factors that can influence durability include thermal and hydrothermal stability, resistance to poisons, and mechanical strength. Potential poisons can be either inorganic in nature (sulfur, lead, or phosphorus) or organic (carbon deposition), depending on the process. The mechanical strength of a catalyst can sometimes be determined by measuring crushing strength, attrition resistance, or thermal shock.

Acknowledgement

The authors would like to thank Dr. Robert J. Farrauto for his suggestions and for editing this article.

Catalyst Preparation

In the past, the manufacturing of catalysts was regarded to be more of an art than a science. Successful recipes were acquired by trial and error, rather than through scientific understanding and careful process design. However, since the 1980s, the design of catalysts with specific and controlled properties has become possible.

In many catalytic processes, the number of reactant molecules that are converted to products in a given time period is directly related to the number of catalytic sites available. To increase the availability of active sites to reactants, catalytic materials are often dispersed on a highly porous, high-surface-area, thermally stable carrier. This generally stabilizes the active sites by preventing their migration and coalescence.

The most commonly used method for preparing supported metal and metal oxide catalysts involves two steps. First, it is necessary to distribute precursor compounds containing the catalytic component (metal salts, cations, or clusters) within the pore structure of the high-surface-area carriers, using impregnation, ion exchange, or precipitation. Second, the supported precursors must be transformed into catalytically active phases using one or more of these pretreatment steps: drying, calcination (heating to high temperatures in air), reduction (treating with reducing agents such as hydrogen gas or hydrazine), and sulfidation.

In some catalytic applications, nonsupported metal oxides or mixed metal oxides can be used. Generally, these catalysts are prepared by precipitation from aqueous metal salt solutions. Some processes use nonsupported metal wire gauzes. For example, platinum-rhodium alloy gauzes are used for nitric acid production by the oxidation of ammonia.

Some important commercial processes that utilize catalysts prepared by the procedures described in this article are given in Table 1. This article is intended as a very short review of the most general catalyst preparation procedures. The references should be consulted as sources of more complete information.

Table 1 Industrial processes and relevant catalysts

Application	**Reaction**	**Active catalytic component**
Chemicals		
Steam reforming (H_2 production)	$CH_4 + H_2O \rightarrow 3H_2 + CO$	Ni/Al_2O_3 (pellet)
Methanol synthesis	$2H_2 + CO \rightarrow CH_3OH$	Cu, ZnO/Al_2O_3 (pellet)

Ammonia synthesis	$3H_2 + N_2 \rightarrow 2NH_3$	Bulk Fe (pellet)
Hydrogenation	(1) Fats and oils + H_2 $\rightarrow$ hydrogenated products	Ni/Al_2O_3 (powder)
	(2) Organic functional groups + H_2 $\rightarrow$ hydrogenated products	Pd or Pt/carbon (powder)
		$CuO\text{-}Cr_2O_3$ (powder)
Polyethylene synthesis	$CH_2{=}CH_2 \rightarrow CH_3(CH_2)_nCH_3$	Cr_2O_3/SiO_2 (powder)
Nitric acid synthesis	$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O$	PtRh gauze
Sulfuric acid production	$SO_2 + O_2 \rightarrow SO_3\ H\ \underline{2}\ O\ H_2SO_4$	V_2O_5/SiO_2 (pellet)
Environmental processes: catalysts on monoliths		
Three-way catalyst automotive catalyst	CO + hydrocarbons + NO $\rightarrow$ $CO_2 + H_2O + N_2$	Pt, Rh, $Pd/Al_2O_3/Ce$
Volatile organic compound destruction	Hydrocarbons + O_2 $\rightarrow$ $CO_2 + H_2O$	Pt/Al_2O_3
Selective catalytic reduction of NO_x	$NH_3 + NO_x\ O_2N_2 + 3/2H_2O$	V_2O_5/TiO_2
Ozone abatement	$2O_3 \rightarrow 3O_2$	Pd/Al_2O_3
Petroleum processes		
Fluid catalytic cracking to produce gasoline	High- $\rightarrow$ low-molecular-weight hydrocarbon (C_5-C_{13})	Acidic *Y* zeolite in
		SiO_2/Al_2O_3 matrix (microspheres)
Catalytic reforming to produce high-octane gasoline	(1) Dehydrogenation	Pt, PtRe, or PtSn on acidified Al_2O_3 (pellet)
	(2)Isomerization	
	(3)Aromization	
Methanol to gasoline process	CH_3OH $\rightarrow$ aromatics	ZSM-5 zeolite (pellet)
Paraffin isomerization	Linear $\rightarrow$ branched hydrocarbons	Pt/H mordenite in alumina matrix (pellet)

Impregnation is one of the simplest ways to prepare a supported metal or metal oxide catalyst. A porous carrier with a high internal surface area, such as alumina, silica, and titania, is contacted with an impregnating solution, usually aqueous, of one or more metallic salts or compounds.

The carrier and the impregnated metal compound are then dried and subjected to further pretreatments, such as calcination and/or reduction before use. Drying at approximately 100 °C (210 °F) in air, followed by calcination to higher temperatures, is a common method used to decompose metal salts and to fix active metal oxide components on carriers. For example, silica can be impregnated with an ammonium metavanadate solution, and then dried and calcined to give a catalyst (vanadium pentoxide supported on silica) that is similar to the product used commercially in sulfuric acid production.

Incipient Wetness Impregnation. In this method, impregnating solution is used in a sufficient volume to completely fill the pores of the carrier, without excess solution. This allows the precursor to disperse evenly within the pore structure of the carrier.

In some cases, the active component can be precipitated onto the carrier by adjusting the pH of the impregnating solution. This will immobilize, or fix, the active material on the carrier. For example, it is common to treat noble metals (platinum, palladium, rhodium, etc.) on carriers with hydrazine, in order to reduce the metal, or with acids or bases, in order to neutralize the impregnating solution (i.e., the addition of ammonium hydroxide to a H_2PdCl_4 impregnating solution) and precipitate the metal oxide to obtain dispersions. This step is carried out after impregnation, but before drying and further processing.

Impregnation by Precipitation. One modification of the standard impregnation method is achieved by suspending the carrier material (powder or particulate) in a solution of the catalytic precursor materials. The catalytic material is then slowly precipitated onto the carrier by adjusting the pH of the liquid impregnating solution. The resulting catalyst is collected by filtration. Metal oxides supported on zeolites, such as CuO/ZSM-5, can be prepared using this method.

Eggshell Impregnation. Some catalytic reactions are conducted under conditions in which only the exterior of the catalyst particle contains the active component. Thus, the interior of the catalyst particle is inactive, and all of the reaction occurs on its exterior. This procedure is sometimes used to reduce the formation of byproducts and unwanted side reactions that can occur in a pore diffusion controlled reaction. It is also used to prepare catalysts containing expensive noble metals in order to increase the effectiveness per unit of noble metal.

In this process, a carrier, usually particulate, is coated with a thin layer of up to 200 μm (8 mils) of catalytic material. The procedure involves placing the carrier in a rotating drum along with the catalytic material. The degree to which the active component penetrates the carrier can sometimes be controlled by either adjusting the pH of the solution or varying the quantity of alkali metals present on the surface of the carrier. This technique has the advantage of producing catalysts with shallow metal concentration profiles near the surface of the catalyst particles, which decreases pore-diffusion resistance.

Ion exchange is a very effective method for dispersing metals, oxides, and cations on carriers. However, only carriers that have cation-exchange capacities can be used. The ion-exchange procedure is often used to prepare metal supported on aluminas and molecular sieves (i.e., zeolites, metallosilicates, etc.). Metal-loaded zeolite catalysts are easy to prepare using this technique because of their unusually high cation-exchange capacity. Catalysts prepared by this procedure initially result in highly dispersed metal cations. Reduction can lead to highly dispersed metal particles. Further oxidation results in highly dispersed oxide phases.

To carry out the exchange procedure, the carrier must possess negatively charged ions to which exchangeable cations are bonded. The cation initially bonded to the surface (H^+, NH_4^+, Na^+) is ion exchanged with the desired cation, maintaining electrical neutrality during the procedure. The exchange is carried out by mixing the carrier with the desired cation salt in a dilute aqueous solution for 1 to 24 h at temperatures up to 100 °C (210 °F). The exchanged carrier is then collected by filtration and washed with excess water before further processing.

Sometimes, a single ion-exchange procedure is not sufficient to obtain the desired level of metal loading. Multiple ion-exchange procedures with optional drying and calcining steps in between can then be conducted.

Precipitation. Amorphous and crystalline metal oxide and mixed metal oxide catalysts can be prepared using a variety of precipitation techniques. Examples of these unsupported oxide catalysts include coprecipitated $NiO \cdot Al_2O_3$ for steam reforming to produce hydrogen, $CuO \cdot ZnO \cdot Al_2O_3$ for methanol synthesis, and $SiO_2 \cdot Al_2O_3$ for fluid catalytic cracking (FCC) of heavy oils to lower-molecular-weight fuels.

In a typical procedure, an aqueous solution of one or more metal salts contacts a basic solution, such as an aqueous alkali, ammonium hydroxide, or ammonium carbonate, to cause the precipitation of insoluble metal hydroxides or carbonates. The catalyst is then collected by filtration and washed repeatedly, prior to drying. Catalysts prepared by this method are often calcined at temperatures that exceed 300 °C (570 °F) after drying in order to decompose metal oxide precursors, such as hydroxides, and form the desired oxides. Temperatures that are even higher are used to form crystalline mixed oxides, such as perovskites or spinels. Catalysts that are prepared using these procedures sometimes need to be crushed into powder form prior to use, as in slurry-phase processes.

The precipitation method used to prepare metal oxide catalysts is also used to prepare some standard catalyst carrier materials, such as Al_2O_3, TiO_2, and SiO_2. Their preparation is discussed in detail below.

Preparation of Common Carriers Used in Supported Catalysts

Catalyst carriers are usually high-surface-area inorganic materials with complex pore structures, into which catalytic materials such as palladium, platinum, cobalt, chromium oxide, and vanadium pentoxide are deposited using the methods described above. At one time, it was thought that catalyst carriers only served to provide inert high surface areas with suitable strength and durability, on which catalytic substances could be dispersed, thus maximizing the number of active sites. However, it is now widely recognized that the carrier often plays a critical role in the performance of the catalyst, in terms of activity, selectivity, and durability.

The selection of the appropriate carrier is the first and most important step in designing a supported metal or metal oxide catalyst. Parameters such as surface area, porosity, thermal stability, acidity, and the inherent activity of the carrier itself are all critical to the carrier selection process. Because reactants and product must diffuse within the carrier, the size of its pores is critical for optimum transport. Carrier materials can be categorized as:

- Active carriers, such as alumina, silica-alumina, zeolites, titanium oxide, and carbon in powder or particulate form
- Inert carriers, such as silica, in powder or particulate form
- Structural supports, such as the monoliths upon which catalyzed carriers are deposited

The most important catalyst supports for experimental and industrial use are high-surface-area inorganic oxides and carbon. Their characteristics and preparations are described briefly below. Structural supports are described in the section "Catalyst Powder Processing" in this article.

Alumina (Al_2O_3) is one of the most important commercial carrier materials used in industrial applications. It is a component of many environmental catalysts, including automobile catalytic converters and catalysts for the oxidation of volatile organic compounds. It is also used in petroleum catalysts, for hydrodesulfurization and reforming, and in chemical catalysts, for hydrogenation, isomerization, and oxidation reactions.

Aluminas with high surface areas (100-600 m^2/g, or 2-14 ft^2/lb) are generally prepared by the thermal decomposition of well-crystallized hydroxides or precipitated colloidal gels. The high surface area of alumina is due to a network of $Al(OH)_x$ species (particles of 2 to 5 nm, or 0.08 to 0.2 μin.) bonded together to form polymer-type chains. Precipitation can be performed by the acidification of aluminate, the neutralization of aluminum salts, or the hydrolysis of alcoholate.

The phase of alumina that is formed strongly depends on the pH used in the precipitation step and the thermal history of the resulting solid support. For example, precipitation at a pH of 11, followed by drying, forms aluminum trihydrate, known as Bayerit, whereas precipitation at a pH of 9, followed by drying, forms pseudo-Boehmit, the monohydrate crystal ($AlO{\cdot}OH$). The gamma phase of alumina, obtained by calcining at 350 to 600 °C (660 to 1110 °F), is the most widely used. Treatment at temperatures above approximately 800 °C (1470 °F) results in the conversion to lower-surface-area phases of alumina.

Silica (SiO_2). The preparation of different silicas has been reviewed in great detail in the literature (Ref 1). Silica is often used in polymerization catalysts, such as 0.1% chromium oxide impregnated on silica, for the formation of polyethylene.

Most silicas used in catalysis are synthetic. Preparation conditions have a dramatic influence on the properties of the silica that is formed. Variations of pH, rate of precipitation, aging of the precipitate, and drying and calcination conditions can lead to silicas with controlled porosities and surface areas.

Silica gel can be prepared by the polymerization of silicic acid or the aggregation of colloidal silica. Alkaline solutions of silicates (pH of 12) can be neutralized with acid, resulting in the formation of polymeric silicic acid, which precipitates as a hydrogel. When chains of silicic acid polymerize, they form a high-surface-area network with interconnecting pores of varying sizes. After controlled drying and calcination, silicas with high surface areas (200 to 600 m^2/g, or 5 to 14 ft^2/lb) can be obtained.

Zeolites are highly crystalline silicoaluminates with well-defined pore structures comprising tetrahedral silicon and aluminum oxide units. They have pore diameters of 0.3 to 1.0 nm (0.01 to 0.04 in.) and surface areas of 300 to 700 m^2/g (7 to 17 ft^2/lb), both of which primarily depend on the type of zeolite. Zeolites have a three-dimensional framework structure with this empirical formula:

$$M_{x/n}^{+n}\ [(\mathrm{AlO_2})_x\ (\mathrm{SiO_2})_y]\cdot w\mathrm{H_2O}$$

where w is the number of water molecules associated with the zeolite and the bracketed term is the zeolite framework and the crystallographic unit cell. The cation M with valence n is present to balance the negative charge on the lattice created by the substitution of Si^{+4} by Al^{+3} in the framework structure. Silicon/aluminum ratios vary with the type of zeolite and the preparation conditions.

Zeolites are generally synthesized by a hydrothermal process. Sodium hydroxide is commonly added to sodium silicate and sodium aluminate, causing gelation to occur (Ref 2). The freshly coprecipitated silica/alumina gel is allowed to age at 25 to 200 °C (75 to 390 °F) to cause crystallization. The zeolite is collected by filtration, and then washed, dried, and calcined. The conditions of aging (temperature and pressure), pH, and silicon/aluminum ratio are some of the important factors determining the type of zeolite that is prepared.

Zeolites are of great interest catalytically, primarily because of their high activity and unusual selectivity in a variety of acid-catalyzed reactions. They are also interesting as catalyst carriers for metals, metal cations, and oxides. They are used in the petroleum industry in fluid catalytic cracking (acidic *Y* zeolite) and isomerization catalysts (platinum/mordenite), and for the methanol-to-gasoline process (ZSM-5). Most important, catalytically, are the zeolites from the faujasite group (*X* and *Y* zeolite), as well as chabazite, erionite, offretite, mordenite, and the pentasil zeolites ZSM-5 and ZSM-11.

Titanium oxide (TiO_2), or titania, is currently used as a catalyst carrier for the selective catalytic reduction of nitrogen oxide (NO_x, or NO + NO_2) using ammonia in stationary source applications. It has two crystal structures, anatase and rutile. The anatase form is more important catalytically, because of its high surface area (25 to 100 m^2/g, or 0.06 to 2 ft^2/lb). The rutile structure has a much lower surface area (<10 m^2/g, or 0.2 ft^2/lb). Titania in the anatase form is prepared by precipitation from boiling titanium (IV) sulfate solution. The rutile form can be prepared directly from the precipitation of a chloride solution or by calcination of the anatase phase at 600 °C (1110 °F) for several hours.

Carbon exists in several morphological forms, such as charcoals, carbon blacks, graphite, and molecular sieve structures. Many carbons occur naturally from wood, peat, nuts, shells, and other organic matter. Charcoal, known for its adsorptive properties, is prepared by the pyrolysis of organic polymers. Charcoals are highly porous with surface areas of approximately 1000 m^2/g (25 ft^2/lb). Carbon blacks are prepared by the controlled pyrolysis of hydrocarbons. The nature of the precursor hydrocarbon and the pyrolysis conditions determine the surface area, pore structure, and surface chemistry of the carbon black.

Carbon carriers have been used extensively for precious metals, transition metals, and alkali and alkaline earth metals. Carbon-supported catalysts (platinum, palladium, and nickel on carbon) are used in a variety of catalytic processes, such as alkylation, hydroalkylation, and hydrogenation.

Other inorganic oxides that are sometimes, but not commonly, used as catalyst carriers include zirconia, rare-earth oxides, alkaline earth oxides, chromia, niobia, tin oxide, and zinc oxide. These are often prepared simply by precipitation of the corresponding metal salts (nitrates or sulfates), followed by washing and calcination. Zirconia can be prepared with a fairly high surface area (approximately 150 m^2/g, or 5 ft^2/lb), and therefore is finding use in more catalyst applications.

Many of the mixed metal oxide catalysts described in the section "Precipitation" can also serve as potential catalyst support materials.

Catalyst Powder Processing

The form of the catalyst used for a specific reaction depends on the type of reactor being used. Powder catalysts are usually used for slurry-phase processes, whereas tablets or extruded catalysts are used in fixed-bed reactors, and microsphere catalysts (50 to 120 μm, or 2 to 5 mils) are used in fluidized bed reactors. Catalyzed honeycombs or monoliths are used in numerous environmental applications. Therefore, catalyst powders are often converted into a suitable form (particulates or washcoats for honeycombs) for a specific reactor design. In general, powder processing techniques are made easier by using powders having well-defined particle sizes in order to yield catalyst products that are homogeneous and have attrition resistance.

In the tableting process, the powder is firmly pressed into a die and shaped into small cylinders, rings, or beads. Powders composed of deformable particles acquire reasonable cohesion upon tableting. Plastifying agents (talc, graphite, stearic acid, etc.) are sometimes added to powders to prevent them from sticking to the sides of dies and stamps.

In the beading or granulation process, individual particles of different sizes are rotated under a spray of liquid to form larger, more homogeneously sized particles. The operation is done in a horizontal rotating cylinder or pan with a rotation axis of approximately 45° inclined. The particles roll over one another to give almost perfectly spherical particles (0.5 to 20 mm, or 0.02 to 0.8 in.).

In the paste extrusion process, catalyst powders are converted into a paste that is used to form larger particles. The paste is moved through a drilled plate and made into cylinders with diameters of 1 to 10 mm (0.04 to 0.4 in.). The paste must have enough plasticity to give granules with sufficient cohesion. The rheological properties of the paste can be adapted by adding volatile materials (acids, stearates, methyl cellulose, or polymers) or other materials that will not influence the activity of the catalyst (colloidal alumina, silica, clays, etc.).

Spray drying, a simultaneous drying and shaping procedure, is a widely used technique to produce spherical materials. A suspension or slurry that contains about 20 to 60% solids is sprayed in hot gases (100 to 400 °C, or 210 to 750 °F). The tiny drops that form are dried very quickly, which results in almost perfectly shaped microspheres. This process is used to make catalysts for fluid catalytic cracking (FCC). The average life of an FCC catalyst during use is about 6 mo, during which it experiences temperatures as high as 750 °C (1380 °F). Therefore, a highly attrition resistant and thermally stable catalyst is necessary. Several binders have been developed that can be added to the slurry to substantially increase the hardness of FCC microspheres.

Catalyzed honeycomb or monolith structures with parallel channels are utilized in high-flow-rate processes where pressure drops must be minimized. They have been used in numerous environmental applications, including automobile catalytic converters and abatement systems for volatile organic compounds and selective catalytic reduction. In general, honeycombs provide good mechanical strength and resistance to thermal shock. However, because they have low surface areas, a catalyzed carrier (washcoat) must be deposited on their channels. The most widely used monolith is made from cordierite ($2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$). Some metallic materials also are being used.

The finished catalyst is prepared by dipping the honeycomb into an aqueous slurry containing catalyzed carriers that will adhere to the walls of each channel. Excess slurry is then blown from the channels to avoid plugging. The washcoated honeycomb is then dried and calcined (300 to 600 °C, or 570 to 1110 °F) to fix the catalyzed washcoat securely to the honeycomb walls and to decompose precursor compounds (Fig. 1).

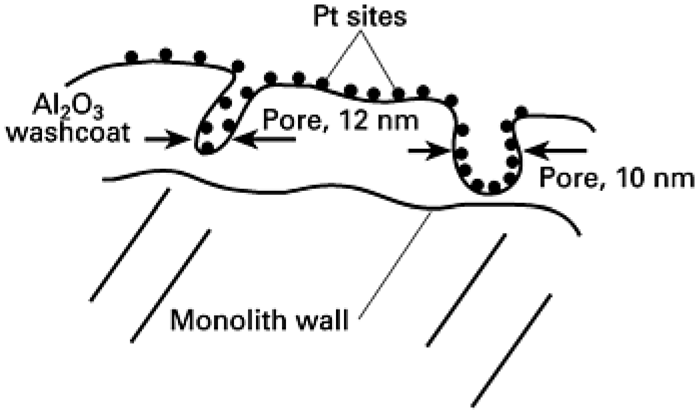

Fig. 1 Impregnated catalyst washcoated on a substrate honeycomb

The rheology of the catalyst slurry is determined by its solids content (25 to 60%), the pH, and the particle size of the catalyst (preferably, 10 to 25 μm, or 0.4 to 1 mil). Sometimes the addition of binders, such as alumina or silica sols, is required to improve adhesion onto the monolithic support. The honeycomb has some porosity, which ensures adhesion of the catalyzed washcoat.

Protective Coatings for Carbon-Carbon Composites

James R. Strife, United Technologies Research Center; James E. Sheehan, MSNW, Inc.

Introduction

CARBON-CARBON is a unique composite material in which a nonstructural carbonaceous matrix is reinforced by carbon fibers to create a heat-resistant structural material. The carbon fibers are generally employed as woven fabric in two-dimensional laminates, or as multidimensional preforms created by textile processing of multifilament tows (Ref 1, 2). Composite densification is typically accomplished using phenolic resins in a preforming process, followed by liquid impregnation, vapor phase carbon infiltration, or combinations of the two to achieve pore filling (Ref 3, 4, 5, 6, 7, 8, 9, 10). High-temperature pyrolysis is used to convert liquid impregnants to carbon while vapor phase infiltration is conducted in reduced-pressure reactors where flowing hydrocarbon gas infiltrates the composite and is thermally decomposed to deposit carbon. The result is a low-density (1.5 to 1.9 gm/cm^3) composite that derives its mechanical performance from the carbon fiber reinforcement.

Because carbon fibers tend to increase in strength with increasing temperature (Ref 11), carbon-carbon composites retain their tensile strength at extreme temperatures. Carbon-carbon composites provide unmatched specific stiffness and strength at temperatures from 1200 to 2200 °C (2192 to 3992 °F). At temperatures below 1000 °C (1832 °F), carbon-carbon composites exhibit specific strength equivalent to that of the most advanced superalloys (Ref 12). As a result of their carbon constituents and weakly bonded reinforced matrix, carbon-carbon composites also have superior thermal shock, toughness, ablation, and high-speed friction properties. These properties have led engineers to apply carbon-carbon in reentry bodies, rocket nozzles, and exit cones for strategic missiles, and in brake discs for military aircraft (Ref 8, 9, 10, 13). Recently a commercial aerospace application, brake discs for transport aircraft, has become prominent (Ref 14).

Coating technology for carbon-carbon has been driven primarily by the aerospace and defense industries, in applications where the composite is exposed to high-temperature oxidizing environments. Advanced applications include hot-section components for limited-life missile engines, exhaust components for fighter aircraft, hypersonic vehicle fuselage and wing components, and structures for space defense satellites (Ref 13). The most notable application of coated carbon-carbon is for the nose cap and wing leading edges of the Shuttle Orbiter vehicle (Ref 15, 16, 17). Over 40 successful missions have been flown, demonstrating the flight worthiness of coated carbon-carbon in reentry applications.

Fundamentals of Protecting Carbon-Carbon

Historical Development of Protecting Carbon Bodies. Many of the constituents and approaches for protecting carbon-carbon have grown from early research work aimed at protecting synthetic graphite bodies. Sixty years ago, a patent was issued to the National Carbon Co. (Ref 18) for a coating method to render carbon articles oxidation resistant at high temperatures. Coating systems composed of an inner layer of SiC and outer glazes based on B_2O_3, P_2O_5, and SiO_2 were described. This work demonstrated the utility of glassy materials as coating constituents to enhance oxidation resistance. Work on JTA graphite for reentry applications (Ref 19, 20, 21) was particularly significant. In these materials, refractory compounds containing boron, silicon, zirconium, and hafnium were used as additions to impart oxidation resistance. Oxidation resulted in formation of a borate glass coating that was protective for several hours up to 1700 °C (3092 °F). Enhancement of oxidation resistance through additions of boron to the body of carbon materials was an important contribution of this work.

The investigation by Chown and coworkers of refractory carbides for protecting graphite (Ref 22) was an important early contribution to coating technology. Their results showed that chemical vapor deposition (CVD) of SiC could provide reliable protection for long periods of time at temperatures below 1700 °C (3092 °F). Experiments with a variety of refractory carbides and boride coatings formed by reaction sintering demonstrated that protection for short times up to 2200 °C (3992 °F) could be achieved with sintered ZrC and ZrB_2 coatings.

Coatings based on the use of iridium (Ref 23, 24) were investigated in the 1960s to protect graphite up to temperatures as high as 2100 °C (3812 °F). This concept relied on the very low carbon diffusivity and oxygen permeability of iridium as a solid oxygen barrier. While some success was achieved, significant problems associated with volatile oxide formation, adherence, and the high thermal expansion of iridium limited the usefulness of this technology.

Carbon-carbon was thrust into the forefront as a high-temperature materials research topic by the requirement for a reusable, lightweight thermal protection system for the Shuttle Orbiter (Ref 25, 26, 27, 28). The oxidation-protected carbon-carbon presently used for the shuttle nose cap and wing leading edge is based on a substrate containing low-strength, low-elastic-modulus rayon precursor fibers. The coating system is composed of a SiC coating, formed by conversion of the carbon-carbon in a pack process, and an outer silicate glaze coating filled with SiC powder (Ref 25, 26, 27). The process also involves sealing cracks in the coating system with silicon ethoxide (Ref 28). The SiC conversion layer is over 1 mm (0.025 in.) thick.

Throughout the 1980s, a significant level of research activity focused on the protection of high-performance carbon-carbon that used heat-stabilized polyacrylonitrile (PAN) or pitch-based fibers. These composites have higher strength, higher elastic moduli, and lower thermal expansion coefficients than the rayon-based materials. Applications have focused on using high-performance carbon-carbon in structural-weight-critical roles requiring substrates and coatings of minimum thickness. For example, coating thicknesses normally are targeted to be 0.2 to 0.4 mm (0.005 to 0.010 in.). These physical factors, coupled with the significant increase in coating-substrate thermal mismatch stresses, have proved to be significant barriers to acceptable performance and broader use of carbon-carbon composites.

Carbon-Carbon Constituents and Microstructure. Applications requiring coatings typically use carbon fibers in laminated woven cloth or three-dimensional woven reinforcements. The fibers used are derived from rayon, PAN, or petroleum pitch and have a wide range of properties. For example, the elastic modulus along the fiber axis ranges from approximately 41.4 GPa (6 Msi) for rayon fibers to 414 GPa (60 Msi) for heat-stabilized PAN to 690 GPa (100 Msi) for pitch fibers. The axial fiber expansion coefficients become lower as the fiber modulus increases.

The characteristics of the matrix vary, depending on the method of densification. Generally, the matrix microstructure spans a range from being glasslike, with small, randomly oriented crystallites of turbostratic carbon, to having strongly oriented and highly graphitized large crystallites. Weak interfaces usually exist between the fibers and matrix, because strong covalent atomic bonding prevents the carbon constituents from sintering, even at very high temperatures. Because the mechanical properties of the matrix are substantially inferior to those of the fibers, the fibers generally control the mechanical performance and expansion characteristics of the composites. A rayon-fabric-reinforced laminated construction typically exhibits the following in-plane properties: a tensile strength of 51.7 MPa (7.5 ksi), a tensile elastic modulus of 13.8 GPa (2 Msi), and a thermal expansion coefficient of 2.4×10^{-6} $°C^{-1}$ (1.3×10^{-6} $°F^{-1}$). Laminated constructions that have high-performance fibers exhibit the following typical in-plane properties: a tensile strength of 276 MPa (40 ksi), a tensile elastic modulus of 90 GPa (13 Msi), and a thermal expansion coefficient of 1.4×10^{-6} $°C^{-1}$ (0.8×10^{-6} $°F^{-1}$).

Matrix Inhibition. Carbon begins to oxidize at measurable rates at approximately 371 °C (700 °F). Carbon-carbon composites exhibit high internal surface areas due to the porous nature of the structure (typical levels of interconnected porosity are 10 to 15%). Adding inhibitor phases to the matrix has become an important facet of an overall oxidation protection system, because inhibitors allow some control of oxidation that can occur through defects in coatings. Inhibitors can also prevent catastrophic oxidation failure due to coating spallation at high temperatures.

Additions of boron, boron compounds, and phosphorus compounds have been effective in protecting carbon bodies (Ref 29, 30, 31, 32, 33, 34) by true chemical inhibition and formation of internal and external glass layers that act as diffusion barriers. The practice of making boron additions to carbon-carbon for improved oxidation resistance was first disclosed in a 1978 patent (Ref 35). Since that time, many improvements and variations on this theme have been reported (Ref 36, 37, 38, 39, 40, 41, 42, 43, 44, 45).

Internal chemical modifications can be made either by mixing the carbonaceous and nonoxide inhibitor powders and consolidating the constituents to form the carbon body, or by impregnating the porous body with liquids that contain the inhibitors, usually in oxide form. Boron and many nonoxide boron compounds are quite refractory, so the powder mixing and carbon processing route has often been used (Ref 32, 33, 34). In composite fabrication, submicron refractory compound additives are normally carried within impregnating resins and are dispersed through the fiber tows as well as between the fabric plies.

Coating Selection Principles. The most critical component of any coating architecture is the primary oxygen barrier. The oxygen barrier prevents oxygen ingress to the underlying composite by providing a physical permeation barrier and, in some cases, by gettering oxygen in the process. The critical parameters that guide the selection of the oxygen barrier are its oxidation characteristics, thermal expansion coefficient, and inherent oxygen permeability. A material that forms an adherent, low-permeability oxide scale is preferred as an oxygen barrier because it oxidizes slowly and has the potential to self-heal. An Arrenius plot of rate constants for oxidation of refractory materials typically considered for coating applications (Ref 46, 47) is presented in Fig. 1. Scale growth as a function of time can be estimated from Fig. 1 using the relationship $x^2 = Kt$, where x is the scale thickness, K is the parabolic rate constant, and t is time in hours. The silicon-base ceramics exhibit substantially lower oxide growth kinetics than the aluminum-, hafnium-, or zirconium-base ceramics. Time and temperature of service will dictate material selection and coating thickness. However, from the standpoint of forming thin protective scales in thermal cycles with peak temperatures in the range of 1400 to 1700 °C (2552 to 3092 °F), only Si_3N_4 and SiC exhibit sufficiently low rate constants for oxide growth over extended time periods.

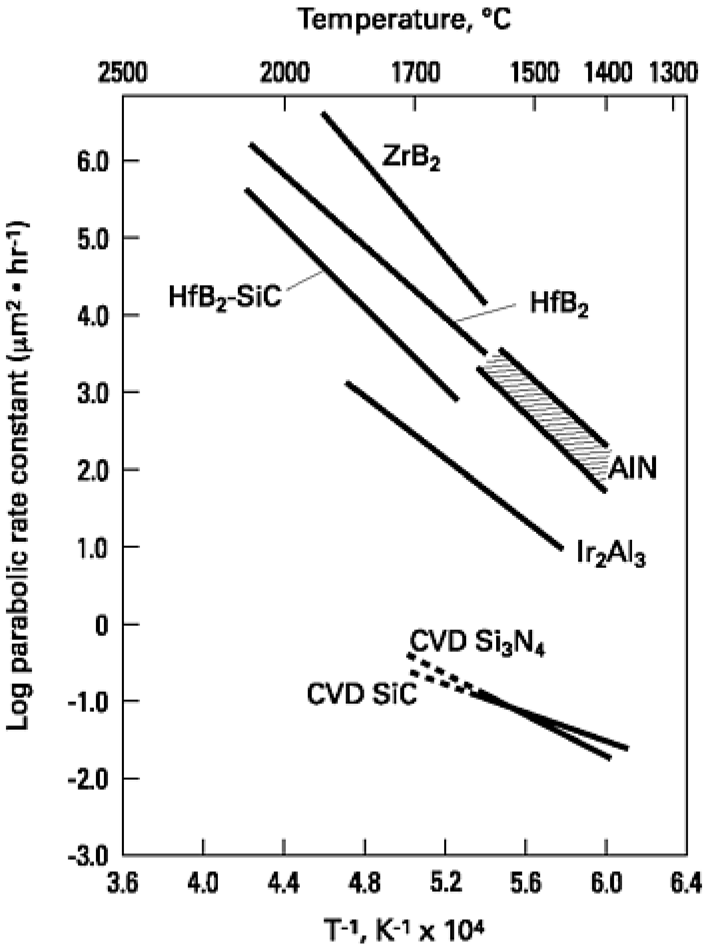

Fig. 1 Oxidation kinetics of refractory materials. CVD, chemical vapor deposition

Figure 2 compares the thermal expansion behavior of refractory coating candidates with that measured for high-performance, fabric-reinforced carbon-carbon (Ref 12, 46, 47). The expansion of carbon-carbon in the in-plane directions is substantially lower than for any of the refractory ceramics. This expansion difference, coupled with the high modulus of the refractory materials, results in significant thermal mismatch stresses when they are employed as coatings. An estimate of the thermal mismatch stresses when the coating thickness is small relative to the carbon-carbon substrate thickness can be calculated using the relationship

$$s_c = \frac{E(a_{c-}a_{s})\Delta T}{1-v}$$

where σ_c is the stress in the coating, E is the coating elastic modulus, u is the Poisson ratio of the coating, α_s is the thermal expansion coefficient of carbon-carbon, α_c is the thermal expansion coefficient of the coating, and ΔT is the difference between the deposition temperature and the selected temperature for stress calculation.

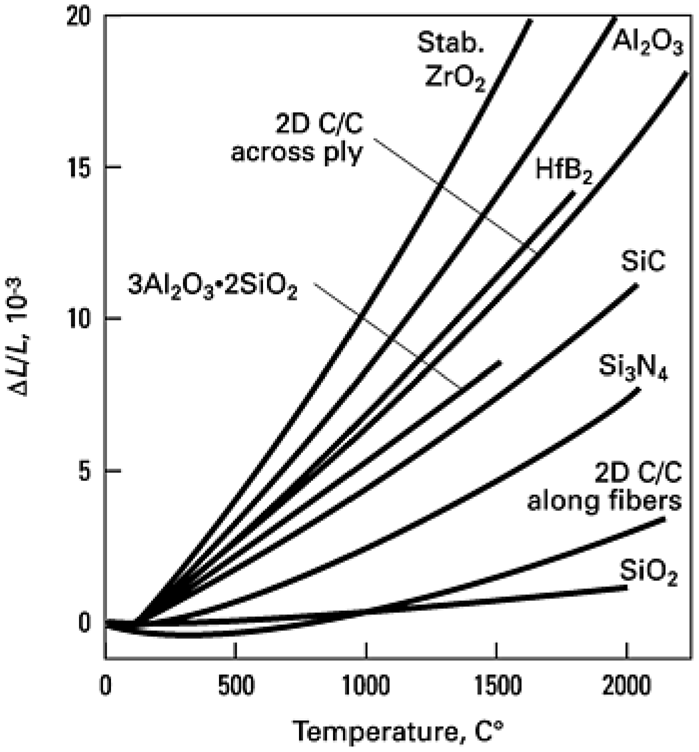

Fig. 2 Thermal expansion characteristics of ceramics and carbon-carbon laminates. C/C, carbon-carbon laminate; *L*, specimen length

The properties of refractory materials that have been used in deposition studies are summarized in Table 1. Figure 3 presents the thermal stresses calculated as a function of temperature when these coatings were deposited onto high-performance two-dimensional carbon-carbon laminates. For the refractory ceramics, silicon nitride provides the lowest thermal mismatch stresses of any of the ceramic coating candidates. These stresses are still high enough to cause cracking, however. Therefore, it is usually found that deposited ceramic coatings exhibit microcracking and that the crack pattern depends on the coating thickness and deposition temperature. Iridium metal deposited by electron-beam physical vapor deposition techniques can have low thermal mismatch stresses upon cooling. However, such a coating must then be able to withstand extremely high compressive stresses upon heating. In previously reported work (Ref 47), it has been shown that iridium-base coatings deposited by this technique onto high-performance carbon-carbon fail by compressive spalling at elevated temperatures.

Table 1 Properties of refractory materials deposited on carbon-carbon composites

Materials	Deposition process	Deposition temperature, °C	Bulk properties		
			Modulus Msi	Poisson's ratio	CTE (20-1900 °C), ppm/°C
SiC	CVD	1050	65	0.19	5.2
TiC	CVD	1000	65	0.19	9.5

AlN	CVD	1250	50	0.3	6.1
Si_3N_4	CVD	1420	46	0.3	3.6
Ir	Sputtering	250	76	0.3	7.9
HfO_2	EBPVD	1000	20	0.25	10.6

Preferred Coating Approaches

Coating approaches are dictated by both application requirements and fundamental behavior. Generally speaking, SiC-base and Si_3N_4-base coatings have found broad use at temperatures below 1700 °C (3092 °F) because of minimum thermal mismatch stresses and low oxide-scale growth kinetics. In the higher temperature range, 1700 to 2200 °C (3092 to 3992 °F), refractory carbides and borides have been used for short time periods. Coating deposition techniques that have been used include pack cementation, CVD, and slurry processes. Coating architectures are normally built using combinations of these techniques. In the following sections, typical coating architectures are discussed in accordance with the process used to deposit the primary oxygen barrier.

Pack Cementation. The coating system used on the Shuttle Orbiter vehicle is the preeminent example of the use of a pack process to create an oxidation protection system for carbon-carbon (Ref 17). In this process, the carbon-carbon part is packed in a retort with a dry pack mixture of alumina, silicon, and silicon carbide. The retort is placed in a furnace, and under argon atmosphere a stepped time-temperature cycle is used to activate conversion of the carbon-carbon surface to SiC. Peak process temperature is approximately 1760 °C (3200 °F). This creates a porous SiC surface nominally 1.0 to 1.5 mm in thickness. Multiple impregnation and curing with an acid-activated tetraethoxysilicate liquid produces SiO_2 coating of the porous surfaces. A surface sealant consisting of a mixture of a commercial alkali silicate bonding liquid filled with SiC powder is then applied.

This system was designed to provide protection during multiple reentry cycles where surface temperatures of 1538 °C (2800 °F) are anticipated. The success of the shuttle missions and further testing (Ref 15, 16, 17) has proven this to be an effective approach for low-performance rayon-based composites. Attempts to use similar coatings modified with boron (Ref 48, 49) for other aerospace applications requiring high-performance carbon-carbon have met with only limited success.

Chemical Vapor Deposition. Attempts to expand carbon-carbon use to turbine engine hot-section and exhaust components fostered the need for protective coatings that could be applied as thin layers over the structural components without compromising mechanical performance. The coating architectures developed have been dependent on the application lifetime as well as on dynamic or static structural requirements. The CVD coatings are normally applied in multiple cycles to ensure even deposition rates over curved surfaces. A substrate pretreatment is normally used to enhance adherence. Silicon nitride overlay coatings have been shown to be effective for limited-life (<20 h) cycles where heating above the deposition temperature occurs rapidly and peak temperatures reach 1760 °C (3200 °F) (Ref 46, 47, 50). These coatings have employed a thin reaction layer of SiC (formed in a pack process, of the order of 5 μm) to serve as a reaction barrier and to enhance adherence. The Si_3N_4 has been applied in thicknesses ranging from 125 to 250 μm (0.005 to 0.010 in.) in a multiple-step CVD process.

Other applications require that carbon-carbon withstand hundreds of hours of exposure to peak temperatures in the range of 1400 to 1500 °C (2552 to 2732 °F) and undergo thermal cycling to temperatures in the range of 600 to 1200 °C (1112 to 2192 °F). In these extended-life applications, a boron-rich inner layer is used to provide a source of glassy phase to seal microcracks in the outer coatings. Elemental boron, boron carbide, and combinations of boron compounds mixed with silicon carbide or silicon are inner layer approaches. These layers are deposited in thicknesses normally in the range of 25 to 50 μm (0.001 to 0.002 in.) using CVD, conversion of the carbon surface, and slurry coating (Ref 51, 52, 53). Depositing SiC or Si_3N_4 by CVD is the preferred method to provide hard, erosion-resistant surfaces that cover the boronated inner layers and inhibit vaporization of borate glass sealants (Ref 54, 55). Overlay thicknesses in the range of 200 to 300 μm (0.008 to 0.012 in.) are normally deposited in a multiple-step process. A typical coating architecture on an inhibited composite is shown schematically in Fig. 4.

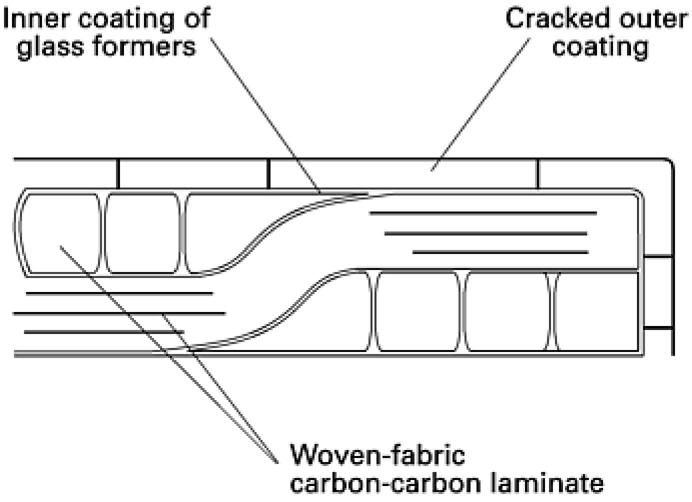

Fig. 4 Schematic of coating architecture used to protect carbon-carbon for extended-life applications

Silicate glazes are frequently applied to fill the microcrack network existing in SiC and Si_3N_4 coatings. Although the glaze is applied externally and is susceptible to vaporization and physical removal, it has been shown to improve cyclic oxidation lifetimes. Glaze overcoats are normally applied as aqueous sols incorporating boron and silicon that can be painted, sprayed, or dip coated. Typical processing involves air drying and firing above 1038 °C (1900 °F) in an argon atmosphere (Ref 54). The glaze can be periodically replenished.

Slurry coatings are produced by dispersing appropriate ceramic or metal powders in a liquid vehicle to make the slurry, applying the slurry as a paint to the component surface, evaporating or gelling the liquid to harden the coating, and then heating to a high temperature to stabilize and densify the coating. Slurries are applied by brushing, spraying, or dipping. The liquids can be water or volatile organics with organic binders in solution, inorganic or organic sols or solutions that form oxides, or thermosetting preceramic polymers or polymer solutions (Ref 56, 57).

Hardening produces a coating that is composed of the powder particles bound together and bonded to the substrate by the solid that is precipitated or condensed from the liquid. Heating to a high temperature decomposes the binder phase to form carbon or a ceramic. The shrinkage associated with binder decomposition and incomplete solid state sintering of the powder particles will result in a cracked, porous, and often weakly bonded coating unless a flowable and wetting liquid is formed by one of the constituents. This can be a glass, molten metal, or ceramic melt.

Coatings meant to provide oxidation protection for graphite and carbon-carbon composite articles at temperatures below 1000 °C (1832 °F) often contain large amounts of boron in the form of elemental boron, B_4C, BN, metal borides, or B_2O_3 (Ref 58, 59). Employing B_2O_3 glass provides a wetting liquid at low temperatures on initial heating, and the nonoxides rapidly oxidize in use to produce the same result. Coatings composed mostly of refractory oxide particles bound together with small amounts of borate glass have shown utility at temperatures in the range of 1200 to 1500 °C (2192 to 2732 °F) in configurations where evaporation of the B_2O_3 is inhibited (Ref 38). In making such coatings the boron can be present in the powder constituents, the liquid vehicle, or both. Water or alcohol solutions of boric acid and liquid boron alkoxides are often used (Ref 38, 44). Solutions of preceramic boron polymers are also a possibility (Ref 60, 61).

Slurry coatings meant for higher temperatures, in which borates are replaced by glassy alkali silicates or aluminum phosphate, are prominent (Ref 28, 48). The use of siloxane fluids as preceramic polymers has also been disclosed (Ref 62). Converting the carbon surface to SiC is often recommended as a pretreatment to ensure the adherence of glassy borate, silicate, and phosphate coatings (Ref 28, 48).

The bonding and densification of slurry coatings with molten metal and melted ceramic phases has been used to produce protective layers with intermediate to very high temperature capabilities. Dense, very adherent coatings capable of extreme-temperature service can be made from paints containing fine refractory boride particles (Ref 22). The coatings are fully stabilized by heating the borides in contact with the carbon surface to temperatures over 2000 °C (3632 °F) in an inert environment to form a boride-carbon eutectic liquid. Coatings made by melting certain combinations of metal powders and reacting these with the carbon surface to form refractory carbides (Ref 63) are protective to 1800 °C (3272 °F). Recent work of this type (Ref 64) using a mixture of silicon, hafnium, and chromium powders reacted with the carbon surface at 1450 °C (2642 °F) has produced carbide coatings that provide excellent oxidation protection for short times at 1200 °C (2192 °F).

Practical Limitations of Coatings

As mentioned above, carbon-carbon composites can be used as structural materials to at least 2200 °C (3992 °F). At the time of this writing, viable coating concepts to match this capability have not been consistently demonstrated, especially for times greater than a few hours. SiC and Si_3N_4 are limited thermodynamically to temperatures of approximately 1800 to 1815 °C (3272 to 3300 °F). At higher temperatures, the SiO_2 layers that form and protect these materials are disrupted by CO and N_2 interfacial pressures that become greater than 10^{-1} MPa (1 atm), causing the coatings to erode by uncontrolled oxidation (Ref 12, 47). Use of more refractory materials such as HfC or HfB_2 is limited by the very rapid oxidation rates pointed out in Fig. 1. Rapid conversion of these films to high-expansion oxides leads to severe spallation in thermal cycles. Thus, above approximately 1760 °C (3200 °F), coating lifetimes are currently limited to a few hours.

For the range of applications where coating architectures incorporating borate sealant glasses are used, coating use temperatures are limited to approximately 1500 to 1550 °C (2732 to 2822 °F). When B_2O_3 contacts carbon at atmospheric pressure, the CO reaction product pressure will exceed 10^{-1} MPa (1 atm) at approximately 1575 °C (2867 °F). Borate glasses also cause dissolution of the protective SiO_2 scale forming on SiC or Si_3N_4, leading to more rapid corrosion because of the high oxygen permeability of the mixed glass. Experience in test cycles with peak temperatures about 1400 °C (2552 °F) has shown that accelerated dissolution of coatings along microcrack boundaries eventually causes gross oxidation of boron-base inner layers, leading to massive dissolution of the silicon-base overlays.

Moisture sensitivity of borate glasses (Ref 65) can be a major limitation. Hydrolysis at low temperatures in moist air converts adherent B_2O_3-containing layers into loosely bonded boric acid particulate. Under long-term exposure, sealant glasses forming beneath the hard overlays undergo moisture attack that leads to spallation. Subsequent heating cycles that rapidly release moisture can cause catastrophic failure. Finally, high-temperature exposure to moist environments makes borate glass susceptible to vaporization by the formation of HBO_2 (Ref 44).

Plasma Surface Engineering of Plastics

Om S. Kolluri, AIRCO Coating Technology

Introduction

THE NATURE of the surface of the materials used in a product increasingly determines its success in almost every industry. This is true whether one is dealing with surface cleanliness, bonding of different components, biocompatibility, or mechanical performance of the part under conditions of use. Designers must often select specially formulated and expensive polymeric materials to ensure satisfactory performance, even though these materials often require surface preparation. In some cases, entire design concepts must be abandoned due to the prohibitive cost of the required polymer or the inability of available materials to deliver the desired performance attribute. The alternative to this scenario is to choose the material for its bulk properties and modify the surface of the material to achieve the desired performance attributes. In most cases the final step in the process is the application of a coating that offers the desired performance.

Conventional Methods. Historically, surface engineering methods have included mechanical abrasion, solvent wiping to remove surface contamination, solvent swelling, wet chemical etching, and the application of specialized coatings. Application of functional coatings has invariably required surface preparation to achieve an adequate bond between the substrate surface and the coating of choice. Each of these surface engineering methods has limitations, thus providing a strong driving force for the development of alternative surface preparation methods. Many of the common methods mentioned are accompanied by safety and environmental risks, increased risk of part damage, and expensive pollution and disposal problems.

Abrasion only increases the surface area of the part prior to adhesive bonding, and it is thus of limited utility. It often does not reach hidden areas of complex part geometries, and it is operator sensitive, dirty, and difficult to do on small or delicate parts.

Solvent cleaning is useful for removing gross contamination. In ultraclean applications, solvent cleaning merely replaces one contaminant with another. Solvent surface treatment is beneficial in cases where swelling of the polymer substrate can improve adhesion of coatings without adversely affecting the mechanical properties of the substrate. The equipment required is inexpensive, and the process works reasonably well in many cases. The major drawbacks of this technology are the environmental and process hazards associated with the use of large quantities of chemicals. Any savings in equipment cost is usually offset by the increased cost of environmental controls. Solvent-based surface treatment has limited utility when a distinct change in the chemical nature of the substrate surface is desired.

Acid etching is more effective than solvent-based methods, but it can easily result in overtreated and damaged parts, in addition to serious hazard and disposal problems. For example, other than plasma treatment, the most effective method for improving the bonding of materials to fluoropolymers has been to etch the surface with a material commonly referred to as *sodium etch.* The process consists of brief immersion of the component to be bonded in a solution of sodium naphthalene in tetrahydrofuran or another suitable solvent. Although sodium etch is quite effective in treating fluoropolymers, concerns with operator safety and the problems of disposal have caused many users to seek alternatives.

Energetic Processes. Flame, ultraviolet (UV), and corona surface treatment have often been suggested as alternatives to wet chemical methods. Of these three methods, flame treatment and corona surface treatment have been adopted on a larger scale. In flame treatment, the surface to be modified is passed through a flame generated by combustion of hydrocarbon gases. In the case of corona treatment, the surface to be modified is exposed to a point discharge across a pair of electrodes. The discharge acts to ionize the gas present in the gap, which subsequently introduces changes in the chemistry of the surface. Flame and corona, although useful in oxidizing the surfaces of plastics, have limited utility in many applications. In addition, the transitory nature of these modifications prevents their widespread use in many applications.

Limitations. Corona treatment is limited by the materials and part configurations that are responsive to this method of surface preparation. Complex shapes cannot easily be treated, because the treatment quality is a function of the distance of the part from the electrode. Thus, small-diameter holes and surfaces that are difficult to access in complex parts prove particularly troublesome. The result is an uneven surface treatment at best. Because corona discharge surface treatments are typically conducted in ambient air, the process is subject to change from day to day as the environment changes in the location where such treatment is being conducted. Finally, the high-voltage discharge often results in thermal damage to sensitive materials such as thin-wall plastics and film.

Flame treatment suffers from many of the limitations of corona treatment: difficulty in reaching recessed areas and evenly treating complex shapes. Thermal damage from overtreatment is another common problem with flame treatment.

Cold gas plasma technology is rapidly becoming the preferred industrial process for many applications requiring surface chemical modification. Plasma surface treatment, which is conducted in a vacuum environment, affords a wide latitude of possibilities in chemically changing the surface of a plastic to suit a particular application. Three mechanisms contribute to improvement in the adhesion of two components and the adhesion of coatings:

- Removal of surface contaminants and weakly bound polymer layers
- Enhancement of wettability through incorporation of polar groups that facilitate spontaneous spreading of adhesive or matrix resin
- Formation of functional groups on the surface that permit covalent bonding

When specialized surface characteristics are desired, coatings with unique chemical and physical characteristics can be deposited by plasma polymerization. Examples include antiscratch or antifog coatings, lubricious coatings, biocompatible coatings, and chemical and vapor barrier coatings. Because plasma treatment is a process of surface modification, the bulk properties of the material are retained. The nature of the process also allows precise control of the process parameters and ensures repeatability of the process in industrial applications. Finally, several studies have demonstrated that these surface modifications can be achieved with minimal impact on the environment.

Plasma Processing Equipment

Most, if not all, plasma equipment consists of similar components, but the design of the reactor chamber, the distribution of power, the excitation frequency, and the gas dynamics can all be critical parameters influencing the efficiency and properties of plasma reactions. An extensive amount of work has been published that shows a direct correlation between excitation frequency and plasma reactivity. Manufacturers of plasma equipment employing radio-frequency (RF) excitation use either low frequencies (i.e., less than 400 kHz) or the higher frequencies 13.56 or 27.12 MHz as specified by the Federal Communications Commission. For applications involving the treatment of plastics, 13.56 MHz is the preferred frequency.

Also important is whether the material being treated is in a primary or a secondary plasma. Older equipment using large cylindrical barrels typically comprises secondary plasma systems (Fig. 1a). The plasma is created either between closely spaced, paired electrodes, which may function as shelves, or in the annulus between the outer wall of the vessel and a ring electrode, when employed. Treatment of materials placed within the working volume depends on the diffusion of active species created in the primary plasma (i.e., within the RF field). Diffusion of these active species is very dependent on pressure; the higher the pressure, the shorter the mean free path. The mean free path is the distance that active species can probably travel before undergoing collisions that deactivate radicals or neutralize ions. Therefore, when using a secondary plasma, the concentration of active species varies either across the diameter of a barrel system or between electrode pairs, as the case may be. Thus, by the physical laws of nature, the treatment within the working volume of a secondary plasma system cannot be uniform.

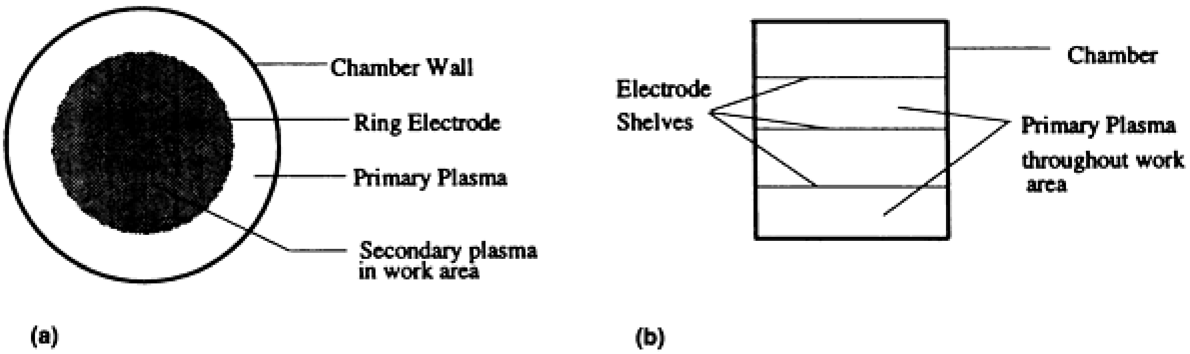

Fig. 1 Schematic of plasma processing equipment. (a) Barrel-type reactor, typical of secondary plasma systems. (b) Primary plasma reactor

By contrast, when working within the RF field, or primary plasma, the gas is constantly being excited. Thus, polymeric articles being treated are immersed in a constant concentration of active species. Further, because diffusion is not a mechanistic limitation, significantly higher operating pressures may be used. This allows a higher process gas flow rate, ensuring that out-gassing species from the polymer are sufficiently dilute, providing the full benefits of the desired process gas. In addition, the primary plasma is rich in UV radiation, which is often an important initiation step in polymer reactions. Ultraviolet radiation is line of sight, so uniform treatment of multiple parts can be obtained only when working within the primary plasma. Otherwise, any part in the shadow of another will receive different radiation, and therefore the effectiveness of the treatment will vary.

The types of reactors used for the deposition of plasma polymers have been varied. Glass and/or quartz reactors or aluminum chambers with metal parallel-plate electrodes seem to predominate in the literature, although several investigators have used inductively or capacitively coupled systems with external electrodes. High rates of deposition are found in the glow area, with the rate of deposition decreasing as one moves farther away from the glow discharge region. Consequently, primary plasma systems that use a 13.56 MHz RF source are favored. The RF excitation used by various equipment manufacturers can be as low as 2 to 4 kHz, or it can be the more typical 13.56 MHz (high frequency). Microwave plasma systems have also been used for the deposition of plasma polymers. Previous studies have shown that the densities of films deposited by low-frequency systems are significantly lower than those of films deposited by either the high-frequency or microwave plasma systems. The choice of equipment used for plasma polymerization and deposition is thus dictated by the rate of deposition desired, the film properties that can be obtained by the various systems, and practical considerations such as the size of the parts to be treated and the processing rates that are feasible in any given system.

Plasma Technology

Overview of Plasma Treatment

There are many definitions of the term *plasma,* according to the various disciplines with which it is involved. It has often been referred to as "the fourth state of matter," the generation of plasma being analogous to the transitions that occur when energy supplied to a material causes solids to melt and liquids to become gases. Sufficient additional energy supplied to a gas creates a plasma. In the case of cold gas plasma, typical of that used in this work, the process is excitation of a gas at reduced pressure by RF energy. Typically, a plasma is composed of a large concentration of highly excited atomic, molecular, ionic, and radical species. On an atomic scale, plasma generation cannot be construed as a room-temperature equilibrium process, because the bulk of the material remains near room temperature. The plasma contains free electrons as well as other metastable particles that break covalent chemical bonds upon collision with the surfaces of polymers placed in the plasma environment, thus creating free radicals on the polymer surface (Ref 1). The free radicals then undergo additional reactions, depending on the gases present in the plasma or subsequent exposure to gases in the atmosphere. The result is that these gas radical reactions form a surface that is potentially very different from that of the starting bulk polymer. Because the process is conducted in a reactor under very controlled conditions, the end result is very reproducible.

Plasma processing is not one process, but rather a "field of opportunities" that can be classified into three overlapping categories: plasma surface modification, plasma-induced grafting, and plasma film deposition. These processes are described in more detail in the section "Plasma Processes" in this article.

Plasma surface modification (plasma activation) is the alteration of surface characteristics by the substitution of chemical groups or moieties for groups normally present on the polymer chain being modified. The assumed mechanism is free-radical creation and coupling of these free radicals with active species from the plasma environment. Depending on the process gas selected, a large variety of chemical groups can be incorporated into the surface: hydroxyl, carbonyl, carboxylic, amino, or peroxyl groups. Most important, the insertion or substitution of these groups in the polymer chain is under the control of the operator. In this manner, the surface energies and the surface chemical reactivity of plastics can be altered completely without affecting their bulk properties.

Plasma-induced grafting is another method by which plastic surfaces can be modified. If a noble gas is employed to generate a plasma, a multitude of free radicals are created along the polymer backbone. If an unsaturated monomer such as allyl alcohol is introduced into the reaction chamber after the plasma is extinguished, but prior to the introduction of air, it will add to the free radical, yielding a grafted polymer. The range of functional and reactive sites that can be incorporated onto a surface is increased significantly with this technique. This process differs from activation in that instead of functional modification of the surface polymer chains, material is added to the polymer backbone.

Plasma film deposition (plasma polymerization) uses gases or vapors that fractionate and undergo polymerization under the influence of RF energy. For example, methane (CH_4) under the influence of plasma will deposit as a polyhydrocarbon that has a density approaching 1.6 g/cm^3. Any material that can be introduced into the process chamber is a potential candidate as a feed material for plasma polymerization. The properties of materials polymerized in this manner are very different from those of polymers obtained via conventional polymerization methods. These properties include a high degree of cross-linking and the ability to form pinhole-free films that adhere tenaciously to various substrates.

Plasma Process Applications

The particular plasma process used in a given application is dictated by the desired end result. For example, when contamination removal is the primary goal, the process of choice is plasma surface modification. When the goal is to improve the adhesion of two materials, the most commonly used process is surface modification, with plasma-induced grafting offering an attractive alternative. The particular process used is application-specific rather than industry-specific. For example, cleaning processes are used in many industries, such as aerospace, electronics, packaging, and medical products.

All plasma processes have a common thread in that the surface change is accomplished by an ionized gas. As a result of this common basis, it is easy to accomplish several objectives in a single system. For example, surface cleaning and the application of protective coatings is always accomplished in a single reactor with a multiple-step process, instead of using two separate process areas as is common with conventional technology.

Figure 2 illustrates the components of a typical plasma surface treatment system. As described above, the chamber is evacuated to a specified pressure using a mechanical vacuum pump, and gas is introduced into the chamber through flowmeters. During normal operation, gas is continuously introduced into the chamber, and the unreacted species and byproducts are continuously evacuated. The chamber thus operates in a steady state. Application of RF energy to the electrodes ionizes the gas in the reactor. A capacitance matching network tunes the chamber impedance to a constant load.

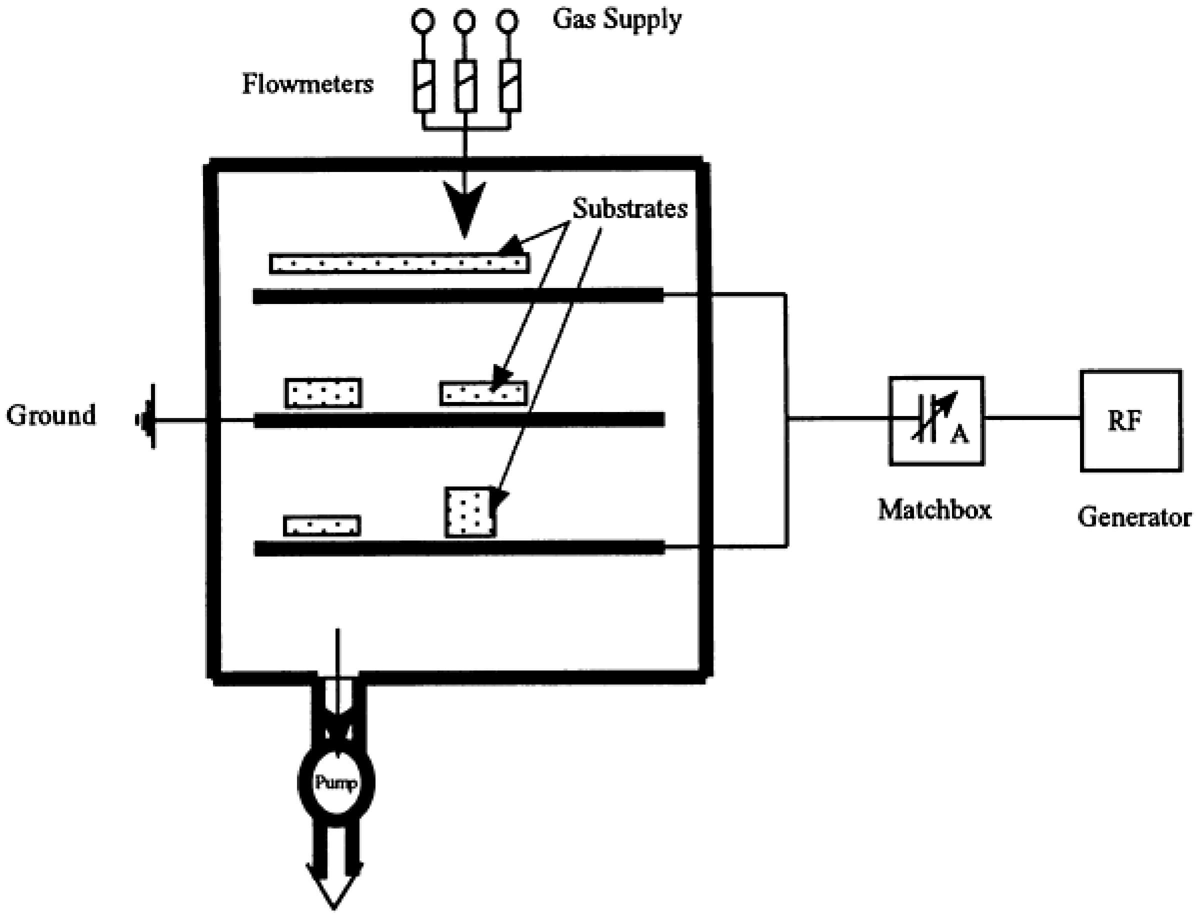

Fig. 2 Typical plasma surface treatment system

All commercial reactor systems consist of similar components, but there are variations in design parameters, such as power coupling efficiency and the gas-handling capacity of the vacuum pump. For this reason, it is difficult to translate process conditions from one system design to another. Nonetheless, Table 1 shows suggested starting process conditions for various materials and adhesive systems.

Table 1 Typical plasma surface treatment conditions

Substrate	Adhesive system/ paint system	Process gas	Operating pressure, torr	Radio-frequency power,W	Process time, min
Polypropylene	Urethane	Oxygen	0.400	200	1.0
Nylon	Epoxy	Ammonia	0.200	400	3.0
Polyphenylenesulfide	Epoxy	Nitrous oxide	0.150	300	0.5
Polytetrafluoroethylene	Epoxy	Ammonia	0.100	550	1.5
Polyethylene	Epoxy	O_2/CF_4	0.200	300	1.5

Adhesion performance for a specific system can be optimized by designing experiments in which the RF power, gas, process pressure, and process time are varied. In the case of plasma-induced grafting and plasma polymerization, process conditions are highly dependent on reactor geometry and reactor design. The experimenter should refer to appropriate references for guidance about starting process conditions.

Plasma Discharge Reactions and Surface Interactions

Although any gas can be ionized using RF excitation, a gas such as O_2, N_2, He, Ar, NH_3, N_2O, CO_2, CF_4, and air, or some combination of these gases, is commonly used in most plasma processes. One of the more commonly used plasma processes is surface treatment in an oxygen plasma, which is aggressive in its reactivity and forms numerous components. Within an oxygen plasma O^+, O^-, O_2^+, O_2^-, O, O_3, ionized ozone, metastably excited O_2, and free electrons are generally observed. The ionization of oxygen into the various species found in an oxygen plasma can be represented by the following reaction scheme:

$$
\begin{aligned}
&O_2 + e \rightarrow O_2^- \rightarrow O + O^- \\
&e + O \rightarrow O^+ + 2e \\
&e + O_2 \rightarrow O_2^+ + 2e \\
&e + 2O_2 \rightarrow O_2^- + O_2^- + O \rightarrow O_3 + e
\end{aligned}
$$

These reactions represent a small sampling of those that occur in an oxygen glow discharge. As the components formed during the ionization recombine, they release energy and photons, emitting a faint blue glow and much UV radiation. The photons in the UV region have enough energy to break the carbon-carbon and carbon-hydrogen bonds in the materials on the surface that are exposed to the plasma. In the case of contaminants, the net effect appears to be degradative, such that lower-molecular-weight materials are created. These materials are subsequently removed by the vacuum, and in this manner the surface that has been exposed to a plasma is cleaned. Lower-molecular-weight polymer fractions that comprise the weak boundary layers on the surface are also removed in this manner.

Once the contaminants have been removed, the virgin polymer surface is exposed to the plasma environment. The electrons, ions, and free radicals in the plasma act on this exposed polymer, creating free radicals in the molecular chains on the surface (Ref 1, 2, 3). The free radicals that are created on the polymer surface by this process can then react with the various molecular and active species present in the plasma environment. In a low-pressure oxygen plasma, the following oxidation reaction scheme has been suggested:

$$
\begin{aligned}
&RH + O\bullet \rightarrow R\bullet + \bullet OH \\
&R\bullet + O_2 \rightarrow RO_2. \\
&RO_2. + R'\,H \rightarrow RO_2H + R'\bullet \\
&RO_2\bullet + R'\bullet \rightarrow RO_2R'
\end{aligned}
$$

Here RO_2H and RO_2R' indicate the formation of acids and esters. Not indicated in the above reaction scheme are the possible formation of alcohols, ethers, peroxides, and hydroperoxides.

Thus, besides the reactions resulting from the bombardment of the surface by photons, ions, and neutral particles, all of the active species in the plasma react with the polymer surface. The byproducts that consist of CO_2, H_2O, and low-molecular-weight hydrocarbons are readily removed by the vacuum system. The use of co-reactants can modify the surface chemistry obtained with a single gas chemistry or accelerate the reaction kinetics. For example, in an oxygen plasma, the breaking of the carbon-carbon and carbon-hydrogen bonds is the rate-limiting step. When tetrafluoromethane is introduced as co-reactant, the O_2-CF_4 plasma yields excited forms of O, OF, CO, CF_3, CO_2, and F. Fluorine or fluorine-containing species are more effective in breaking the carbon-carbon and carbon-hydrogen bonds, so the reaction rate is accelerated. These examples illustrate how plasma technology can be used as a "limitless box" to accomplish the desired surface engineering objectives.

Contamination Removal

Vapor degreasing or sonication in organic solvents is the most common form of contaminant removal. However, the Montreal protocol on ozone-depleting chemicals has mandated the replacement of chlorofluorocarbon-based cleaning solutions, and use of many of the traditional solvents is also being restricted due to environmental concerns. The alternatives, including water-based systems, have proven to be less effective than expected. Plasma cleaning is now being looked upon as an effective alternative and is beginning to find increasing use (Ref 4, 5, 6, 7, 8).

Ablation is the key process by which contaminants are removed from the surface of materials placed in a plasma (see the description in the previous section about how carbon-carbon and carbon-hydrogen bonds are broken). The choice of gas used for cleaning applications depends on both the contaminant and the substrate to be cleaned. Contaminants that are difficult to remove, such as silicone oils, require aggressive chemistries containing tetrafluoromethane or sulfuroushexafluoride. When delicate materials are to be cleaned, a less aggressive chemistry such as that offered by the noble gases, argon or helium, is commonly used.

Plasma Surface Modification (Plasma Activation)

Plasma treatment using commonly available gases (air, oxygen, nitrogen, and the others described above) is often referred to as *plasma surface modification.* The distinguishing factor is the absence of reactive gases, such as unsaturated hydrocarbons or saturated hydrocarbons, or any other materials that would result in the deposition of a film on the substrate. In many industries, surface chemical interactions play a central role in the functional performance of the product. For example, the interaction between the surface and a specialized coating is important in the successful performance of the coating. Another example is that in the biomedical industry, one encounters interactions between the surface and proteins or chemical reagents in applications involving cell culture or diagnostic devices (Ref 9, 10, 11, 12). A similar phenomenon exists in adhesive bonding when two dissimilar surfaces are joined. Adhesive bonding represents a large percentage of the applications requiring surface modification, so it will be used to illustrate this process, but the basic principles are equally valid for other applications.

The strength of an adhesive joint is influenced by several factors (Ref 13, 14, 15). Removal of contaminants and process aids provides a means for the adhesive to interlock with the substrate surface rather than with a boundary layer that is merely resting on the surface. In addition, increasing the surface energy of the substrate above the surface tension of the adhesive makes it possible for the adhesive to wet the entire surface of the polymer substrate. The increase in the apparent surface area of contact increases the strength of the adhesive bond (Fig. 3).

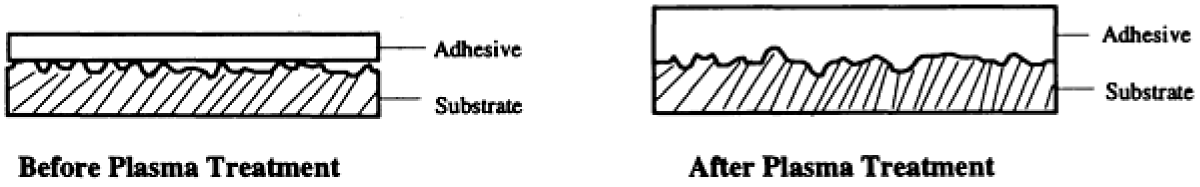

Fig. 3 Schematic of ablation, or microroughening, of the surface layer of a polymer substrate by plasma surface modification. Microroughening increases the area of contact between an adhesive and a substrate to strengthen the bond.

Ablation of the surface layers of the exposed polymer can result in a microroughened surface that increases the area of contact between the adhesive and the substrate. Adhesion strength is further enhanced by modification of the surface chemistry in a manner that facilitates covalent bonding between the adhesive and the substrate surface. These changes are accomplished by competing molecular reactions that take place on the surface of a polymer substrate in a plasma. Ablation of the surface layers of the polymer can also take place in a plasma and occur through a similar mechanism. If the substrate consists of a blend or alloy of materials that react differently in a plasma, differential ablation of these components can be used to create a microroughened surface.

Substitution of atoms in the polymer molecule with chemical groups from the plasma is often referred to as *activation.* The surface energy of the polymer placed in a plasma can be increased very rapidly by plasma-induced oxidation, nitration, hydrolization, or amination. The higher surface energy of the polymer surface increases its wettability, which describes the ability of a liquid to spread over and penetrate the surface. The resulting increase in apparent bonded surface area increases the strength of the bond. The process of activation can also be used to replace surface polymer groups with those that facilitate covalent bonding between the polymer substrate and the adhesive.

The use of plasma surface treatment to improve adhesion is well known (Ref 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30), and several literature sources provide an in-depth discussion of the nature of gas plasmas and their chemistries (Ref 1, 16, 18, 21, 22, 23). The gases most commonly employed for surface modification are O_2, N_2, He, Ar, NH_3, N_2O, CO_2, CF_4, and air or some combination of these gases. The first step of the process is contaminant removal by chain scission, and several reports documenting the efficacy of plasma surface cleaning in improving adhesion have been published (Ref 1, 24, 26). Once the contaminants have been removed, the virgin polymer surface is exposed to the plasma environment. The electrons, ions, and free radicals in the plasma act on this exposed polymer, creating free radicals in the molecular chains on the surface (Ref 1, 2, 3). The free radicals that are created on the polymer surface by this process can then react with the various molecular and active species present in the plasma environment.

The permanent nature of these changes on the polymer surface have been confirmed by spectroscopy and documented in several studies (Ref 31, 32, 33, 34). The use of other gases permits the incorporation of other functional groups on the polymer surface. Examples include the use of ammonia, nitrogen, and oxides of nitrogen plasmas that are used to incorporate nitrogen in the surface and create nitrogen-base functional groups such as primary and secondary amines (Ref 35, 36).

One result of modification of the polymer surface is an increase in the surface energy of the polymer and an attendant improvement in surface wetting. As stated above, adequate wetting of the surface by the adhesive contributes to the improvement in bond strength by increasing the apparent area of contact over which the load is distributed. Published studies suggest that this improvement in wetting contributes directly to the observed improvement in the strength of the adhesive bond (Ref 37, 38, 39). As stated above (Fig. 3), another factor that contributes to improved adhesion is an increase in surface area of the polymer surface through microroughening (ablation of the polymer surface through exposure to a plasma). This is particularly the case when the plasma is highly reactive, as when oxygen is used as one of the gas components that is being ionized. The nature of the gas being ionized to create the plasma is not the only factor that determines the extent of ablative etching; the nature of the polymer that is exposed to the plasma also plays a key role. Studies have shown that etching through ablation of surface polymer layers does occur in polymers such as polyethylene, polyethylene terephthalate, and nylon 66 (Ref 22, 40), whereas polyaramid materials such as Kevlar appear to be resistant to microroughening through ablation of the polymer chains (Ref 41).

Evidence presented in several studies indicates that the strength of the adhesive bond depends on the particular functional group that has been created on the surface of the polymer. Some of these studies draw a direct correlation between the nature of the chemical groups on the surface, the nature of the adhesive used, and the observed improvement in adhesion (Ref 22, 39, 42). Other studies relate the improvements to effects of hydrogen bonding and specific surface chemical interactions that do not necessarily result in covalent bonding between the polymer surface and the adhesive (Ref 43). Sometimes it is left to the reader to deduce the conclusions from the adhesion data presented, along with data describing the nature of the surface chemistry (Ref 44, 45).

As these examples illustrate, the selection of the process gas determines how the plasma will alter the polymer. Very aggressive plasmas can be created from relatively benign gases. Oxidation by fluorine free radicals that are generated when tetrafluoromethane is included as one of the gases is as effective as oxidation by the strongest mineral acid solution. The primary difference is that the byproducts of the plasma process do not require special handling, because the active species recombine to their original stable and nonreactive form outside the RF field. In all cases, profound and permanent changes in the chemical nature of the polymer surface are implemented. The stability of these surface changes is a function of the materials themselves and the storage conditions used (Ref 46). For instance, plasticizers that can migrate to the surface, or contaminants in the storage area that can be attracted to these high-energy surfaces, will negate the effects of the chemical changes that have been created on the surface of these materials. Contact angle measurements and electron spectroscopy of plasma-treated surfaces have confirmed the permanent nature of plasma surface modification of polymers. For example, plasma-modified fluorinated ethylene propylene (FEP) was shown to retain its surface chemical characteristics over an 18-month observation period (Ref 47). Similar phenomena have been observed by other investigators for other materials, such as polyethylene and polystyrene (Ref 48). These changes ultimately lead to significant improvements in adhesion strength, as Table 2 suggests.

Table 2 Lap shear strength of untreated and plasma-treated surfaces

Material	Plasma chemistry	Adhesive	Bond strength, MPa	Failure mode	Reference

Vectra A625	Control	Epoxy	6.47	Adhesive	19
	Oxygen plasma	Scotchweld 2216 (3M)	11.02	Cohesive

Plasma-Induced Grafting

As effective as plasma surface modification might be, the extent to which the surfaces of polymers can be modified is limited. Plasma-induced grafting is another method by which chemical functional groups can be incorporated. In this process, free radicals are generated on the surface of a polymer through the use of an inert gas plasma. Because of the nonreactive nature of the inert gas plasma, surface chemical modification of the polymer does not occur. However, if a polymer surface that has been treated in this fashion is exposed to vapors of unsaturated monomers, the monomers get attached to the surface. A variety of vinyl monomers are available, and the possibilities for incorporating many different chemical functional groups are endless. Unlike surface modification, this is a two-step process, which adds a degree of complexity. Few studies have appeared in the open literature; the majority of such processes are being used in proprietary applications (Ref 49, 50, 51).

Plasma Film Deposition (Plasma Polymerization)

Compared to the processes described above, plasma film deposition is an entirely new avenue for bonding dissimilar materials. For example, films deposited from a methane plasma have been shown to dramatically improve the adhesion properties of many materials when tested in both the dry and wet states (Ref 49). The process of plasma film deposition is often called *plasma polymerization,* although the process that takes place is not polymerization in the classical sense.

Gases in plasma may undergo polymerization, usually through a free radical initiation process. When a gas is ionized by RF energy, the resulting plasma contains free electrons as well as other metastable particles. When the process gas mixture used consists wholly or in part of hydrocarbon gases, the hydrocarbon molecule is fractured into free radical fragments, which become the sites at which the polymerization process is initiated. As the molecular weight of the plasma-polymerized product increases, the product is deposited onto the substrate placed within the plasma chamber. The fragmentation of the feed gas in the plasma generates free radical species for initiating the polymerization process, so gases that have zero functionality, such as methane (CH_4), can be used to form plasma polymers. In addition to methane, plasma polymers have been formed from other hydrocarbon gases such as ethylene or propylene, fluorocarbon monomers such as tetrafluoroethylene, and organosilicon compounds such as hexamethyldisiloxane (HMDSO) or vinyltrimethylsilane. Due to the complex nature of the fragmentation process, the resulting polymer structure is unlike any that can be deduced from conventional polymerization mechanisms (Ref 52). The physics of plasma polymerization has been described in depth elsewhere in sufficient detail for the interested reader (Ref 49, 53, 54).

The conditions used during glow discharge polymerization determine not only the structure of the resulting film but also the rate at which these films are deposited onto the target substrate materials (Ref 49, 55, 56). The degree to which the monomer is fragmented depends on the amount of energy supplied per unit weight of monomer that is allowed to flow through the reactor. When sufficient energy is supplied to break all the bonds of the monomer molecule, the recombination or polymerization process becomes atomic in nature. In addition, the structure of the plasma polymers can be varied by changing the reaction conditions, including the use of co-monomers or the introduction of oxygen, nitrogen, or ammonia into the reaction chamber during the polymerization process. Studies have correlated the power input, the type of monomer used, and the monomer flow rate to the density and type of active species in the plasma, and these factors in turn determine the rate of deposition and the film structure (Ref 56, 57). Table 3 shows typical deposition rates for some common plasma-polymerized films.

Table 3 Deposition rates for various compounds

Compound	**Deposition rate (D), $10^8 \times$ gm/cm^2/min**	**D/D_0**
Hexamethyldisiloxane	$233 = D_0$	1.00
Acrylic acid	28	0.12
Styrene	173	0.74
Tetramethyldisiloxane	191	0.82
Divinyltetramethyldisiloxane	641	2.75
Ethylene	42	0.18
Benzene	110	0.47

Source: Ref 49

Plasma of ammonia, mixtures of hydrogen and nitrogen, and oxides of nitrogen have been used to incorporate nitrogen atoms in the surface layers of the polymer (Ref 35, 36), but the level of nitrogen incorporation has been less than 10 at.% (Ref 36). In contrast, films deposited from allyl amine have shown to contain up to 25 at.% nitrogen, as measured by spectroscopic methods (Ref 58). Despite this high nitrogen content, however, Ref 58 reports a lower-than-expected concentration of amino groups. Other studies have shown concentrations of up to 2 molecules/nm^2 of reactive amine groups on the surface of films deposited from allyl amine onto FEP substrates. These surface concentrations were determined by derivatization of the amine groups with fluoroscein isothiocyanate and subsequent detection of the fluoroscein chromophore by optical spectroscopy (Ref 59). Electron spectroscopy does not always allow precise determination of functional sites, so the earlier data may reflect limitations of the analytical methods used.

In a similar vein, hydroxyl and carboxylic acid functionalities can be incorporated by plasma polymerizing acrylic acid (Ref 60) or allyl alcohol (Ref 58). Another technique commonly employed to incorporate specific atomic species is the use of co-reactants along with the primary monomer. In one such example, ammonia or acrylonitrile was used as the co-reactant during the deposition of films from a methane plasma (Ref 61). Two additional techniques for modifying plasma-deposited films are plasma surface modification of the deposited film in a second process step and wet chemical reaction methods. As an example, carbonyls formed during the plasma deposition of films from N-vinylpyrrolidone were reacted with lithium aluminum hydride and sodium borohydride to convert these carbonyls to hydroxyl groups (Ref 62).

The use of plasma-deposited films for adhesion enhancement is not limited to polymeric substrates. Such films have also been deposited onto inorganic materials, such as mica (Ref 60), and metal substrates, such as aluminum and steel, in an effort to improve adhesion of these materials to polymers (Ref 49).

Plasma film deposition technology has become a significant tool in achieving performance attributes beyond simple adhesion improvement. The diverse applications include biocompatibility, permeation control of films, corrosion resistance of metal surfaces, and hard coats or abrasion-resistant coatings for plastic substrates. Plasma-polymerized films have been successfully used for developing gas separation membranes and as barrier coatings for packaging applications. Such coatings are typically deposited from the plasma polymerization of siloxane monomers (Ref 63, 64, 65, 66). As shown in Table 4, plasma-deposited films offer barrier properties that are significantly better than those obtained by films deposited by evaporative methods.

Table 4 Oxygen transmission rates of evaporated and plasma-deposited SiO_x coatings on polyethylene terephthalate

Process	**Material**	**Thickness, Å**	**O_2 rate, cc/m^2/day**	**H_2O rate, g/m^2/day**
Resistance evaporation	SiO	600	2.2	2.5
Electron-beam evaporation	SiO	600	3.0	2.0
Plasma-enhanced chemical vapor deposition	SiO_2	200	1.0	1.0

Source: Ref 64

Table 5 compares the physical properties and permeation characteristics of plasma-deposited films with those of a silicone rubber membrane for use in gas separation. The membranes prepared from HMDSO are similar to silicone rubber but of a higher density, and they appear to offer better selectivity. Note that the structure of the plasma-deposited film significantly influences the permeation properties, as evidenced by the differences between HMDSO films and hydroxymethyldisilazane films. Other applications include optical coatings (Ref 67), abrasion-resistant coatings (Ref 68, 69), and coatings that act as semiconducting films (Ref 70). As shown in Table 6, plasma-deposited coatings offer a 300% improvement in the abrasion resistance of polycarbonate substrates compared with that of uncoated plastic.

Table 5 Physical properties and permaselectivity of plasma-polymerized (PP) films

Parameter	**PP HMDSO, 0.5 µm**	**PP HMDSN, 0.5 µm**	**Silicone rubber, 1.0 µm**

Biomedical applications of plasma-polymerized films are primarily devoted to biocompatible coatings (Ref 71, 72, 73, 74). The interaction between plastics and body fluids such as human blood and proteins is complex and not well understood. Because plastic materials offer an opportunity to develop and design lifesaving devices and prosthetics, the focus in these applications has been biocompatibility for both short-term use and long-term implants. Several literature sources offer excellent summaries of these applications (Ref 74).

Surface Engineering of Carbide, Cermet, and Ceramic Cutting Tools

A.T. Santhanam and D.T. Quinto, Kennametal Inc.

Introduction

RAPID TECHNOLOGICAL DEVELOPMENT has produced global competition in manufacturing, and the incentive to improve productivity has never been greater. This article discusses the expanding role of surface engineering in increasing the manufacturing productivity of carbide, cermet, and ceramic cutting tool materials used in machining operations.

Acknowledgements

The authors wish to express their appreciation to P.C. Jindal and W.A. Bryant for their contributions to this article and to E.J. Oles and P.K. Mehrotra for reviewing the manuscript.

Tool Material Classes

The classes of tool materials currently in use for machining operations are high-speed tool steels, carbides, cermets, ceramics, polycrystalline cubic boron nitrides (CBN), and polycrystalline diamonds (PCD). The different materials vary greatly in wear resistance and toughness. Figure 1 shows schematically their relative application ranges in terms of machining speeds and feed rates. Higher machining speeds require tool materials with greater wear resistance, whereas higher feed rates require tools with increased toughness. High-speed tool steels are the toughest materials; however, their relatively low wear resistance limits their application to low-speed machining. (Cleaning, finishing, and coating of tool steels are discussed in the article "Surface Engineering of Specialty Steels" in this Volume.) At the other end of the spectrum, superhard materials such as CBN and PCD are highly wear resistant and can be employed at high speeds. There is, however, a tradeoff between wear resistance and toughness that can limit the application of these superhard tools to lighter feed rates.

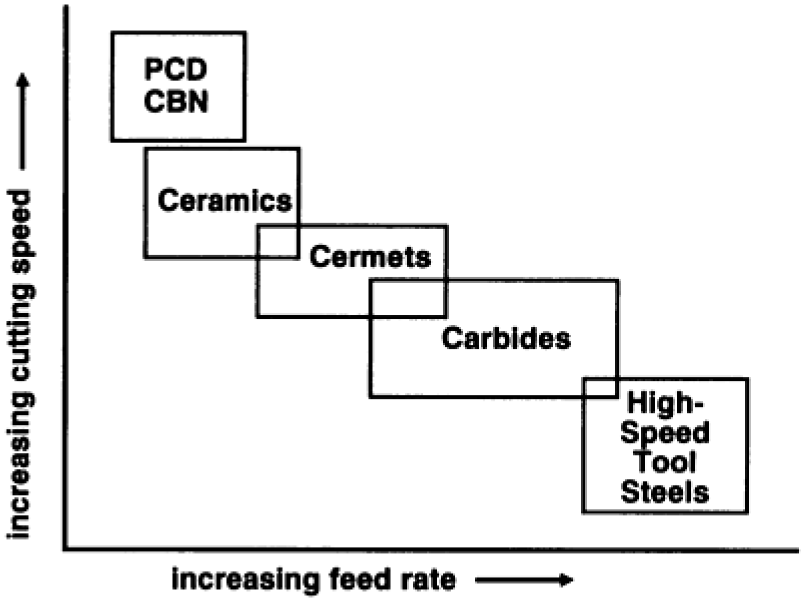

Fig. 1 Relative machining application ranges of cutting tool materials

In between the two extremes of high-speed tool steels and superhard materials are carbides, cermets, and ceramic tool materials, which are used over a wide range of speeds and feed rates to suit the diverse machining needs of the automotive, aerospace, and other manufacturing industries. Tables 1, 2, and 3 list the representative properties of carbide, cermet, and ceramic tool materials, respectively. In the past two decades, surface modification technologies have significantly expanded tool application ranges, particularly for carbides, and have dramatically improved manufacturing productivity.

Cemented carbides belong to a class of hard, wear-resistant, refractory materials in which the hard carbides of Group IVB-VIB metals are bound together or cemented by a ductile metal binder, usually cobalt or nickel. The first cemented carbide was produced in the 1920s and consisted of tungsten carbide (WC) with a cobalt binder (Ref 1). A remarkable feature of cemented carbides is that they can be tailored to provide different combinations of abrasion resistance and toughness by controlling the amount of cobalt and WC grain size.

Over the years, the basic WC-Co material has been modified to produce a variety of cemented carbides containing WC-TiC, WC-TiC-TaC, WC-TiC-(Ta,Nb)C, and other solid-solution cubic carbides that cover a wide range of applications, including metalcutting, mining, construction, rock drilling, metal forming, structural components, and wear parts. The commercially significant alloys for machining contain 5 to 12 wt% Co and up to 15 wt% cubic carbides. Carbide grain sizes from 0.5 to 5 μm are commonly used.

Cermets. The technical definition is that a cermet is a composite of a ceramic material with a metallic binder. Although WC-Co tools also fit this definition, in the North American machining industry the term *cermets* is applied more specifically to TiC-based tools that contain mainly nickel as a binder. Cermet tools have lower density than WC tools but are heavier than ceramic inserts of equal size. The first cutting tool in this family, a TiC-Ni alloy, was commercialized as early as the 1930s, but it could not compete with the inherently stronger WC-Co-based tools. Additions of molybdenum to TiC-Ni alloys in 1960 brought cermets closer in performance to WC-Co-based tools in finish machining of steels.

Titanium carbonitride cermets based on Ti(C,N)-Ni-Mo were introduced in 1970, followed by (Ti,Mo)(C,N)-based compositions that provided a balance of wear resistance and toughness due to their finer microstructures (Ref 2). Continued development in this area has now resulted in complex cermets having a variety of additives, such as Mo_2C, TaC, NbC, ZrC, HfC, WC, VC, Cr_3C_2, and aluminum (Ref 3). Various mixes of these additives impart different combinations of wear resistance, thermal shock resistance, and toughness, and they allow tools to be tailored for a wide range of machining applications. The newer cermets are used in semifinishing and finishing of carbon and alloy steels, stainless steels, ductile irons, free-machining aluminum and other nonferrous alloys, and some high-temperature alloys. The metal removal operations may include turning, boring, milling, threading, and grooving.

Ceramic tools are inherently more stable than carbide tools at high temperatures (high cutting speeds) but are less fracture resistant; hence, recent developments have been focused on improving their fracture toughness. There are basically two classes of ceramic cutting tools: Al_2O_3 ceramics and tools based on silicon nitride (Si_3N_4) and solid solutions of aluminum and oxygen in silicon nitride (Sialons).

Al_2O_3 Ceramics. The white Al_2O_3-based ceramics may contain low levels of zirconia (ZrO_2) as a sintering aid and are used for machining cast iron. Higher levels are used in tools to machine steels. The ZrO_2 improves fracture toughness by a transformation toughening or crack deflection mechanism (Ref 4, 5), but it decreases the thermal conductivity and hardness of the tool.

Additions of up to 30 vol% TiC to Al_2O_3 make the inserts black and improve the thermal conductivity, hardness, and toughness of the tools without seriously degrading their chemical stability. Al_2O_3-TiC ceramics are employed on a wide range of workpiece materials, including cast iron, steel, and nickel-base superalloys.

SiC-whisker-reinforced Al_2O_3 ceramics, developed in the early 1980s (Ref 6), offer better toughness than white ceramics due to crack deflection by the dispersed SiC whiskers in the microstructure (Ref 7). The whiskers also increase hardness and improve thermal shock resistance by increasing thermal conductivity and reducing the thermal expansion coefficient. The major application of these tool materials is high-speed/high-feed machining of nickel-base superalloys. These ceramics can be used on cast irons but are rarely used on steels because of the poor chemical stability of SiC.

Si_3N_4/Sialon ceramics were introduced in the early 1980s. Their whisker-like grain structure makes them tougher than the white Al_2O_3 ceramics, and they also possess excellent hot hardness and thermal shock resistance. These characteristics permit them to be used at high speeds and feed rates and in interrupted cutting of nickel-base superalloys and cast irons (Ref 8, 9). However, the lower chemical stability of Si_3N_4/Sialon tool materials (compared to Al_2O_3 ceramics) prohibits their application in most steel machining.

Superhard Materials. As discussed earlier, superhard materials are extremely wear resistant. CBN is the tool of choice for machining hard steels (i.e., steels with hardnesses greater than 50 HRC). PCD, on the other hand, cannot be used for steel machining because of diamond's solubility in iron and the catalytic effect of iron, which causes graphitization of the diamond. The primary application of PCD tools is in the very-high-speed machining of aluminum-silicon alloys, composites, and other nonmetallic workpieces.

Tool Failure Mechanisms

Machining of metals is a complex process. The cutting tool environment features high localized temperatures (~1000 °C, or 1830 °F) and high stresses (~700 MPa, or 100 ksi). The tool may experience repeated impact loads during interrupted cuts, and the workpiece chips may chemically interact with the tool material. The response of a tool material to the above conditions dictates its performance. High temperatures and stresses can cause blunting from the plastic deformation of the tool tip, and high stresses alone may lead to catastrophic fracture. In addition, the useful life of cutting tools may be limited by a variety of wear processes, such as crater wear, flank wear or abrasive wear, builtup edge, depth-of-cut notching, and thermal cracks (Fig. 2). The origin of the various tool failure mechanisms is now well understood (Ref 10).

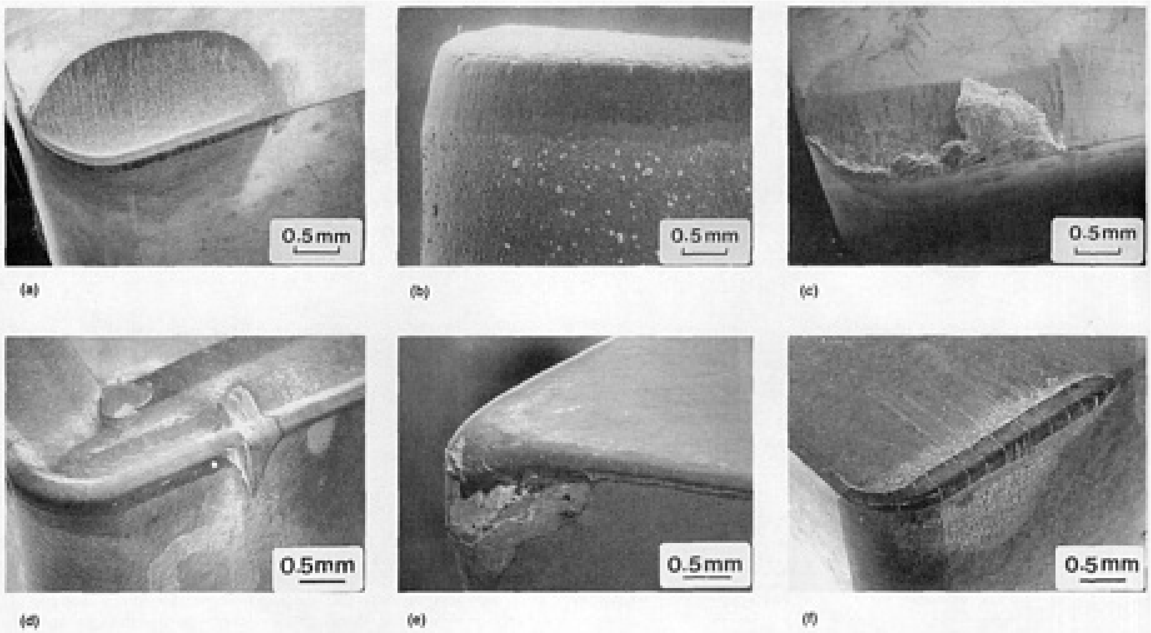

Fig. 2 Tool wear mechanisms. (a) Crater wear on a cemented carbide tool produced during the machining of plain carbon steel. (b) Abrasive wear on the flank face of a cemented carbide tool produced during the machining of gray cast iron. (c) Builtup edge produced during low-speed machining of a nickel-base alloy. (d) Depth-of-cut notching on a carbide tool produced during the machining of a nickel-base superalloy. (e) Carbide insert showing nose wear (tool-tip blunting) due to insufficient deformation resistance of the tool. (f) Thermal and mechanical cracks in a carbide insert after interrupted cutting of low-alloy steel

Crater wear (Fig. 2a), observed on the rake face of cutting tools, generally occurs during machining of relatively soft steels and ductile irons at high speeds. It is primarily caused by a chemical interaction between the rake face of a metalcutting insert and the hot metal chip flowing over the tool. This interaction may involve diffusion or dissolution of the tool material into the chip. Adhesion of tool material and chip follows, with consequent microfracture of the tool underneath the adhered material.

Flank wear (Fig. 2b), on the other hand, is observed on the flank or clearance face of a metalcutting insert and is caused by abrasion of the flank face by the hard constituents of the workpiece. This failure mechanism is commonly observed during machining of cast irons and steels where the abrasive particles are mainly Fe_3C and nonmetallic inclusions.

Builtup edge (Fig. 2c) refers to welding of the workpiece material to the tool tip. It typically occurs when soft low-carbon steels and nonferrous materials are machined at low speeds and light feed rates. This may result in attrition wear if small fragments of tool material are carried away as the builtup edge breaks off.

Depth-of-cut notching (Fig. 2d) occurs at the depth-of-cut line and is often attributed to the chemical reaction (oxidation) of the tool material with the atmosphere (Ref 11) or to abrasion by the hard, sawtooth outer edge of the chip (Ref 12). Notching is a problem with workpieces that tend to work harden and generate high tool-tip temperatures, such as austenitic stainless steels and nickel-base superalloys. Depth-of-cut notching can lead to tool fracture. Aside from selection of a tool material that is relatively chemically inert and possesses high fracture toughness, notching can be minimized by applying optimized geometries, such as chamfered edges and round insert styles, that spread the depth of cut over a wider area of the cutting edge.

Nose wear (Fig. 2e), or tool-tip blunting, results from insufficient deformation resistance of a tool material in a given machining application.

Thermal cracks (Fig. 2f) develop when the repeated heating and cooling associated with interrupted cutting, such as milling, create temperature gradients at the cutting edge. With prolonged interrupted cutting, lateral cracks may appear parallel to the cutting edge. The thermal and lateral cracks may join together and cause small fragments of tool material to break away.

Fracture is the least desirable mode of tool failure because it is unpredictable and catastrophic. The preferred mode is flank wear, because it progresses gradually and can be easily monitored for tool-changing protocol. Most tool material development work is focused on minimizing flank wear and preventing unwanted tool failure modes such as catastrophic fracture, gross plastic deformation, builtup edge, crater wear, and depth-of-cut notching.

Applicable Methods for Surface Engineering of Cutting Tools

A major breakthrough in controlling cutting tool wear came in the 1960s with the advent of protective hard coatings for cemented carbide inserts. This mode of surface modification increased tool life on steels and cast irons by a factor of at least two to three (Ref 13). Coatings also permitted the use of higher cutting speeds, boosting machining productivity.

The precursor to the development of coated carbide tools occurred in the mid-1960s, when laminated inserts consisting of a base of WC-Co alloy with a sintered layer of high TiC were produced. Although metalcutting productivity increased, thermal stresses during machining often caused the laminate to spall during use.

Chemical Vapor Deposited Coatings. Further development of laminated tools was superseded in 1969 by the application of a thin (~5 μm) layer of hard TiC coating to the cemented carbide tool by chemical vapor deposition (CVD) (Ref 13). In the CVD coating process, the tools are heated in a sealed reactor to about 1000 °C (1830 °F) with gaseous hydrogen at atmospheric or lower pressure; volatile compounds are added to the hydrogen to supply the metallic and nonmetallic constituents of the coating.

In TiC deposition, a reaction often occurs in which titanium combines with carbon from the cemented carbide substrate. The resulting surface decarburization leads to the formation of a brittle eta phase and to associated substrate microporosity at the coating-substrate interface. The early coated tools were particularly notorious in this regard and showed inconsistent performance during interrupted cuts (Ref 14). Such performance inconsistencies have now been largely eliminated by a number of metallurgical and processing innovations that have resulted in coatings with greater thickness uniformity, more adherence, and more consistent morphology and microstructure with minimum interfacial eta phase and associated porosity (Ref 15). Additional information is available in the article "Chemical Vapor Deposition of Nonsemiconductor Materials" in this Volume.

Multilayer CVD Coatings. During the 1970s, CVD coatings evolved from single-layer TiC coatings to multilayer hard coatings comprising various combinations of TiC, TiCN, TiN, HfN, and Al_2O_3 (Fig. 3). Multilayer coatings, through a combination of properties, suppress crater wear, flank wear, and builtup edge and extend the range of application. A variation of the multilayer coating employs multiple alternating layers. Figure 3(e) shows a coating with alternating layers of Al_2O_3 and TiN that is particularly effective in high-speed machining of steels and cast irons (Ref 16).

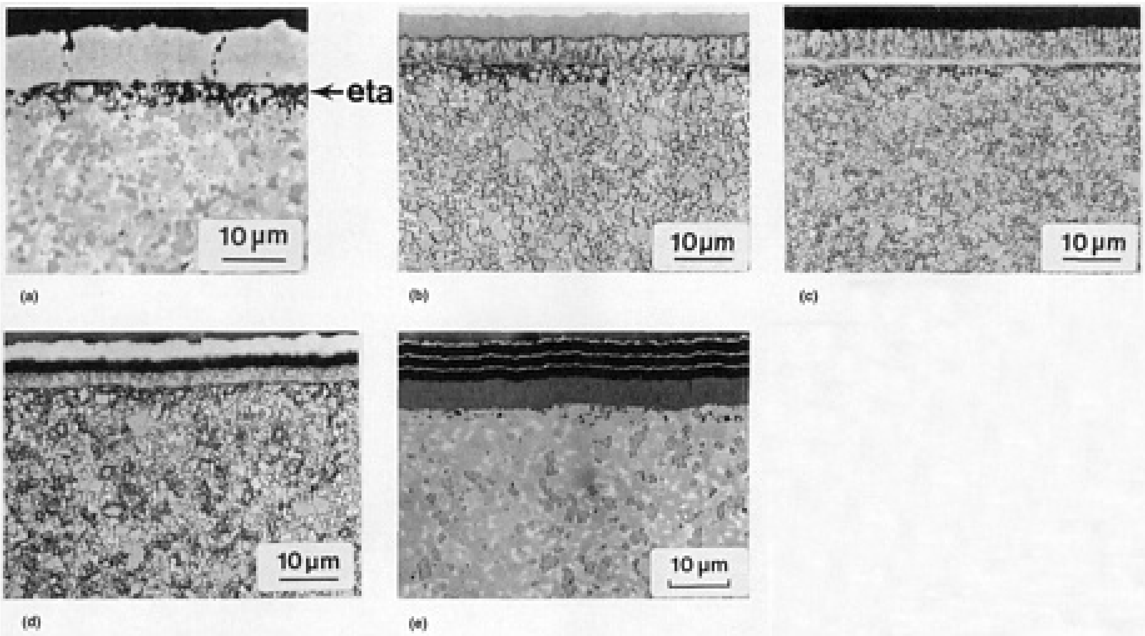

Fig. 3 Chemical vapor deposition coatings. (a) Cemented carbide insert with TiC coating. Note eta phase at the coating-substrate interface. (b) 73WC-19(Ti,Ta,Nb)C-8Co alloy with a TiC/TiCN/TiN coating about 10 μm thick. (c) 85WC-9(Ti,Ta,Nb)C-6Co alloy with a TiC/Al_2O_3 coating about 9 μm thick. (d) 85WC-9(Ti,Ta,Nb)C-6Co with a TiC/Al_2O_3/TiN coating about 10 μm thick. (e) TiCN coating supporting multiple alternating coating layers of Al_2O_3 and TiN

The high temperatures employed during CVD coating generally ensure good bonding between the substrate and the coating. The thermal expansion coefficients of the coating materials (TiC, TiCN, TiN, and Al_2O_3) are higher than those of the WC-Co-based substrates, so CVD coatings are in residual tension at room temperature. In certain cases, the stresses may be relieved by transverse cracks that form in the coating. These cracks do not affect coating adhesion, but they may initiate tool fracture in interrupted cutting operations in which the cutting edge is subjected to fatigue-type loading. Residual tensile stresses are most severe at tool corners. To minimize their effect, and also to minimize the formation of eta phase, which tends to develop to a greater extent at sharp tool edges, CVD-coated tools are honed before coating.

Tailored Substrates for CVD-Coated Tools. Although the early CVD-coated tools substantially improved metalcutting productivity, they were prone to catastrophic fracture when applied at high feed rates or in intermittent cutting operations. One solution to this problem is to improve the fracture toughness of the substrate by increasing its cobalt content. Unfortunately, this approach decreases deformation resistance, which can result in tool-tip blunting.

A major breakthrough in resolving the conflict between fracture toughness and deformation resistance occurred in the late 1970s, when a TiC/TiCN/TiN-coated tool was developed with a peripheral cobalt-enriched zone, 10 to 30 μm thick (Fig. 4a), that provided superior edge strength while maintaining the deformation resistance of the bulk of the coated tool (Ref 17). This development permitted users to make heavy interrupted machining cuts such as those encountered in scaled forgings and castings at lower speeds. Further advancements in the cobalt enrichment concept (Fig. 4b) have expanded the application range of this type of tool to higher speeds (Ref 18).

Medium-Temperature CVD Coatings. In the mid-1980s a new CVD process for depositing TiCN was commercialized. Using a mixture of $TiCl_4$, H_2, and an organic C/N compound such as acetonitrile, it was shown that TiCN can be deposited at moderate temperatures (700 to 900 °C, or 1300 to 1650 °F) at faster deposition rates than in the conventional CVD process (Ref 19). The reduced process temperature and the faster deposition rate minimize the formation of the embrittling eta phase at the coating-substrate interface (Fig. 5) and lessen the thermally induced tensile cracks that are common to higher-temperature CVD coatings (Ref 20).

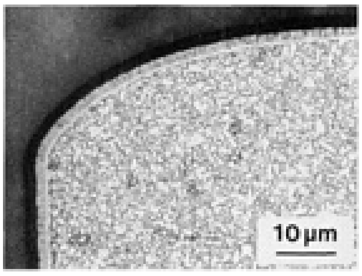

Fig. 5 Medium-temperature chemical vapor deposition TiCN/Al_2O_3 coating on a cemented carbide substrate

Physical Vapor Deposited Coatings. In the 1980s, physical vapor deposition (PVD) emerged as a commercially viable process for applying hard TiN coatings to cemented carbide tools. In this process the coating is deposited in a vacuum by condensation from a flux of neutral or ionized atoms where the metal species are derived from a variety of sources, including electron-beam evaporation, magnetron sputtering, and arc evaporation (Ref 21, 22). In the ion plating variation of the basic PVD process, the flux of atoms and ions is activated by an electrical glow discharge plasma, and the charged species are accelerated toward the substrate by applying a negative bias potential on the substrate. For hard coatings, the evaporated or sputtered metal or cation species (titanium, hafnium, zirconium, etc.) are evaporated or sputtered and are made to react with the gaseous species (N_2, NH_3, CH_4, etc.) introduced into the vacuum chamber. Because PVD coatings are produced at low pressures (10^{-3} to 10^{-2} torr), the atoms and molecules have long mean free paths and undergo fewer collisions, making PVD a line-of-sight deposition technique. This necessitates moving the tool fixtures during the PVD deposition to ensure uniformly thick coatings on both the rake and flank faces of tool inserts.

A number of factors make the PVD process attractive for use with cemented carbide tools:

- Lower deposition temperature (<500 °C, or 930 °F) prevents eta-phase formation and produces crack-free coatings with finer grain sizes.
- The coatings are smooth and thus generate less frictional heat during machining.
- Depending on the deposition technique, compressive residual stresses, which are beneficial in resisting crack propagation, may be introduced into the coating (Ref 23).
- PVD coating preserves the transverse rupture strength of the carbide substrate, whereas the CVD

process generally reduces the transverse rupture strength by as much as 30% (Ref 24, 25).

- PVD coatings can be applied uniformly over sharp cutting edges (Fig. 6a). A sharp edge is desirable in a cutting tool because it leads to lower cutting forces, reduced tool-tip temperatures, and finer workpiece surface finishes.

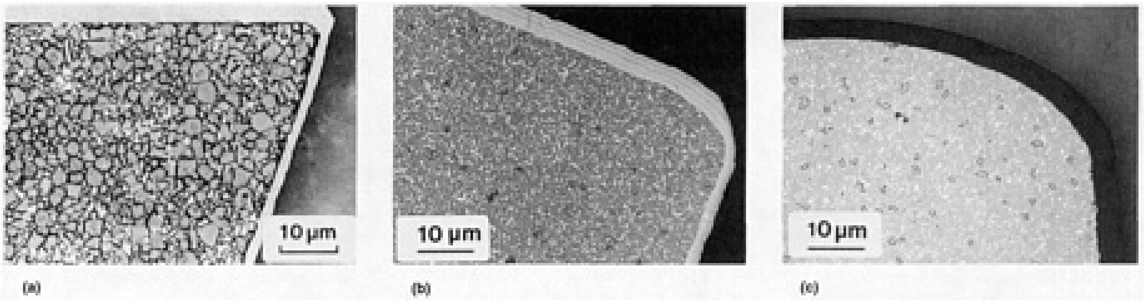

Fig. 6 Physical vapor deposition coatings on cemented carbide substrates. (a) TiN. (b) TiCN. (c) TiAlN

In the last three years, newer compositions such as TiCN (Fig. 6b), TiAlN (Fig. 6c), TiZrN, and CrN have been commercialized using the PVD process. PVD Al_2O_3 coatings, however, are not yet commercially available.

Additional information about PVD coatings is available in the articles "Growth and Growth-Related Properties of Films Formed by Physical Vapor Deposition Processes" and "Vacuum Deposition, Reactive Evaporation, and Gas Evaporation" in this Volume.

Plasma-Assisted CVD Coatings. The high deposition temperatures (~1000 °C, or 1830 °F) of CVD coatings can degrade the strength of the cemented carbide substrate. On the other hand, the PVD coating process, which takes place at lower temperatures (~500 °C, or 930 °F), has a line-of-sight disadvantage. A compromise between the two techniques is the plasma-assisted CVD coating process, which offers a combination of moderate deposition temperature (~600 °C, or 1110 °F) and good thickness uniformity without the need to rotate the tools during the coating process.

In the traditional CVD process, thermal energy activates the chemical reaction that forms the hard coating compounds. In plasma-assisted CVD, lower-temperature activation is enabled by the energetic particles in a plasma, typically an argon discharge. Both direct-current and radio-frequency power supplies are used to deposit the conducting (TiN and TiC) and insulating (Al_2O_3) coatings (Ref 26). Use of plasma-assisted CVD for hard coatings on cemented carbide substrates is not yet widespread, probably due in part to the process economics relative to the competing CVD and PVD methods. Additional information is available in the article "Plasma-Enhanced Chemical Vapor Deposition" in this Volume.

CVD/PVD Coatings. A recent development in carbide cutting tool coatings combines an outer PVD TiN layer with inner CVD TiN/TiCN layers on a tough cobalt-enriched substrate for interrupted cutting applications such as milling (Fig. 7). The inner CVD layers provide excellent adhesion and wear resistance, and the outer PVD layer offers a hard, fine-grain, crack-free, smooth surface endowed with compressive residual stress. The synergistic effects of this combination contribute to excellent tool performance in milling of steel components at relatively high speeds (Ref 27).

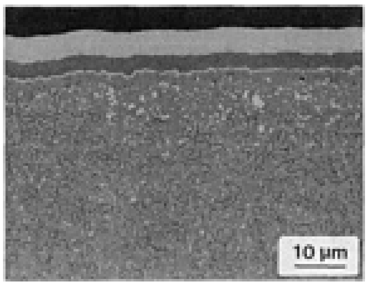

Fig. 7 Combination of a chemical vapor deposition TiN-TiCN coating and a physical vapor deposition TiN coating on a cobalt-enriched cemented carbide insert

Diamond Coatings. The most recent addition to the development of hard coatings is the low-pressure synthesis of diamond films by carbonaceous gas decomposition in the presence of hydrogen ions. This process is an alternative to the high-pressure, high-temperature synthesis of bulk diamond, which is used to fabricate PCD tips that are brazed onto WC-Co substrates. These PCD-tipped inserts are relatively expensive, but they provide a 20- to 100-fold increase in tool life over uncoated WC-Co inserts in the machining of highly abrasive nonferrous alloys (e.g., aluminum-silicon).

The progress in thin-film diamond coating research has been significant in the last few years. The outstanding problem to date has been unsatisfactory adhesion of the diamond coating to the carbide substrate, partly due to an inherently large mismatch in the coefficients of thermal expansion. Although a ceramic substrate such as silicon nitride presents a better match with diamond, WC-Co-based substrates are more economical when good diamond coating adhesion is obtained. Diamond-coated carbide inserts with good coating adhesion are now being introduced commercially. Recent data from field tests indicate that such diamond-coated inserts can approach the performance of the PCD counterparts (Ref 28). Additionally, diamond-coated inserts will eventually feature chipbreaker designs that are difficult to fabricate in PCD inserts. Research continues regarding the control of diamond grain morphology (Fig. 8) as it relates to the final workpiece surface finish.

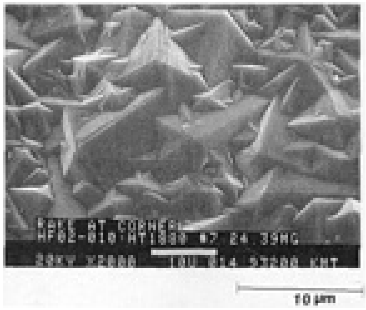

Fig. 8 Diamond coating on a cemented carbide insert

Ion implantation is a surface modification process that consists of injecting energetic ions into the surface layers of a material. It has been applied to carbide wear products and end mills with limited success (Ref 29). Its main drawback is that the implantation depth and subsurface region disordered by knock-on collisions are no deeper than tenths of a micron. This is much too thin compared to hard coatings that are typically 5 to 10 μm. Ion implantation has therefore not been successfully applied in machining applications. Additional information about this process is available in the article "Ion Implantation" in this Volume.

Properties of Hard Coatings

The successful application of hard coatings on cutting tool substrates is due to the combination of physical and mechanical properties of the coating. From a functional standpoint, chemical stability, hot hardness, and good adhesion to the substrate are essential; optimum coating thickness, fine microstructures, and compressive residual stresses can further enhance their performance.

Chemical Stability. The criterion for chemical inertness is either a high negative standard free energy of formation of the coating material or low solubility in the workpiece material at temperatures encountered during machining. As can be seen in Fig. 9 and Table 4, CVD Al_2O_3 coatings singularly meet these requirements for machining of irons and steels. However, amorphous PVD Al_2O_3 coatings are unstable and are not as satisfactory as the crystalline Al_2O_3 obtained in CVD. PVD TiAlN coatings are also chemically stable and offer the potential for high-speed machining of steels. Diamond-coated tools are suitable for machining nonferrous alloys containing abrasive second-phase particles (e.g., aluminum-silicon alloys) as well as for machining nonmetallic materials that do not react with carbon (e.g., metal-matrix composites and fiber-reinforced plastics).

Table 4 Properties of chemical vapor deposited coating materials

Material	Room-temperature microhardness kg/mm^2	Coefficient of thermal expansion µm/·K	Thermal conductivity at 1000 K, W/m·K	Relative dissolution rates into iron at:	
				500 °C (932 °F)	1100 °C (2030 °F)
TiC	2800-3200	7.7	38	1.0	1.0
TiN	2000-2200	9.4	25	1.8×10^{-3}	2.2×10^{-1}
HfN	1700	6.9	10	3.8×10^{-5}	2.5×10^{-2}
Al_2O_3	2100-2300	8.4	7.5	8.9×10^{-11}	4.1×10^{-5}

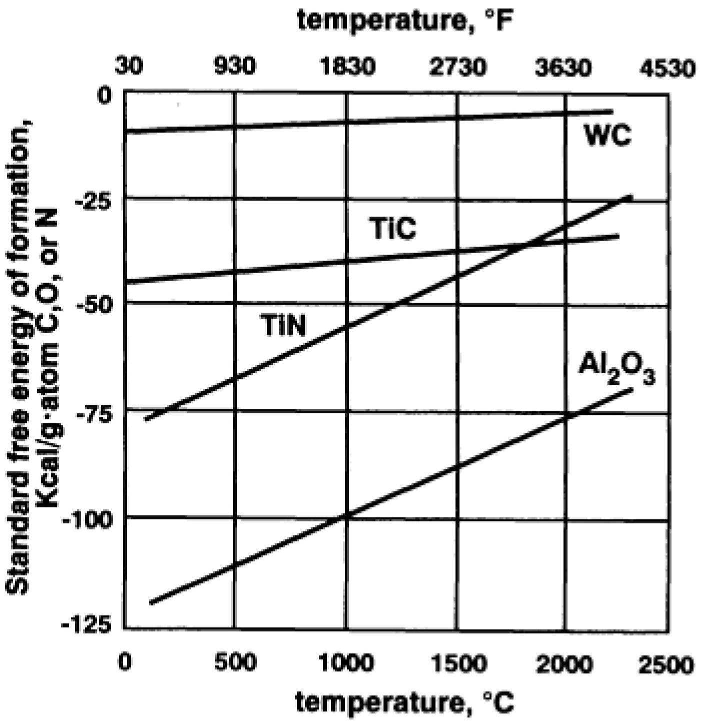

Fig. 9 Variation in the standard free energy of formation of WC, TiN, TiC, and Al_2O_3 with temperature. This parameter gives an indication of the extent to which these materials will undergo diffusion wear.

Hot Hardness. The importance of coating material hardness in resisting abrasive wear has been well documented (Ref 30). High coating hardness is also believed to be beneficial in resisting the abrasive wear component of crater wear (Ref 31). The relevant hardness corresponds to the high temperatures characteristic of those prevalent during machining. Figure 10 shows Vickers microhardness as a function of test temperature for Al_2O_3, TiN, and TiC. Although TiC has high room-temperature hardness, it loses hardness rapidly with temperature. Al_2O_3, on the other hand, has lower room-temperature hardness but retains its hardness to higher temperatures. The data thus suggest that TiC coatings would be more effective at lower speeds, whereas Al_2O_3 coatings, by virtue of high hot hardness and chemical stability, would be most effective for high-speed machining. These concepts have been validated in the machining of 1045 steel and gray cast iron (Ref 32).

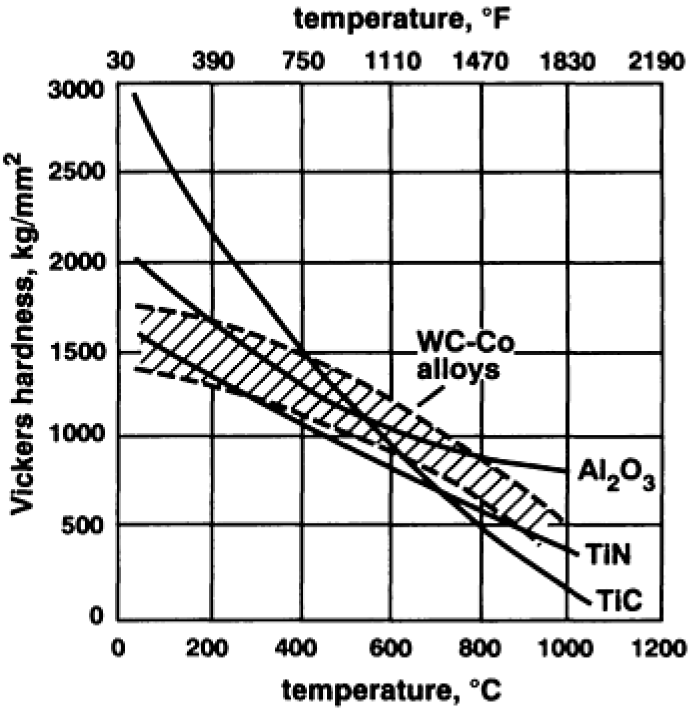

Fig. 10 Temperature dependence of hardness of TiC, Al_2O_3, and TiN. The range of hardness of WC-Co alloys is also shown.

Microstructure. The microstructure of hard coatings controls their mechanical properties and metalcutting performance. A generalized Hall-Petch relationship between grain size of the coating and microhardness has been shown to hold true for CVD and PVD coatings (Ref 33). The higher measured microhardness of PVD TiN relative to that of CVD TiN has been attributed not only to the finer grain sizes obtained in the PVD process but to the presence of compressive residual stresses (Ref 33). Compressive residual stress developed during ion bombardment in certain PVD processes retards crack propagation and thus produces a fracture toughness advantage for PVD-coated tools.

Grain boundary voids developed during columnar growth of some PVD coatings do not allow retention of residual stresses and lead to lower hardness (Ref 34). Likewise, CVD coarse-grain alpha-Al_2O_3, which grows with intergranular voids, is not expected to be as hard as the void-free, fine-grain kappa-Al_2O_3. Alternating multilayers of CVD kappa-Al_2O_3, which have fine grain sizes due to periodic interruption of growth, are harder than Al_2O_3 that has been allowed to grow as a single, thick coating (Ref 17). However, transformation from the metastable kappa phase to the stable alpha phase at high temperatures (~1050 °C, or 1920 °F) may induce stresses and a subsequent decrease in coating adhesion.

Coating morphology can also affect surface roughness, which in turn may increase the frictional forces and generate heat at the chip-tool interface. It is known that the relatively smoother PVD TiN-coated carbide tools decrease cutting forces and produce better workpiece surface finishes than CVD-coated tools (Ref 25). In contrast, rough surface morphology is still an issue in diamond coatings (Ref 28).

Adhesion. Good coating adhesion to the substrate is a necessary condition for satisfactory performance of the coated tool. It has been shown that varying levels of measured adhesion directly relate to tool life, other variables being constant (Ref 33).

During the high-temperature CVD process, initial coating nucleation on the carbide substrate occurs under conditions that allow interdiffusion of coating and substrate atoms at the interface. In plasma-assisted PVD processes, energetic ion bombardment creates lattice defects that enhance diffusion of coating species at the interface, even at lower deposition temperatures.

It is necessary to choose compatible coating-substrate combinations that accommodate film growth stresses and thermal mismatch stresses at the interface. As noted earlier, coating phase transformations can also induce stresses that may affect adhesion. Substrate surface contaminants prior to coating, particularly in the PVD process, can have detrimental effects on coating adhesion and should be minimized. The use of a thin titanium interlayer to remove residual oxide contaminants, as well as to accommodate interfacial stress, is now common in industrial PVD TiN deposition (Ref 35). Current PVD technology provides well-adhered coatings that are as effective as CVD coatings in demanding applications.

Coating Thickness. To achieve maximum metalcutting productivity, the thickness of the modified surface layer has to be optimized. If the modified tool surface region is too thin, the effect persists for a negligibly short time during cutting. If the coating is too thick, the layer acts as a bulk material and the advantage of an engineered composite may be lost. It is established that functional tool coatings should be at least 2 μm thick and that they may be as thick as 20 μm. Coatings deposited by CVD are typically 10 μm thick, while PVD coatings are usually less than 5 μm thick. As mentioned above, ion implantation, which affects no more than 0.1 μm of surface depth, has been found to be ineffective.

Application of Coated Tools

The advent and evolution of various coating technologies has produced a wide array of coated carbide tools with broad application ranges. At the same time, specialized areas of application exist where specific coatings and/or substrates offer outstanding performance. Typical applications for each category of coated metalcutting tools are highlighted below. Table 5 gives a few examples of machining productivity enhancements that are due to surface modification of carbide, cermet, and ceramic tool materials.

Table 5 Effect of surface treatments on the performance of cemented carbide, cermet, and ceramic tool materials

CVD-Coated Tools. Normal-temperature (~1000 °C, or 1830 °F) CVD-coated cemented carbides make up over 80% of all coated carbide metalcutting tools in use. These tools are employed in a variety of metalcutting applications, including turning, boring, parting, threading, grooving, and milling. They are used in machining carbon, alloy, and stainless steels and gray and ductile cast irons, covering a very wide range of speeds and feeds.

CVD-Coated Tools with Cobalt-Enriched Substrates. Multilayer CVD-coated tools with specially tailored cobalt-enriched substrates combine the wear resistance of the hard coatings with an edge-toughened substrate. These tools can therefore handle medium to heavy roughing to semifinishing operations on cast irons and high-temperature alloys, as well as stainless, low-carbon, and alloy steels. The broad application range of cobalt-enriched tools enables them to cover a large percentage of the metalcutting operations of a plant, allowing the user to stock fewer grades.

Medium-Temperature CVD and Plasma-Assisted CVD Coated Tools. The microstructures of tools coated by medium-temperature CVD and plasma-assisted CVD are characterized by a negligible amount of eta phase at the coating-substrate interface. This permits them to be used in all applications where normal-temperature CVD tools are applied, in addition to those operations that involve interrupted cuts (Ref 26, 36).

CVD/PVD-coated tools benefit from the synergistic effects of wear-resistant inner CVD layers combined with a smooth, fine-grain, crack-free outer PVD layer featuring compressive residual stresses. CVD/PVD-coated tools are therefore suited for interrupted cutting operations such as milling of low- and medium-carbon steels and alloy steels (Ref 27). The full potential of CVD/PVD coatings on cemented carbide tools has yet to be determined.

PVD-Coated Tools. The PVD coating process offers unique advantages, including the ability to apply a fine-grain, smooth, low-friction, and crack-free coating over sharp edges. When deposited by the ion plating method, PVD coatings also feature compressive residual stresses. These characteristics make PVD-coated tools particularly useful in threading, grooving, parting, finish-turning, and milling operations. Typical workpiece materials include low-carbon and alloy steels, hardened steels, stainless steels, and high-temperature nickel-base alloys.

Diamond-Coated Tools. Diamond coatings, with their extremely high hardness, can provide excellent productivity in the machining of nonferrous alloys containing abrasive second-phase particles, such as aluminum-silicon alloys, and in the machining of composite nonmetallic materials that do not have a chemical reactivity problem with carbon. Initial applications of the diamond-coated tools will be similar to those where PCD tools are applied (Ref 37), with the former providing further flexibility in the use of molded chipbreakers, and in rough cuts where surface finish requirement is not stringent.

Coatings for Ceramic and Cermet Inserts

Coatings for ceramic and cermet tool materials have not received the extensive development efforts enjoyed by coatings for cemented carbide tools. This is mainly because ceramic and cermet tools amount to less than 10% of the inserts employed in North America and Europe (although they account for about 35% of those used in Japan). Nevertheless, hard coatings for the ceramic and cermet tools can and do provide productivity benefits in certain applications (Table 5).

The chemical reactivity of silicon-nitride-based ceramics is relatively high and limits their usefulness in machining ferrous workpieces. However, application of an Al_2O_3 coating (which is chemically inert) enables users to exploit the high hot hardness of the silicon nitride substrate (Ref 38).

Current developments in cermets emphasize raising toughness through increases in nickel and cobalt binder contents. These changes have the desired effect but also raise the tools' chemical reactivity, compromising their usefulness on ferrous workpieces. Coatings can provide a solution to the problem, but the high process temperatures of conventional CVD coatings tend to produce brittle intermetallic compounds involving nickel and titanium. Hence, coatings for cermet tools have focused on those applied by the PVD process.

Future Potential

After two decades of material and process innovations, CVD hard coating technology is now mature. The multilayer approach has been very successful in expanding the functionality of the hard coating, and it is anticipated that this design will be duplicated with the newer PVD technology. The property enhancements obtainable in PVD, such as controlled residual compressive stress and fine grain morphology, are expected to be exploited further; indeed, the PVD counterparts may challenge similar CVD coatings as the process economics of the two methods begin to converge. PVD processes are also environmentally cleaner because they do not produce the gaseous effluents characteristic of CVD.

How will the newer coating technologies compare against conventional CVD? To truly compete with all present CVD coatings, an adherent PVD Al_2O_3 coating with crystalline microstructure must be developed. Beyond the conventional hard coating compounds, however, PVD techniques offer a larger range of possible compositions, including metastable compounds, that can perhaps be exploited in particular applications (Ref 39). Polycrystalline superlattice coatings such as TiN/NbN, TiN/Ni, and TiN/Ni-Cr are reported to have significantly higher microhardnesses than those of homogeneous nitrides and are promising for metalcutting applications (Ref 40).

The lower-temperature processes, such as medium-temperature CVD TiCN and plasma-assisted CVD, will grow as alternative coating technologies if the ability to deposit a variety of compositions is demonstrated. Combinations of various coating technologies will make sense when material and process economics are justified.

Diamond coatings on metalcutting inserts are expected to be commercially available soon (Ref 28, 41) as upscaling of equipment and optimization of performance are achieved in industrial tests. The major challenge in the coming years will be the successful synthesis of CBN superhard coatings by low-pressure methods. CBN coatings have more industrial potential than diamond because they will be useful in high-volume ferrous cutting applications. Researchers are now taking technical approaches similar to those that led to the realization of diamond coatings (Ref 42, 43), but interrelated issues of film stability, residual stress, coating thickness, adhesion to the matched tool substrate, and upscaling to large-area deposition are still outstanding.

Environmental Regulation of Surface Engineering

David J. Smukowski, Boeing Commercial Airplane Group

Introduction

ENVIRONMENTAL PROTECTION REGULATIONS are often related directly or indirectly to surface engineering processes. This article describes selected U.S. environmental statutes and regulations as they are pertinent to material surface finishers. For information about specific regulatory requirements, permitting conditions, and enforcement issues, the reader is advised to seek assistance from federal, state, and local regulatory agencies, consulting engineering firms, and law offices.

Acknowledgements

The author wishes to acknowledge David J. Wirth for contributing the section on the Clean Water Act and Lorna W. Rubenaker for typing, editing, organizing, and producing the figures and tables.

Environmental Protection System

U.S. environmental protection has become a complex system of statutes, regulations, guidance documents, executive directives, and standards that are intended to protect human health and the environment. A basic understanding of these requirements will assist those who need to reduce or eliminate the environmental impact of their operations in a cost-effective manner.

History of the Environmental Movement. Winston Churchill wrote that "The further back you look, the further forward you can see." The history of the environmental movement shows that environmental management is inextricably linked to population, resources, and technology.

In the 17th and 18th centuries, resources such as land, timber, fish, minerals, and water were considered inexhaustible and free for the taking. This way of thinking changed as the population grew. By the late 18th century, New York, Chicago, and Philadelphia alone contained over one million people. By 1910, 50% of the U.S. population lived in cities.

During the era of the Great Depression, the Tennessee Valley Authority, the Civilian Conservation Corps, the Soil Conservation Service, and the Wilderness Society were created to provide jobs to the unemployed and begin nursing the land. When World War II brought massive industrialization without regard for air or water quality, many states drafted legislation to curtail pollution.

The social revolution of the 1960s and 1970s brought the Clean Air Act and the Clean Water Act, but these did little but divert wastes to landfills. In 1980 the Resources Conservation and Recovery Act (RCRA) was passed for the purpose of tracking hazardous waste from "cradle to grave." The 1990s opened a new era in which we better understand past practices and look less often for end-of-pipe or end-of-stack treatments. We now look at design, materials, and processes to eliminate the root causes of waste production and pollution.

Environmental Law. The term *environmental law* does not fully convey its meaning. Once a law is developed, rules for compliance are promulgated, and recordkeeping systems, monitoring procedures, and inspection schedules are developed to enforce compliance. For example, for the eight federal statutes discussed in this article, which constitute some 1,200 pages of text, another 13,000 pages of federal regulations have been developed to carry out the laws (Fig. 1), along with countless more pages of state and local laws, regulations, and guidance documents. These pages have evolved into a web of requirements that constitutes a classic "command and control" system of enforcement.

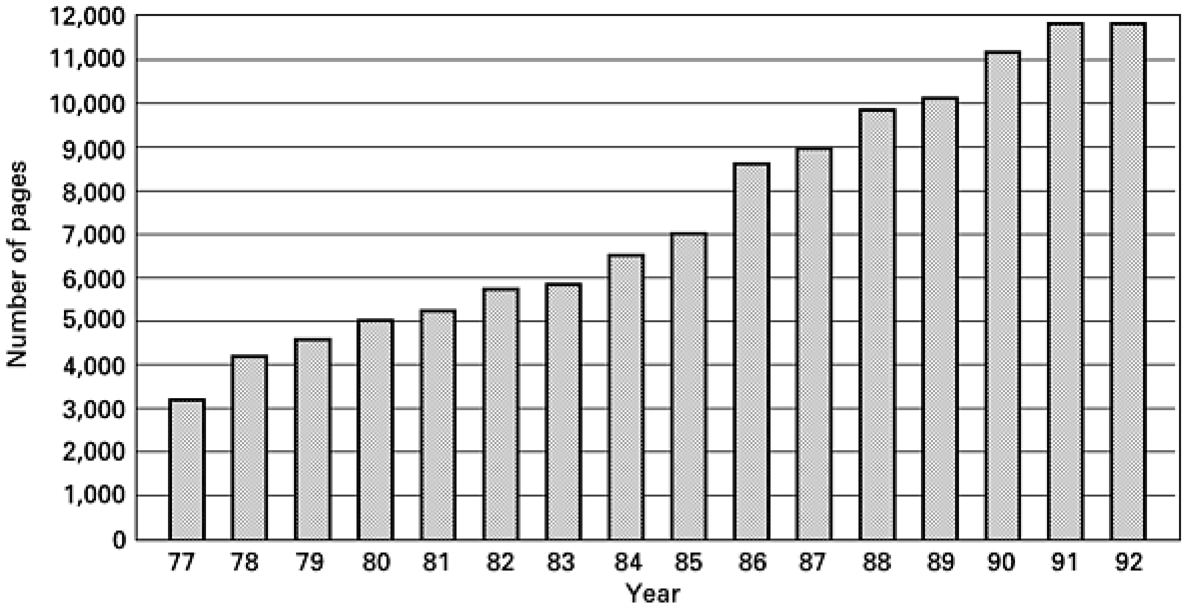

Fig. 1 Growth of federal regulation. The 1992 figure is given as of July 1. Source: 40 CFR

The Legislative Process. Federal and state procedures for making laws are similar. The first step in the federal procedure is that a bill is introduced in either the U.S. House of Representatives or the U.S. Senate. Each bill is assigned a number, preceded by an "S" (for a Senate bill) or "H.R." (for a House bill). Bills are then referred to committees of focused expertise for consideration. These committees hold hearings, study, investigate, and issue a report on the bill. When a bill is "reported out" of a committee, it is debated by the House and/or Senate. The House and Senate typically pass different versions of bills, which are then sent to a joint conference committee. When that committee comes to agreement, a bill is sent to the President for signature or veto within ten days. Once signed, a bill is public law.

State and Local Laws. Federal law generally sets only the minimum requirements of environmental law. States and local jurisdictions have the right to exceed federal standards to meet regional needs. In most large metropolitan areas, local rules will be considerably more stringent than the federal requirements in this article.

The Regulatory Process. Environmental laws empower administrative agencies, such as the Environmental Protection Agency (EPA) and the Occupational Safety and Health Administration (OSHA), to promulgate detailed regulations on how to meet the law. Alternatively, the President can write an Executive Order and direct an agency such as the Department of Defense to promulgate regulations.

Rulemaking includes collecting data from industry. The EPA often uses a mandatory questionnaire called a Section 114 request to collect data. The EPA then interprets the data and proposes regulations in the *Federal Register.* After a comment period, final regulations are published in the *Federal Register,* along with preamble discussion of the comments received and their interpretation by the agency. These regulations have the same effect as law and are incorporated into the *Code of Federal Regulations* (CFR).

Figure 2 shows the typical relationships between the legislative and regulatory processes.

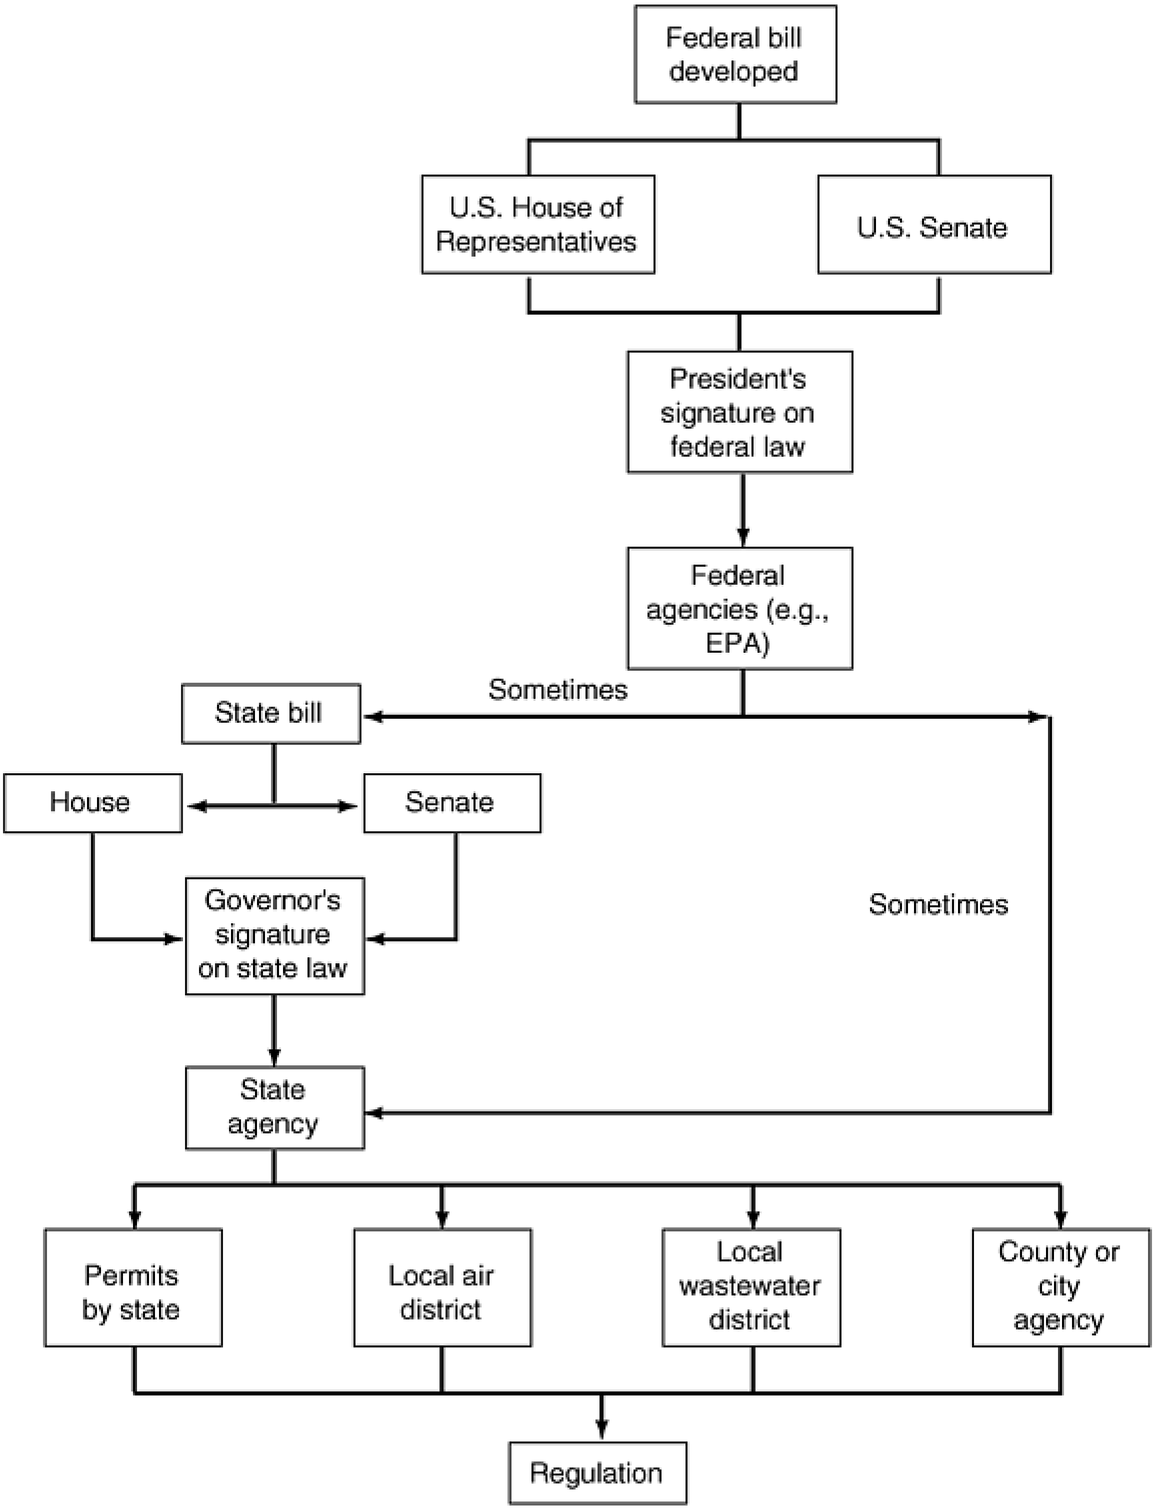

Fig. 2 Typical relationships between the legislative and regulatory processes

Content of Environmental Laws and Regulations. Most environmental laws and ensuing regulations contain the same elements:

- Broad statement of purpose
- Inventory of the problem
- Standards of compliance with emissions, discharges, or disposal
- Notification of the public

- Monitoring and records
- Government fee or funding mechanism
- Prohibitions and/or bans
- Technical control equipment and material standards
- Inspection and assistance
- Reports and/or plans
- Enforcement penalty requirements
- Permits
- Detailed compliance requirements, such as labeling and signs

These elements place the burden on the regulated community to provide information to the government that establishes compliance with the law. A facility must inform the government if it plans to engage in any activity that may result in storing, using, or releasing a regulated material. This begins a complex chain of planning, permit seeking, training, self-monitoring, and reporting. Noncompliance typically results in both civil and criminal penalties. Therefore, it is imperative that all surface preparation processes be understood in the context of environmental law.

The Clean Air Act

The federal Clean Air Act (CAA), written in 1965 and amended in 1970, 1977, and 1990, is the most controversial and industry-intrusive environmental law ever developed. Initially it researched air quality, federalized air pollution control, provided for health protection, and controlled mobile and stationary sources of pollutants (e.g., automobiles and factories).

The 1977 amendments added National Ambient Air Quality Standards (NAAQS), which set criteria for designating regions of the country that do not meet standards for particulates, nitrous oxide (NOX), sulfur oxide (SOX), lead, carbon monoxide, and ozone-depleting substances. These areas of "nonattainment" can then be targeted for stricter requirements.

The 1990 amendments are the most onerous to industry in that they ban, restrict, and/or rigidly control most chemical emissions from industry. Most of the requirements will be effective between 1995 and 2000, posing both drastic changes and opportunities for surface engineering. The basic requirements for surface engineering are scheduled to expand considerably through the year 2000, so the reader should review the most up-to-date literature available.

Overview. The CAA requires that material surface finishers:

- Reduce or eliminate the use of volatile organic compounds (VOCs), which create smog through photochemical reactions. Most VOCs will be reduced, categorically, by industry group.
- Control, reduce, or eliminate 189 chemicals determined to be hazardous air pollutants (HAPs). Under the National Emission Standard for Hazardous Air Pollutants (NESHAP), hundreds of regulations are being written for emitting industries.
- Phase out ozone-depleting substances
- Obtain an operating permit for sources of VOCs and HAPs that trigger threshold amounts
- Reduce emissions from power plants, to reduce the generation of "acid rain" from NOX and SOX

Applicability. Following are the broad thresholds for determining whether a surface finishing process requires an operating permit and may be subject to additional regulations. These thresholds are presented for general information only; the reader is advised to consult local authorities.

- *Source of VOCs:* Has the potential to emit more than 10, 25, 40, or 100 tons/year of VOCs, depending on the region. VOC emissions are the cumulative weight of chemicals emitted from cleaning, degreasing, painting, wiping, and similar processes, assuming operation for 24 hours/day, 365 days/year.
- *Source of HAPs:* Has the potential to emit more than 10 tons/year of any listed HAP (Table 1) or more than 25 tons/year of a combination of HAPs

- *Source of Ozone-Depleting Substances:* Emits any volume of chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), halons, or methyl chloroform (1,1,1-trichloroethane)
- *Source of NOX or SOX:* Has the potential to emit more than 25 tons/year

Table 1 List of hazardous air pollutants regulated by the Clean Air Amendments of 1990

CAS No.	**Chemical name**
75070	Acetaldehyde
60355	Acetamide
75058	Acetonitrile
98862	Acetophenone
53963	2-Acetylaminofluorene
107028	Acrolein
79061	Acrylamide
79107	Acrylic acid
107131	Acrylonitrile
107051	Allyl chloride
92671	4-Aminobiphenyl
62533	Aniline
90040	o-Anisidine
1332214	Asbestos
71432	Benzene (including benzene from gasoline)
92875	Benzidine
98077	Benzotrichloride

100447	Benzyl chloride
92524	Biphenyl
117817	Bis(2-ethylhexyl)phthalate (DEHP)
542881	Bis(chloromethyl)ether
75252	Bromoform
106990	1,3-Butadiene
156627	Calcium cyanamide
105602	Caprolactam
133062	Captan
63252	Carbaryl
75150	Carbon disulfide
56235	Carbon tetrachloride
463581	Carbonyl sulfide
120809	Catechol
133904	Chloramben
57749	Chlordane
7782505	Chlorine
79118	Chloroacetic acid
532274	2-Chloroacetophenone
108907	Chlorobenzene
510156	Chlorobenzilate

67663	Chloroform
107302	Chloromethyl methyl ether
126998	Chloroprene
1319773	Cresols/Cresylic acid (isomers and mixture)
95487	o-Cresol
108394	m-Cresol
106445	p-Cresol
98828	Cumene
94757	2,4-D, salts and esters
3547044	DDE
334883	Diazomethane
132649	Dibenzofurans
96128	1,2-Dibromo-3-chloropropane
84742	Dibutylphthalate
106467	1,4-Dichlorobenzene(p)
91941	3,3-Dichlorobenzidene
111444	Dichloroethyl ether (Bis(2-chloroethyl)ether)
542756	1,3-Dichloropropene
62737	Dichlorvos
111422	Diethanolamine
121697	N,N-Diethylaniline (N,N-Dimethylaniline)

64675	Diethyl sulfate
119904	3,3-Dimethoxybenzidine
60117	Dimethyl aminoazobenzene
119937	3,3'-Dimethyl benzidine
79447	Dimethyl carbamoyl chloride
68122	Dimethyl formamide
57147	1,1-Dimethyl hydrazine
131113	Dimethyl phthalate
77781	Dimethyl sulfate
534521	4,6-Dinitro-o-cresol, and salts
51285	2,4-Dinitrolphenol
121142	2,4-Dinitrotoluene
123911	1,4-Dioxane (1,4-Diethyleneoxide)
122667	1,2-Diphenylhydrazine
106898	Epichlorohydrin (1-Chloro-2,3-epoxypropane)
106887	1,2-Epoxybutane
140885	Ethyl acrylate
100414	Ethyl benzene
51796	Ethyl carbamate (Urethane)
75003	Ethyl chloride (Chloroethane)
106934	Ethylene dibromide (Dibromoethane)

107062	Ethylene dichloride (1,2-Dichloroethane)
107211	Ethylene glycol
151564	Ethylene imine (Aziridine)
75218	Ethylene oxide
96457	Ethylene thiourea
75343	Ethylidene dichloride (1,1-Dichloroethane)
50000	Formaldehyde
76448	Heptachlor
118741	Hexachlorobenzene
87683	Hexachlorobutadiene
77474	Hexachlorocyclopentadiene
67721	Hexachloroethane
822060	Hexamethylene-1,6-diisocyanate
680319	Hexamethylphosphoramide
110543	Hexane
302012	Hydrazine
7647010	Hydrochloric acid
7664393	Hydrogen fluoride (Hydrofluoric acid)
123319	Hydroquinone
78591	Isophorone
58899	Lindane (all isomers)

108316	Maleic anhydride
67561	Methanol
72435	Methoxychlor
74839	Methyl bromide (Bromomethane)
74873	Methyl chloride (Chloromethane)
71556	Methyl chloroform (1,1,1-Trichloroethane)
78933	Methyl ethyl ketone (2-Butanone)
60344	Methyl hydrazine
74884	Methyl iodide (Iodomethane)
108101	Methyl isobutyl ketone (Hexone)
624839	Methyl isocyanate
80626	Methyl methacrylate
1634044	Methyl tert butyl ether
101144	4,4-Methylene bis(2-chloroaniline)
75092	Methylene chloride (Dichloromethane)
101688	Methylene diphenyl diisocyanate (MDI)
101779	4,4'-Methylenedianiline
91203	Naphthalene
98953	Nitrobenzene
92933	4-Nitrobiphenyl
100027	4-Nitrophenol

79469	2-Nitropropane
684935	N-Nitroso-N-methylurea
62759	N-Nitrosodimethylamine
59892	N-Nitrosomorpholine
56382	Parathion
82688	Pentachloronitrobenzene (Quintobenzene)
87865	Pentachlorophenol
108952	Phenol
106503	p-Phenylenediamine
75445	Phosgene
7803512	Phosphine
7723140	Phosphorus
85449	Phthalic anhydride
1336363	Polychlorinated biphenyls (Aroclors)

CAS, Chemical Abstract Service. Note: For all listings that contain the word *compounds* and for glycol ethers, the following applies: Unless otherwise specified, these listings are defined as including any unique chemical substance that contains the named chemical (that is, antimony, arsenic, and so forth) as part of that chemical's infrastructure.

Source: Public Law 101-549, Title II

(a) X'CN where X = H' or any other group where a formal dissociation may occur [e.g., KCN or $Ca(CN)_2$].

(b) Includes monoethers and diethers of ethylene glycol, diethylene glycol, and triethylene glycol $R\text{-}(OCH2CH2)_n\text{-}OR'$ where n = 1, 2, or 3; R = alkyl or aryl groups; and R' = R, H, or groups which, when removed, yield glycol ethers with the structure $R\text{-}(OCH2CH)_n\text{-}OH$. Polymers are excluded from the glycol category.

(c) Includes mineral fiber emissions from facilities manufacturing or processing glass, rock, or slag fibers (or other mineral-derived fibers) of an average diameter of 1 μm or less.

(d) Includes organic compounds with more than one benzene ring and which have a boiling point greater than or equal to 100 °C (212 °F).

(e) A type of atom that spontaneously undergoes radioactive decay.

Requirements for VOCs under NAAQS. In general, under NAAQS an operation that releases VOCs is required to:

- Install and maintain emissions control and monitoring equipment
- Adhere to the regulations for emission limits and control
- Undergo inspections
- Pay emission fees to fund governmental programs
- Before increasing VOC emissions, offset new emissions at a ratio of 1.1 to 1, 1.15 to 1, 1.2 to 1, 1.3 to 1, or 1.5 to 1, depending on local air quality

In addition, existing sources must meet reasonably available control technology (RACT) standards defined by the control techniques guidelines (CTGs) of the EPA. New or modified sources must meet the lowest achievable emission rates (LAERs), typically identified as best available control technology (BACT). For example, control requirements include:

- Limiting the VOC solvent content of paint
- Limiting the vapor pressure of solvents
- Using a hood to capture emissions, which in turn are forced through carbon absorbers or ultraviolet oxidation systems
- Using high-transfer-efficiency application equipment
- Maintaining spent wipe solvent rags in closed containers

- Limiting plantwide emissions

Imposition of a permit incorporates all requirements such as offset limits, BACT and/or RACT, recordkeeping, and fees. These requirements are predicated on local air quality according to the NAAQS. Sections 181 to 185 of subtitle D of the CAA discuss these standards and their applicability.

Requirements for HAPs under NESHAP. Table 1 lists 189 chemicals determined to be HAPs. The EPA has published a list of sources that are to be covered under industry-specific regulations:

- Halogenated solvent cleaning (vapor degreasing)
- Aerospace components and assembly
- Chromic acid anodizing
- Hard chrome plating
- Reinforced plastic parts

By way of example, the following table lists many of the chemicals used in aerospace production:

Process	**Chemicals**
Raw materials	. . .
Machining/etching	Chlorofluorocarbons, volatile organic compounds, acids, oils
Cleaning	Volatile organic compounds, chlorinated solvents, chlorofluorocarbons, alcohol
Plating/anodizing	Heavy metals, acids
Coating/painting	Heavy metals, volatile organic compounds, chlorinated solvents
Stripping	Chlorinated solvents
Assembly	Glues, sealants, lubricants
Painting	Heavy metals, volatile solvents, chlorinated solvents
Maintenance	Halons, freons, oils, solvents

Regulations are required on a statutory timeline that began on November 15, 1992 and is scheduled to end on November 15, 2000. To determine whether a particular industry is covered by all or some of these regulations, the reader should consult local air authorities.

Maximum Available Control Technology. The sources listed above are required to use an emission standard known as maximum available control technology (MACT). For new facilities, MACT is the best demonstrated control technology and practices in a category or subcategory of emission sources. For existing facilities, MACT is defined, in theory, as the average emission limitation of the best controlled 12% of existing sources in the category or subcategory. In developing MACT standards, the EPA can consider:

- Process changes
- Materials substitution
- Enclosed systems and processes
- Collection, capture, or treatment of pollutants
- Design, equipment, work practice, or operational standard
- A combination of the above

Area Source Program. If a particular process does not fall into an identified category or subcategory, but a HAP from Table 1 is in use, it will probably be regulated by 1995 by an area source program. Such programs identify the emission of HAPs from sources that are believed to pose significant health risks even though they are not major sources. A rule of thumb is that if a HAP cannot be eliminated or replaced with a non-HAP, it will eventually be regulated by one or more regulations under NESHAP.

Accidental Releases. A forthcoming EPA regulation, which was due in November 1993, will address the prevention of accidental releases of any of 160 hazardous chemicals. As of this writing, the proposed regulation covers risk management, hazard assessment, training and procedures, emergency response, and the use, operation, replacement, and maintenance of equipment to monitor or prevent releases.

Requirements for Ozone-depleting Substances. Ozone-depleting substances are halogenated compounds that are stable in the lower atmosphere where we live (the troposphere) but are highly unstable at higher levels (the stratosphere). There they react with ozone and form new compounds that deplete the ozone layer, which screens much ultraviolet radiation from reaching the earth. Ozone-depleting substances include CFCs, HCFCs, halons, carbon tetrachloride, and methyl chloroform (1,1,1-trichloroethane).

To prevent further damage to stratospheric ozone, the United States has joined with most other industrialized countries to phase out ozone-depleting substances through production bans. This agreement, which was accomplished at a United Nations meeting, is known as the Montreal Protocol. The U.S. Congress accelerated the production ban schedule to January 1, 2000, and former President Bush, through executive order, further shortened the schedule to December 31, 1995. The phaseout of HCFCs is not scheduled to occur until the year 2015, but in all likelihood it will be rolled back.

Operating Permits. Operating permits are, or will be, required for any source that is subject to NAAQS or NESHAP. Permit programs fund state and local air quality authorities and give them enforcement tools.

Permits were required as early as November 15, 1993, depending on the status of EPA, state, and local rule development. If a source is identified as requiring a permit, it has 12 months to submit an application. The minimum requirements are that:

- A permit application and compliance plan must be prepared and submitted.
- Monitoring and reporting requirements are established and submitted at least every six months.
- Permit holders must certify annually that the facility is in compliance with permit requirements.
- A fee of at least $25/ton of pollutant must be paid annually.
- Permits are valid for no more than five years.
- Public comment periods and hearings are required.

Other Requirements. Regional offices of the EPA can provide detailed information about the subjects discussed in this section, as well as information about acid rain, mobile sources of pollutants, enforcement, and miscellaneous regulations.

The Resources Conservation and Recovery Act

The Resources Conservation and Recovery Act (RCRA, pronounced "rick-rah") is the primary law that governs the management of waste, both hazardous and solid. It provides for technical and financial assistance to resource programs, minimization of waste, safe disposal of waste, and regulation of hazardous waste. RCRA is known as the "cradle to grave" law in that as soon as a waste is conceived (a material is no longer useful) it must be documented and tracked through its storage, transport, treatment, and final disposition (normally by landfill, incineration, or deep-well injection).

Although signed into law in 1976, RCRA regulations were first published in 1980, when day-to-day waste management concerns for industry began. RCRA was amended in 1984 with the Hazardous and Solid Waste Amendments (HSWA), and it now controls the generation, treatment, storage, transportation, disposal, training, and labeling of waste. It also controls underground storage tanks, sumps, pollution prevention, recyclers, and transporters of waste.

The discussion of RCRA in this section is limited to very simple concepts, and the reader should consult a regional EPA office or equivalent state agency for detailed information.

Definition of Hazardous Waste. Fundamentally, once a material is discarded, it is a waste. RCRA regulates solid waste, which includes hazardous waste (such as sludges and spent acids) and nonhazardous waste (such as household garbage). The determination of whether a waste is hazardous (and therefore whether the facility will be subject to the requirements of RCRA) depends on whether the waste is a threat to human health and the environment. A hazardous waste is one that meets any of the following criteria:

- Appears on an EPA list ("F," "K," "P," and "U" lists are found in 40 CFR 261.3)
- Exhibits a hazardous characteristic (flammability, corrosivity, reactivity, or toxicity)
- Is a mixture of solid waste with hazardous waste. The resultant mixture is hazardous with some exceptions.

These criteria are summarized in Fig. 3. As with all environmental regulations, a variety of exclusions apply. If a waste is not hazardous, it generally can be discarded as municipal waste. If it is hazardous, the facility is regulated.

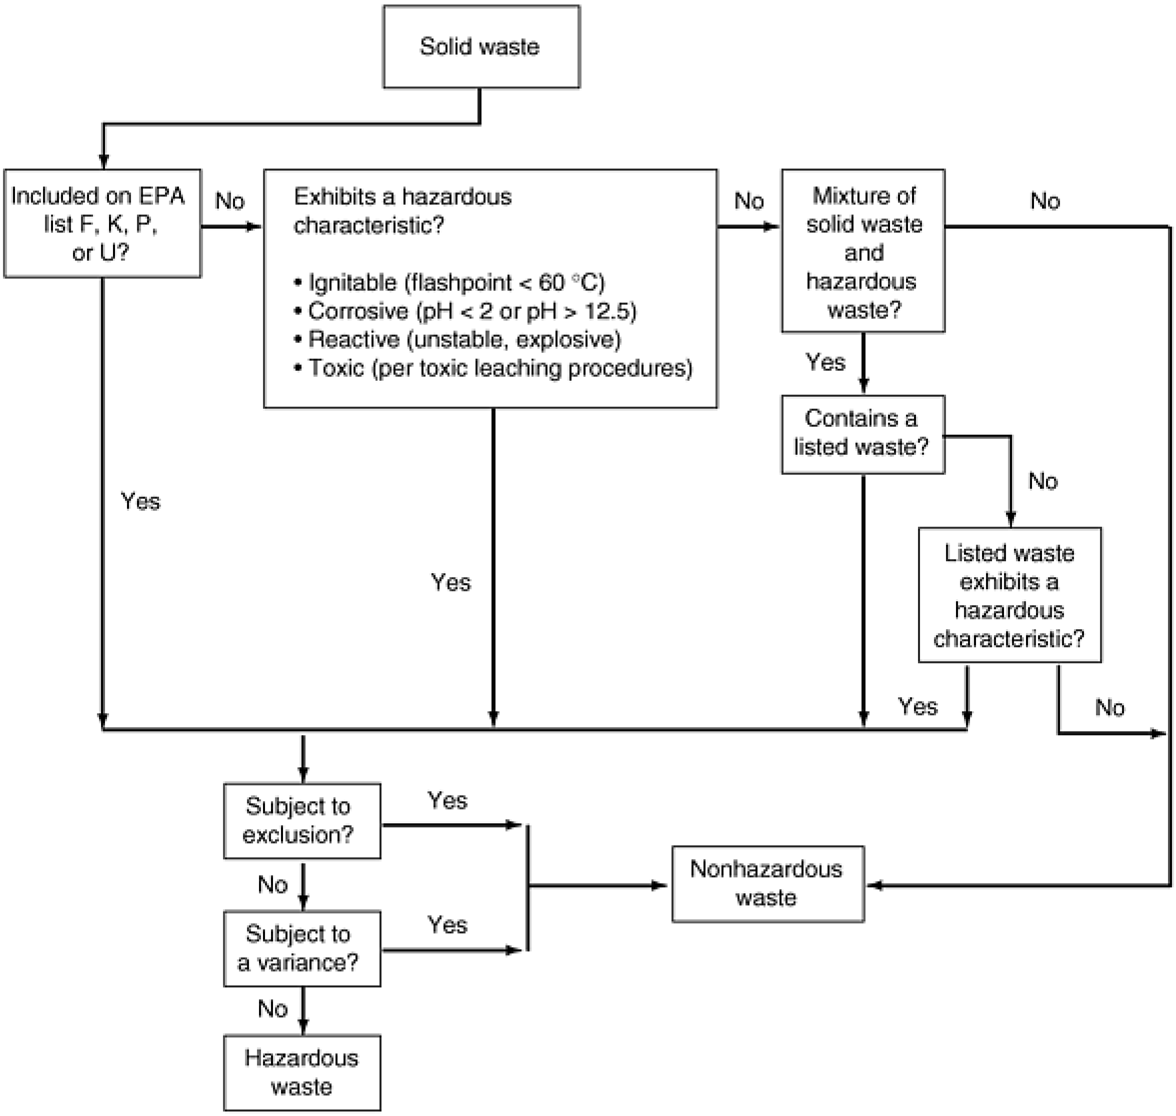

Fig. 3 Criteria for determining whether a solid waste is hazardous

Requirements for Hazardous Waste Generators. If a facility creates a hazardous waste, it must obtain an EPA identification number and follow regulations about such matters as containers and storage tanks, inspections, employee training, waste minimization, transportation, recordkeeping and recording, and selection of treatment, storage, and disposal (TSD) sites. How a facility is regulated depends on the amount of waste generated.

Large-quantity generators produce more than 1000 kg/month of hazardous waste or more than 1 kg/month of acutely hazardous waste. They may store wastes for only 90 days. In addition, they must:

- Use approved containers that are compatible with the waste and are marked with specific information. Storage procedures must meet fire code satellite requirements.
- Comply with sump and tank requirements. Hazardous waste tanks must meet requirements for secondary containment, leak detection, cathodic protection, overfill alarms, spill prevention, labels, integrity, and so on.
- Conduct a daily inspection of hazardous waste storage areas, transfer areas, and tanks.
- Create an emergency response program that includes a preparedness program, a prevention program, and a contingency plan that is carried out whenever there is a release of hazardous waste.
- Develop, and repeat annually, employee training programs for identifying, packaging, labeling, and transporting hazardous waste, as well as training programs about waste handling, identifying the

properties of waste on-site, and the use of safety equipment.
- Employ programs to minimize waste, including an annual report.
- Comply with transportation and packaging requirements.
- Comply with prohibitions on the disposal of certain wastes in landfills.
- Send wastes to a TSD facility that is approved to handle the types of wastes generated.
- Comply with a host of recordkeeping and reporting requirements.

Small-quantity generators produce between 100 and 1000 kg/month of hazardous waste. They may store up to 6000 kg of waste for up to 180 days (270 days if it is to be shipped more than 200 miles to a TSD). Small-quantity generators are subject to most of the same requirements as large-quantity generators, with some exceptions.

Conditionally exempt small-quantity generators produce no more than 100 kg/month of hazardous waste, no more than 1 kg/month of acutely hazardous waste, and no more than 100 kg/month of waste debris such as contaminated soil. They may store 1000 kg of hazardous waste for any period. While exempt from most requirements, they must determine which wastes are hazardous, keep records, store wastes legally, and transport wastes to an approved TSD facility.

Requirements for TSD Facilities. RCRA defines treatment, storage, and disposal as follows:

- *Treatment:* "Any method, technique, or process including neutralization, designed to change the physical, chemical, or biological character or composition of any hazardous waste so as to recover energy or material resources from the waste, or so as to reduce such waste to non-hazardous or less hazardous; safer to transport, store, or dispose of; amendable for recovery or storage; or reduced in volume."
- *Storage:* "The holding of hazardous waste for a temporary period, at the end of which, the hazardous waste is treated, disposed of, or stored elsewhere."
- *Disposal:* "The discharge, deposit, injection, dumping, spilling, leaking, or placing of any solid waste or hazardous waste into or on any land or water so that such solid waste or hazardous waste or any constituent thereof, may enter the environment or be emitted into the air or discharged into any waters, including ground waters."

A TSD facility uses surface impoundments (such as sludge ponds), waste piles, landfills, chemical/physical/biological treatment, and/or incineration to treat, store, or dispose of waste on-site. It is subject to extensive permit application requirements and conditions if it:

- Stores waste longer than 90 days
- Uses surface impoundments or waste piles
- Stores recyclable materials longer than 90 days
- Treats or disposes of hazardous waste

Such facilities typically specialize in waste management, due to the high cost of maintaining permit conditions. However, a manufacturing site can also use one or more of these TSD methods, and if so it is subject to the same rigorous requirements. All TSD facilities must have permits, which regulate such matters as waste analysis, inspections, security, training, waste management, facility maps, emergency response, air emission control, recordkeeping systems, groundwater monitors, infrastructure, containment, financial assurances, and closure. Unless TSD operations are primary to the business, it is unlikely that a surface treatment facility would want or need to maintain a TSD permit.

Superfund Amendments and Reauthorization Act

In December 1980, the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), commonly known as "Superfund," was passed into law. It established a program to identify sites where hazardous materials are released into the environment and ensure that they are cleaned up by responsible parties.

What has more bearing on surface engineering processes is the 1986 reauthorization of CERCLA, known as the Superfund Amendments and Reauthorization Act (SARA). In addition to extending CERCLA, SARA Title III created the Emergency Planning and Community Right to Know Act (EPCRA), a sweeping system for informing. community emergency planners and the public about what chemicals are being used, where they are being used, and how much are being released into the air, water, or land as pollution.

Publicity of "SARA 313 releases" has done more to motivate research into alternative surface finishing processes than any other mechanism.

Overview. The EPCRA section of SARA includes two sets of significant requirements:

- *Requirements about release notification and emergency response planning:* Facilities must inform government agencies of hazardous material releases and have the appropriate equipment, personnel, and training to respond to a cleanup.
- *Requirements about reporting,* which are divided into three sections: 311, 312, and 313. Section 311 requires that material safety data sheets for chemicals used at a facility be given to the local fire department or an emergency planning committee. Section 312 requires a facility-wide inventory of what chemicals are where within the facility. Section 313 requires that an annual report about toxic releases be submitted each July 1 to the federal government.

Section 313. A U.S. facility is required to submit the annual toxic chemical release report if it has more than 10 employees, falls into certain industry categories (Standard Industrial Codes 20 to 39), uses a toxic chemical in excess of 10,000 lb/year, or manufactures a toxic chemical in excess of 25,000 lb/year. For each chemical used at the facility, an EPA form R must be submitted that shows:

- EPA permit numbers
- Storage and treatment data
- A pollution prevention report for the chemical
- The quantity of chemical released to air, water, or offsite transfer
- Business information
- Executive certification of the report's accuracy

Clean Water Act

Protection of water resources is a critical issue in the design and operation of a manufacturing facility that uses surface engineering processes. Nearly every facility of this type uses water in a variety of ways: for cooling, cleaning and rinsing, anodizing, and plating baths. Even facilities that do not use water directly in manufacturing processes should be aware of water issues because of concerns about stormwater and groundwater quality.

Wastewater Discharge. The primary water-related concerns about surface engineering processes are the quality and quantity of wastewater discharges and the design and operation of the facility to protect stormwater and groundwater. The procedure that is most heavily regulated by the Clean Water Act, and probably most costly to deal with, is the discharge of wastewaters to either surface waters or to publicly owned treatment works (POTWs).

NPDES Permits. Federal regulations (40 CFR 122) prohibit the discharge of wastewater to any surface water body without a National Pollutant Discharge Elimination System (NPDES) permit. The permit is administered by either the EPA or a designated state agency, depending on the location of the facility. It requires the discharger to characterize the volume and composition of the discharge, sets maximum discharge temperatures and flow rates, outlines how the discharger must monitor the discharge, and specifies maximum pollutant compositions based on either technology or water quality. (Technology-based limits are established by determining the level of treatment that is both technically and economically feasible for a particular industry. Water-quality-based limits are based on minimizing the potential effects of the discharge on the receiving water body.) NPDES permits remain in effect for five years, and the requirements of subsequent permits are typically stricter, as more aggressive technology-based or water-quality-based standards are developed.

Requirements of Dischargers. Wastewater discharges to POTWs do not require an NPDES permit but are regulated by comparable pretreatment standards imposed on specific industry categories (40 CFR 403). Many states or municipalities have permit programs to regulate these discharges. Pretreatment standards are technology-based and are calculated by determining the level of treatment that is both technically and economically feasible for a particular industry. They are set in a manner that prevents the discharge of materials that would adversely impact the operation of the POTW or that would pass through the POTW without receiving adequate treatment.

Facilities often have the option of discharging treated wastewater either directly to surface waters or to a POTW for further treatment prior to discharge. NPDES-permitted discharges to surface waters usually require more extensive treatment and monitoring than discharges to POTWs. On the other hand, indirect dischargers must pay a fee to the POTW to help cover the costs of its operations. The preferred choice is the option that allows all regulatory requirements to be met at a lower cost.

Requirements of Technology. The pollutants of most concern to operations using surface engineering processes are metals and toxic organics. Treatment technologies are available to remove these materials from wastewater streams.

The traditional method of removing metals is to modify the pH of the wastewater stream to precipitate insoluble metal hydroxides. The principal drawback is that significant quantities of hazardous sludges are formed that are costly to dispose of. These disposal costs can be reduced by using filter presses or dryers to reduce sludge volumes. Other treatment techniques have been developed to more cost-effectively remove, and even recycle, these pollutants.

A variety of techniques are available to remove or destroy toxic organics in wastewater: chemical oxidation, ozonation, and biological treatment. Each treatment process has different capabilities, and the preferred process will be a function of the characteristics of the wastewater stream and discharge requirements.

The costs of complying with increasingly complex safety, health, and environmental regulations are powerful incentives for implementing pollution prevention programs. Many products can be either redesigned or modified to allow the use of more environmentally acceptable materials and processes in manufacturing operations. The use of these materials and processes can help the manufacturer reduce or eliminate the need for additional wastewater treatment equipment. Many of these efforts are win-win situations, where implementing the new material or process results in both reduced emissions to the environment and lower costs to the manufacturer. Examples of successful pollution-prevention efforts are the use of boric-sulfuric acid anodizing to replace chromic acid anodizing operations and the use of zinc-nickel plating to replace cadmium plating.

Stormwater Discharge. Wastewater discharges are not the only area in which facilities are affected by water-related environmental concerns. Most facilities containing typical surface engineering processes need an NPDES permit for stormwater discharges. Facilities are required to obtain NPDES stormwater discharge permits if three conditions are met:

- The Standard Industrial Code of the facility is on the list of regulated operations, as given in 40 CFR 122.
- Stormwater from the facility is discharged to surface waters.
- Operations have the potential to cause stormwater contamination by allowing stormwater to contact hazardous materials at the facility. Examples of this include storing drums of hazardous materials in covered outdoor areas or having uncovered loading docks where hazardous raw materials or finished products are transported.

The NPDES stormwater discharge permit program requires dischargers to develop and implement stormwater pollution prevention plans to identify and correct problem areas.

Water Supply Issues. In addition to the water quality issues described above, water quantity issues are becoming increasingly important. In many areas of the country, water supply costs are rising dramatically, and in some areas increased supplies of water are simply unavailable. While reducing the water usage of a facility is typically not a regulatory concern, strong economic drivers exist for implementing water conservation programs. Many opportunities to cost-effectively reduce water consumption are available, including the use of double (and even triple) countercurrent rinsing, the replacement of once-through cooling systems with closed-loop systems, and the use of wastewater treatment techniques that recycle the treated effluent for use elsewhere in the facility.

Other water-related concerns at a typical facility include the potential impact of leaking sumps and underground storage tanks on groundwater. Requirements for the design, construction, operation, maintenance, and removal of underground storage tanks and sumps are outlined in 40 CFR 280. Recordkeeping and release reporting are also required.

Other Environmental Statutes

Several other federal statutes are germane to this article:

- The Safe Drinking Water Act (SDWA) provides substantial requirements for public water supply systems.
- The Toxic Substances Control Act (TSCA) regulates the invention, use, marketing, and importation of chemicals and evaluates health and environmental effects of chemicals. It requires a chemical manufacturer or importer to provide health and environmental data, limit how much chemical is used, have approval for distribution, provide warnings, and maintain test results. Engineers who reformulate materials are advised to understand TSCA.
- The Federal Insecticide, Fungicide, and Rodentacide Act (FIFRA) regulates the manufacture and use of pesticides.
- The National Environmental Policy Act (NEPA) declares national environmental policy and requires federal agencies to consider environmental concerns when taking actions such as issuing permits.

Local officials and environmental consulting firms can provide information about whether these statutes apply to a particular operation.

Cadmium Elimination in Surface Engineering

Mark W. Ingle, Corrpro Companies, Ocean City Research Corporation

Introduction

CADMIUM is a soft, blue-white metal widely used as a corrosion control coating on ferrous (e.g., mild and high-strength steel) substrates. Electroplated cadmium coatings are typically applied at thicknesses of between 5.1 and 12.7 μm (0.2 and 0.5 mil) (Ref 1). Chromate treatments (based on hazardous chromic acid) are frequently applied to cadmium coatings as a final passivation process. Cadmium coatings have historically provided effective substrate corrosion control performance when applied to threaded fasteners, connectors, and general hardware (Ref 2, 3). The technical performance benefits and limitations associated with cadmium coatings are well established.

However, over the past decade, environmental and worker health regulations affecting cadmium use have been promulgated in the United States and in Western Europe. These regulations have increased the costs associated with cadmium coating application and cadmium-bearing waste disposal, creating economic incentives for industrial users to seek cadmium plating replacements. Unfortunately, no universal cadmium replacement has yet been identified. Thus, viable cadmium replacements must be identified on a case-by-case basis in which technical performance requirements, environmental issues, and costs are considered. Identification of effective cadmium replacements can reduce product costs and minimize regulatory compliance problems. Ineffective cadmium replacements can lead to degraded component-corrosion control performance and, in extreme cases, catastrophic component failures.

Rationale for Replacing Cadmium Coatings

Historically, cadmium coatings have been applied to mild and high-strength steel components as an economical and effective means of controlling in-service substrate corrosion (see the article "Cadmium Plating" in this Volume). Although cadmium coating performance has not changed over the years, recent revisions to environmental and worker health laws in the United States and other countries have created a regulatory climate in which continued cadmium use is becoming cost-prohibitive:

- The U.S. Occupational Safety and Health Administration (OSHA) released the "Occupational Exposure to Cadmium; Final Rules" in 1992. OSHA estimates that compliance with these rules will cost domestic industry $159,616,000/year (Ref 4).
- Environmental laws in the United States make cadmium-bearing waste disposal or emissions expensive. In addition, 29 states have passed pollution prevention acts that mandate reductions in hazardous waste (such as waste that contains cadmium) (Ref 5, 6).
- The Swedish Ban on Cadmium was enacted in 1985. Based on this ban, Sweden can forbid the import of certain products containing cadmium (Ref 7).

These laws may increase operating costs, create liability risks, and restrict markets for certain cadmium-coated products. The following sections of this article provide additional details about regulations in the United States and Europe.

Cadmium Worker Health Effects and Laws. OSHA has evaluated the health effects of cadmium on workers and has determined that exposure to respirable particles/fumes represents the most significant risk factor. Cadmium and its compounds are not readily absorbed through the skin, but they can be ingested. Inhaling cadmium or its compounds can directly cause lung cancer, and it also allows the toxic metal to enter the bloodstream. Once in the blood, cadmium readily accumulates in the kidneys, degrading their function. Table 1 shows the estimated levels of lung cancer and kidney dysfunction resulting from varying levels of cadmium exposure.

Table 1 Impact of cadmium exposure levels on worker health

Cadmium TWA PEL[(a)]	**Effective dates**	**Excess lung cancer rate per 1000 workers[(b)]**	**Excess kidney dysfunction rate per 1000 workers[(b)]**
100 μg/m^3	1971-1992	58-157	900
5 μg/m^3	1993-present	3-15	14-23

Source: Ref 4

(a) TWA PEL, time-weighted average permissible exposure limit.

(b) Based on 45-year workplace exposure history.

From 1971 to 1992, OSHA defined the permissible exposure limit (PEL), over an 8-h time-weighted-average day, as 100 µg of cadmium fumes per cubic meter of workplace breathing air (Ref 4, 8). OSHA redefined the acceptable workplace cadmium exposure limits in 1992 by reducing the allowable airborne concentrations of cadmium in the workplace by 95%, from 100 to 5 µg/m^3 (Ref 8). In addition to redefining the PEL, the document "Occupational Exposure to Cadmium; Final Rules" includes extensive provisions for engineering controls on workplace breathing-air cadmium levels, worker safety training, medical monitoring requirements, and, as a worst case, employee respirator use. The current OSHA PEL of 5 µg/m^3 is one of the lowest for common industrial metals. OSHA estimates that compliance with the revised worker safety requirements will cost industries that produce, use, and dispose of cadmium approximately $159,616,000/year (Ref 4).

OSHA data show that the implementation of the 5 µg/m^3 PEL will reduce workplace health risks. Table 1 summarizes the OSHA health impact data and shows that by reducing cadmium exposure from the earlier 100 µg/m^3 to 5 µg/m^3, worker kidney dysfunction and lung cancer rates will decrease appreciably (Ref 4).

Environmental Regulations Related to Cadmium--United States. Table 2summarizes the impact of selected federal laws on cadmium production, application, and waste disposal. As shown, cadmium is considered a hazardous material and is regulated as a "hazardous chemical" or "toxic substance" (Ref 9). The federal laws shown in the table are typically administered on a state or local level through facility permits. Depending on specific permit requirements, the economic impact on facilities can be significant. Compliance costs for permits vary from state to state and are difficult to assess. However, the general consensus in the metal coating industry is that costs for hazardous materials handling and waste disposal are increasing.

Table 2 Federal environmental laws that affect cadmium use, emission, and waste disposal

Federal law	Acronym	Potential impact
Resource Conservation and Recovery Act	RCRA	Hazardous waste disposal regulations create overhead costs and compliance risks.
Comprehensive Environmental Response, Compensation, and Liability Act (Superfund)	CERCLA	Cadmium is a Section 304 hazardous substance. Applicable only to certain releases of cadmium compounds.
Superfund Amendments and Reauthorization Act (Title III)	SARA	Cadmium is a Section 313 toxic chemical. Emissions must be reported.
Clean Water Act and Amendments	CWA	States are reducing allowable cadmium concentrations in facility effluent. Compliance with the new limits may require additional cadmium recovery equipment.
Clean Air Act and Amendments	CAA	Recent amendments define cadmium as a hazardous air pollutant. Cadmium emissions may be taxed.

Source: Ref 9

In addition to the federal regulations, 29 states have enacted pollution prevention laws (Fig. 1). These laws affect cadmium-bearing hazardous wastes specified by the Resource Conservation and Recovery Act and toxic materials specified by the Superfund Amendments and Reauthorization Act, Title III, including cadmium particulates or solutions (Ref 6). State pollution prevention laws generally require industrial facilities to achieve percentage reductions in hazardous material consumption and hazardous waste generation via "source reduction," but the degree to which these laws encourage source reduction varies. Some states offer incentives and funding grants to eliminate hazardous materials, others employ user fees, and some mandate civil fines (e.g., a $15,000 fine for "blatant violators" of the New Jersey Pollution Prevention Act) (Ref 6, 10). These federal and state laws create a significant incentive for industrial users to replace cadmium coatings.

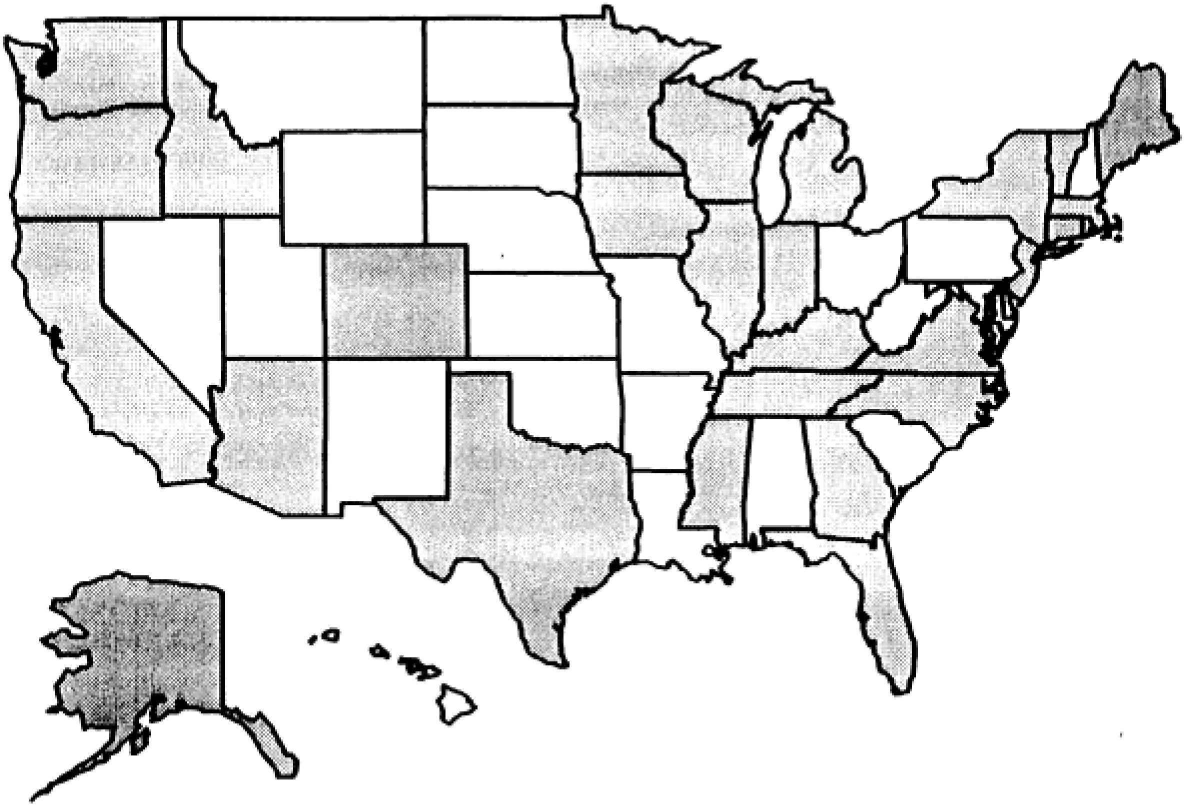

Fig. 1 States that have pollution prevention or hazardous waste minimization laws as of 1994 (shown in gray). Source: Ref 5,

Environmental Regulations Related to Cadmium Use--Europe. Certain European countries have taken more direct steps than the United States to control cadmium use and resulting environmental impacts, including a ban on cadmium use in Sweden, restrictions on cadmium use in Finland, and a virtual ban on cadmium chloride in Germany (Ref 5, 7, 11).

The Swedish Ban on Cadmium summarizes the environmental and worker health risks posed by the metal and then selectively forbids the production or importation of specific items containing cadmium (Ref 7). The following are some specific provisions of the ban:

- Section 45(j)--"The substance cadmium [defined as cadmium plating in Appendix 2 of the Swedish Ban] may not be used for surface treatment, as a stabilize, or as a pigment" (Ref 7).
- Section 45(j)--"Products whose surface has been treated with a cadmium substance or which contain such a substance as a stabilizer or pigment may not be imported commercially" (Ref 7).

The Swedish statute does not ban nickel-cadmium storage batteries and includes exemptions for certain safety products, but its effect on markets for cadmium-plated parts in Sweden is clear.

The trend toward restricting cadmium use is currently spreading throughout Europe. The German government has virtually banned the use of cadmium chloride and is reducing acceptable workplace exposure levels for other cadmium compounds (Ref 4). Finland has announced "prohibitions and restrictions" on products containing cadmium (Ref 11). These actions reflect a trend in the European Economic Community (EEC) that is effectively summarized in the following conclusion from a 1991 EEC report (Ref 12): "There is a significant threat of long term damage to man and the environment by cadmium if appropriate steps are not taken to reduce environmental contamination by this metal."

Cadmium Coating Specifications

Cadmium coatings are applied in accordance with both consensus specifications (e.g., Society of Automotive Engineers) and federal and military specifications. Table 3 lists representative cadmium and cadmium alloy coating specifications. Unless directly specified, cadmium coatings are unlikely to be applied to a component, because cadmium electroplating costs are generally one to two times higher than those for conventional zinc electroplating (Ref 7, 13).

Table 3 Cadmium coating specifications

Specification	Title
General plating	
SAE AMS 2416	Plating, Nickel-Cadmium, Diffused
QQ-P-416E	Plating, Cadmium (Electrodeposited)
MIL-P-23408B	Plating, Tin-Cadmium (Electrodeposited)
SAE AMS 2400S	Cadmium Plating
Plating to minimize potential substrate embrittlement	
AIA NAS 672	Plating, High-Strength Steels, Cadmium

ASTM B 696	Standard Specification for Coatings of Cadmium, Mechanically Deposited
MIL-C-8837B	Coating, Cadmium (Vacuum Deposited)
MIL-C-81562B	Coatings, Cadmium, Tin-Cadmium, and Zinc (Mechanically Deposited)
MIL-STD-870	Cadmium Plating, Low Embrittlement, Electrodeposition
MIL-STD-1500	Cadmium-Titanium Plating, Low Embrittlement
SAE AMS 2401D	Cadmium Plating, Low Hydrogen Content

Cadmium Replacement Identification

Identification of viable cadmium replacements requires engineering analysis of technical performance issues, environmental considerations, and economic factors. As such, a significant portion of the process of identifying cadmium replacements is based on qualitative data and engineering judgment. There is no direct or "one for one" cadmium replacement, so multiple replacements, or no viable replacements, may be identified for specific cadmium applications. This section provides general, qualitative guidance regarding potential cadmium replacements in terms of general performance, environmental, and economic factors. *Caution: Replacing coatings inherently creates performance risks that must be evaluated and accepted by qualified engineers before any coating or material change is implemented*.

To assist with the identification of cadmium replacements, key technical performance, environmental, and economic data have been collected and summarized in Table 4. These data are presented in a qualitative matrix in which the performance of replacements is rated relative to that of cadmium coatings. Because so many of the factors affecting the selection of cadmium replacements are based on case-specific issues, such as substrate material/heat treatment, component configuration, and production volume, specific references are provided to allow engineers to collect additional information. To improve clarity and provide information on how the qualitative ratings were generated, the following paragraphs discuss each column of the table, along with important issues that could affect cadmium replacement decisions.

Table 4 Cadmium replacement identification matrix

Cadmium replacement	**Specifications**	**Corrosion control performance**	**Environment-assisted cracking**	**Coating lubricity**	**Environmental/ worker health regulations**	**Cost/ performance factors**
Zn, Zn-Ni, Zn-Co, or ion vapor deposited	Commercial; MIL-C-83488 with MIL-C-81751 (Ref 3,	Better/comparable (Ref 3, 24)	Worse/comparable (Ref 3)	Comparable or more lubricious (Ref 12, 24)	Better, although some lubricious topcoats may be subject to volatile	Significantly higher costs (Ref 3, 23)

aluminum coating with lubricious topcoat (Ref 3, 24)	24)				organic compound regulations (Ref 24)	
Solid alloy without coating (e.g., nickel alloy, stainless steel) (Ref 17, 18)	QQ-N-281, QQ-N-286 (nickel alloy); AISI 304, AISI 316 (stainless steel)	Better (stainless steel may pit) (Ref 17, 18)	Better (Ref 17, 18, 28)	Not applicable; stainless steel and nickel alloys have been used as fasteners (Ref 17, 18)	Better, no coating process	Initial cost significantly higher; life cycle cost may be comparable
Zinc plating (Ref 7, 11, 21)	ASTM B 633[(a)]	Comparable/worse (Ref 3, 16)	Worse (Ref 7, 21)	Less/comparable (Ref 3, 24)	Better, although the type II or III chromate post-treatment is hazardous (Ref 9, 29, 30)	Initial costs lower; zinc coatings generate voluminous, white corrosion products (Ref 16)
Zinc-nickel plating (Ref 3, 25)	ASTM B 841; commercial (Ref 27)	Comparable (Ref 3, 25)	Worse/comparable (Ref 3, 25)	Less/comparable (Ref 3, 24)	Better, although nickel is included in EPA "Toxic 17" list; chromate post-treatment hazardous (Ref 9, 29, 30)	Initial costs may be higher; life cycle costs comparable (Ref 16)
Tin-zinc plating (Ref 3, 26)	Commercial (Ref 26)	Comparable/worse (Ref 3)	Worse/comparable (Ref 3)	Less/comparable (Ref 3, 24)	Better, chromate post-treatment hazardous (Ref 9, 29, 30)	Initial costs may be higher; life cycle costs comparable (Ref 3)
Ion vapor deposited aluminum (Ref 3, 23)	Commercial; MIL-C-83488 (Ref 23)	Comparable (Ref 3, 23)	Worse/comparable (Ref 3, 23)	Less; ion vapor deposited aluminum coatings on threaded fasteners can gall (Ref 3, 23)	Better, chromate post-treatment hazardous (Ref 9, 29, 30)	Significantly higher costs (Ref 23)

Note: See text for extensive detail.

(a) Specific bath chemistry is not specified and would have to be agreed on with vendors.

Cadmium Replacement. This column in Table 4 briefly describes materials or processes that have proven to be viable replacements for cadmium coatings on steel substrate components. The options presented range from simply substituting common zinc plating to employing solid, inherently corrosion-resistant materials (e.g., nickel alloys or stainless steel) to replace plated components.

Implementing a major design change (e.g., replacing a cadmium-coated fastener with a solid nickel alloy fastener) is sufficiently complex to require component-specific engineering review. To assist with this process, Table 4 lists references for commercial and federal agencies that are using cadmium replacements in specific applications. Generic terms are used to describe replacements; if required, the listed reference may be consulted to identify specific products or processes.

The only cadmium replacements included in Table 4 are those specifically applicable to steel substrates. Cadmium applications to nonferrous parts are typically intended to address complex performance parameters that are beyond the scope of this article.

Specifications. This column in Table 4 provides a brief list of consensus or military specifications for the cadmium replacements. The term *commercial* denotes specifications developed by individual corporations, which are generally available from the referenced sources.

Corrosion Control Performance. This column in Table 4 summarizes the results of corrosion control tests conducted in realistic or natural marine and/or industrial atmospheres. These atmospheres are widely regarded as the most aggressive natural environments used to test coatings. Cadmium replacements that provide effective substrate corrosion control in these atmospheres will perform even more effectively in less harsh environments, such as those that might be encountered inside a climate-controlled building or sheltered compartment.

Corrosion control data generated using artificially accelerated or salt fog tests (e.g., ASTM B 117) are not included because such data have no demonstrable correlation with actual field performance. Figure 2 shows that salt fog and natural marine atmosphere data for an 18-day exposure period are inconsistent and contradictory (Ref 14). Similar data generated by an SAE-AISI task force on corrosion testing led to the following conclusion (Ref 15): "The ASTM B 117 salt spray (fog) gives a very poor simulation of on-vehicle behavior and thus should not be used for ranking the cosmetic corrosion resistance of automotive sheet steel products."

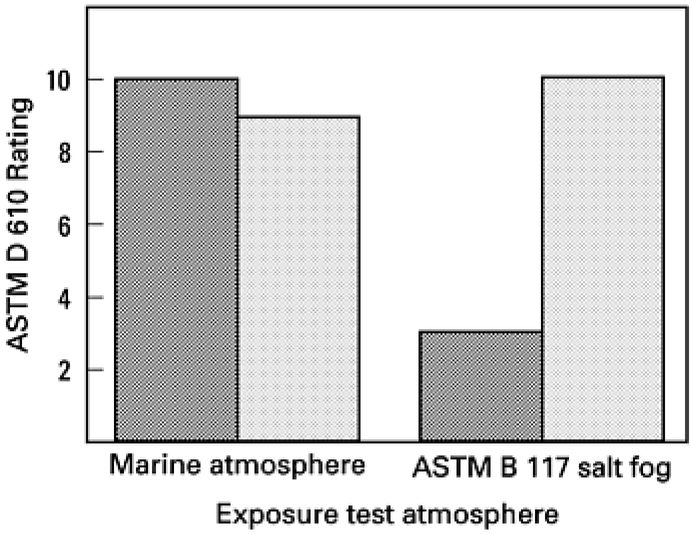

Fig. 2 Lack of correlation between ASTM B 117 salt fog test results and natural marine-atmosphere exposure test data for cadmium-plated (light-shaded bars) and zinc-plated (dark-shaded bars) mild steel. The ASTM D 610 rating scale extends from severe substrate corrosion (rating 1) to no substrate corrosion (rating 10). Source: Ref 14

As such, Table 4 summarizes only data generated by comparing the natural-atmosphere corrosion control performance of the listed replacements with that of the cadmium-coated experimental controls (e.g., AISI 1010 steel specimens coated with QQ-P-416, type I cadmium plating at thicknesses of 5.1, 12.7, and 25.4 μm, or 0.2, 0.5, and 1.0 mil). Only cadmium replacements that could be applied at thicknesses of 12.7 μm (0.5 mil) or less were included in the analysis. Following are the terms used to describe the qualitative ratings:

- *Better:* The replacement (applied at thicknesses similar to those of cadmium) controls steel substrate corrosion for a longer period of time than cadmium.
- *Comparable:* The replacement (applied at thicknesses similar to those of cadmium) controls steel

substrate corrosion as effectively as cadmium for a similar period of time. Coating self-corrosion or cosmetic appearance data did not influence this rating. For example, a zinc-base coating was considered comparable to a cadmium coating if it provided the same degree of protection to the substrate, even if it produced greater amounts of white corrosion product than a cadmium coating.

- *Worse:* The replacement (applied at thicknesses similar to those of cadmium) did not control steel substrate corrosion as effectively as cadmium. Because all of the systems included in Table 4 have already been used to replace cadmium in some applications, a rating of *Worse* typically signifies that thin layers of the replacement did not perform as effectively as thin layers of cadmium, even though thicker layers of the replacement may have been equivalent (Ref 3). Even if a system is rated *Worse* in this table, it still could be considered a viable cadmium replacement in applications that could accept thicker coatings, or applications in less corrosive environments.

As these ratings suggest, the coating thickness of cadmium replacements exerts a significant influence on corrosion control performance. Cadmium and virtually all of the replacement coatings sacrificially corrode to protect the substrate, so coating thickness exerts a significant influence on coating service life. In general, thicker sacrificial coatings contain more metal (i.e., greater coating weight) and will sacrificially corrode to protect the substrate steel for a longer period of time.

Figure 3 shows the relationship of zinc coating weight to service life (Ref 16). Although cadmium is a sacrificial coating, data from natural atmosphere exposure tests do show that cadmium coatings tend to provide effective corrosion control when applied in thin layers, whereas many of the cadmium replacements did not perform as effectively at comparable thicknesses. To maximize the service life of components coated with cadmium replacements, specifications should require the thickest layer possible that does not adversely affect fit or function.

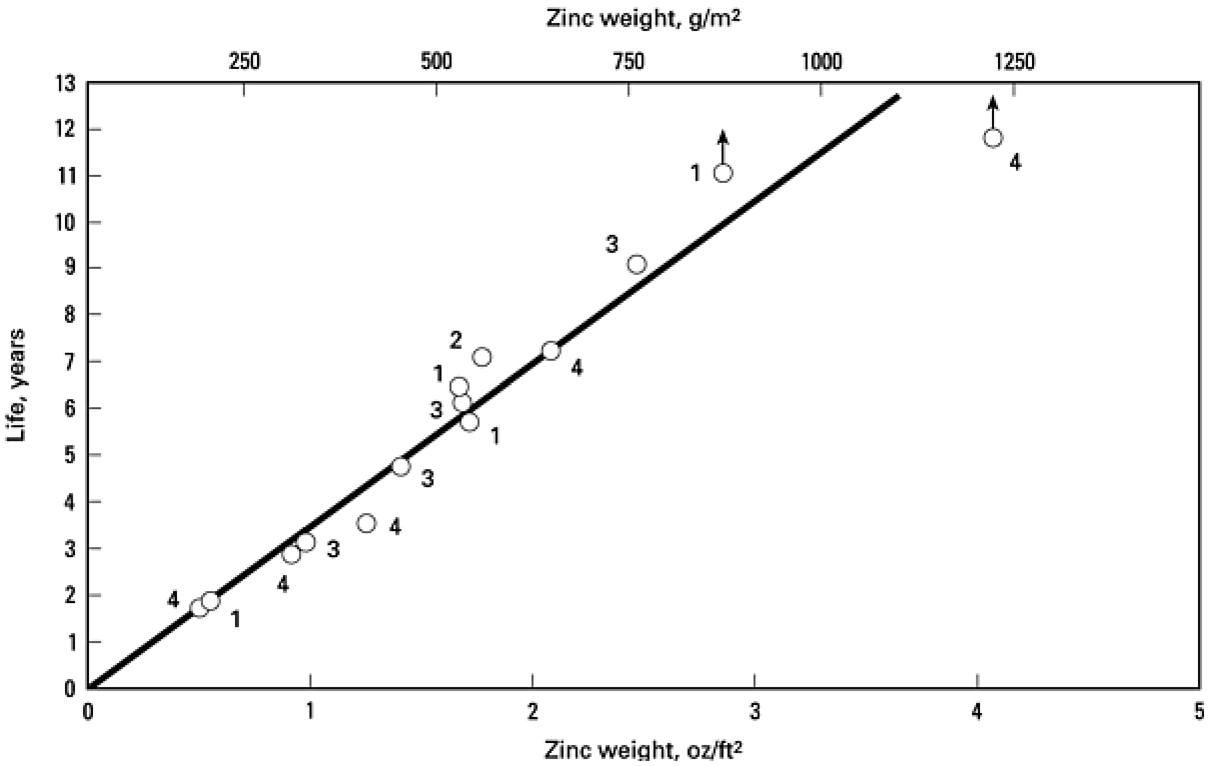

Fig. 3 Service lives of various zinc coatings according to the weight of the zinc present. Results are for exposure in a very aggressive industrial atmosphere. 1, electrodeposited; 2, electrodeposited (passivated with chromate solution); 3, hot-dip galvanized; 4, sprayed. Source: Ref 16

Environment-Assisted Cracking (EAC). This column in Table 4 compares the influence of cadmium replacement coatings on hydrogen embrittlement or overall EAC of a substrate steel. Again, Table 4 compares the performance of replacement coatings to that of cadmium coatings under similar test conditions. A comprehensive analysis of hydrogen embrittlement and EAC is presented in Volume 13 of the *ASM Handbook* (Ref 17, 18), so a similar discussion is not presented here. However, for steels, susceptibility to hydrogen embrittlement or EAC generally correlates with increasing yield strength and hardness. Thus, any analysis of cadmium replacements intended for use on high-strength steels must consider the issues presented in this table.

In general, the Table 4 data were developed by evaluating AISI 4340 steels, heat treated to between 1241 and 1379 MPa (180 and 200 ksi), using constant extension rate tests (CERT) or other applicable EAC tests. Data regarding EAC of the solid nickel and stainless steels are not presented in Table 4 but are available in Ref 17 and 18.

Figure 4 shows how test data were summarized to create the qualitative Table 4 ratings. It presents CERT results from coated, high-strength steel specimens immersed in an aqueous 3.5% NaCl solution and/or an inert medium (Ref 19). The test specimens were baked after plating to reduce hydrogen mobility and/or drive off process hydrogen (Ref 19, 20). Thus, the results show how sacrificial corrosion can embrittle high-strength steels. Reduced CERT times to failure for coated specimens, relative to those for uncoated experimental control specimens, are associated with embrittling effects. Figure 4 shows that cadmium plating (QQ-P-416, type I) caused the least substrate embrittlement.

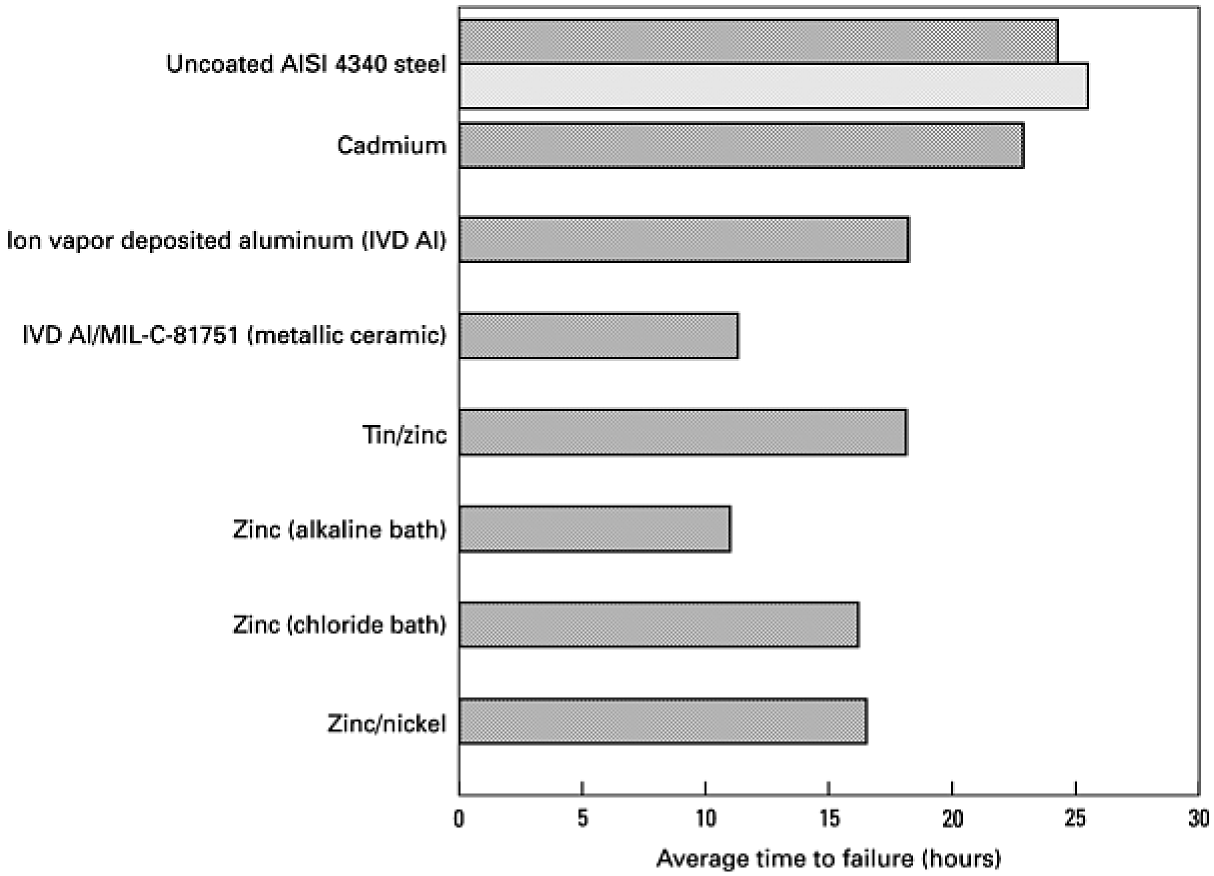

Fig. 4 Results of constant extension rate tests (2.5 × 10^{-2} μm/s, or 2.5 × 10^{-6} in./s) of AISI 4340 steel specimens (1241 MPa, or 180 ksi) with cadmium and replacement coatings evaluated in aqueous 3.5 NaCl (dark bars) and/or an inert medium (light bar). Source: Ref 19

These results are not surprising, given that cadmium has historically been used as a high-strength steel coating. The usefulness of cadmium as a coating for high-strength steels is reflected in the numerous low-embrittlement specifications listed in Table 3. Because cadmium coatings may be applied in accordance with specifications that minimize production-process-induced or corrosion-induced hydrogen charging, and because none of the alternative specifications minimizes embrittlement, any cadmium replacements intended for use on high-strength materials must be evaluated before coating changes are authorized. The evaluation process must consider component strength level, configuration, and intended service environments. *Caution: Failure to evaluate cadmium replacements applied to high-strength steels could result in* *catastrophic component failures.* Analysis of Table 4 data suggests that on some high-strength, high-performance parts for which solid alloys are not acceptable, cadmium may be the only viable, currently available plating process.

Coating Lubricity. This column in Table 4 addresses the established usefulness of cadmium as a threaded fastener or connector coating (Ref 21). Because lubricity is such a complex and difficult-to-define performance parameter, the ratings specifically summarize threaded fastener performance, as measured by differences in curves showing the tensile load created in a threaded fastener as a function of applied torque. Replacement coatings are rated *less* lubricious if they exhibited lower fastener tensile loads for given torque levels than cadmium fasteners subject to the same test conditions. To ensure that the data reflect significant performance differences between coating systems, not simply an effect caused by the test conditions, only results from unlubricated tests (i.e., no added oil or grease) are summarized. Adding lubricants such as grease or oil to threaded fastener systems exerts a significant influence on torque-tension behavior and creates an added degree of complexity which is beyond the scope of this article (Ref 22).

Figure 5 shows the type of data summarized in Table 4 and shows how added lubricants influence threaded fastener lubricity. The average tensile load created in H-11, 22-4-22 threaded bolts is shown as a function of applied torque. The data show that the application of cetyl alcohol (a lubricant) had more impact on the torque-tension relationship for threaded fasteners than the metal coating type. The data also show that for a given torque level, the specimens coated with ion vapor deposited (IVD) aluminum exhibited far less tensile load than the cadmium-coated experimental controls. As a result, IVD aluminum was rated less lubricious than cadmium in Table 4. Any potential use of IVD aluminum as a cadmium replacement on threaded fasteners must account for the inherent limited lubricity of the aluminum coating (Ref 23).

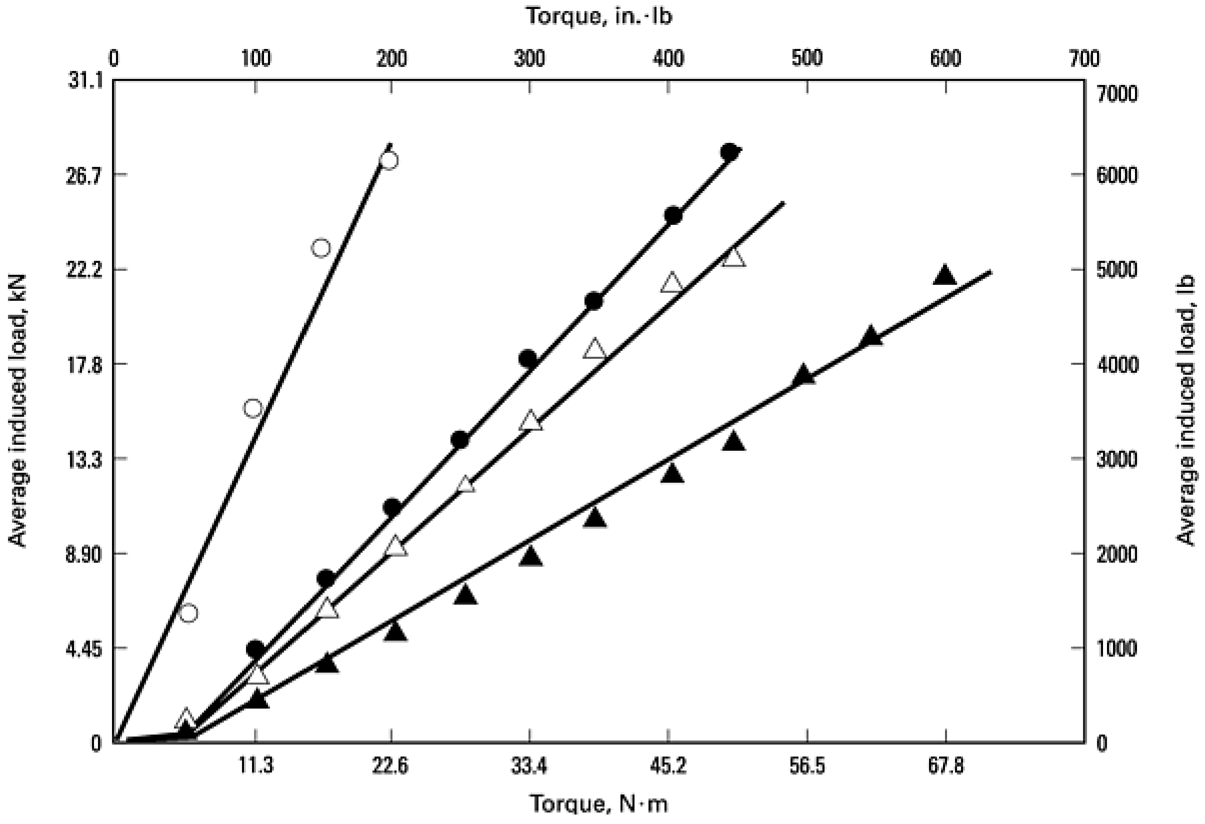

Fig. 5 Torque-tension test results for H-11, 22-4-22 threaded fasteners and alloy steel FN22 locknuts, coated with ion vapor deposited (IVD) aluminum or cadmium. ○, bolt and nut with IVD aluminum and cetyl alcohol; •, bolt with cadmium and nut with cadmium; △, bolt with IVD aluminum and nut with cadmium; ▲, bolt and nut with IVD aluminum. Source: Ref 23

Although results generated using added lubricants (e.g., grease or cetyl alcohol) are not summarized in Table 4, the application of a solid, dry film lubricant as part of the fastener production process was considered. Figure 6 shows average torque-tension curves generated from testing replicate $\frac{1}{2}$-20-UNC, grade 5 fasteners plated with cadmium, zinc-nickel, and zinc-nickel with additional lubricious topcoats (i.e., dry film lubricants and polytetrafluoroethylene, or PTFE, systems) (Ref 24). Although only the averages are plotted in Fig. 6, standard deviation data show a considerable degree of variation around the mean. The standard deviation for the cadmium-plated fasteners (one of the most consistently lubricious or "well behaved" coating systems) was typically in excess of 15% of the average. The threaded fasteners coated with replacement systems demonstrated a similar, or even larger, range in tension for a given torque. Although the considerable data range is significant, the most important conclusion is that addition of a dry film lubricant or PTFE-type product over any sacrificial coating can create a system that is more lubricious than cadmium (Ref 24). The significant influence of dry film lubricants on overall system lubricity shows that cadmium should not be considered a unique or irreplaceable lubricious fastener coating.

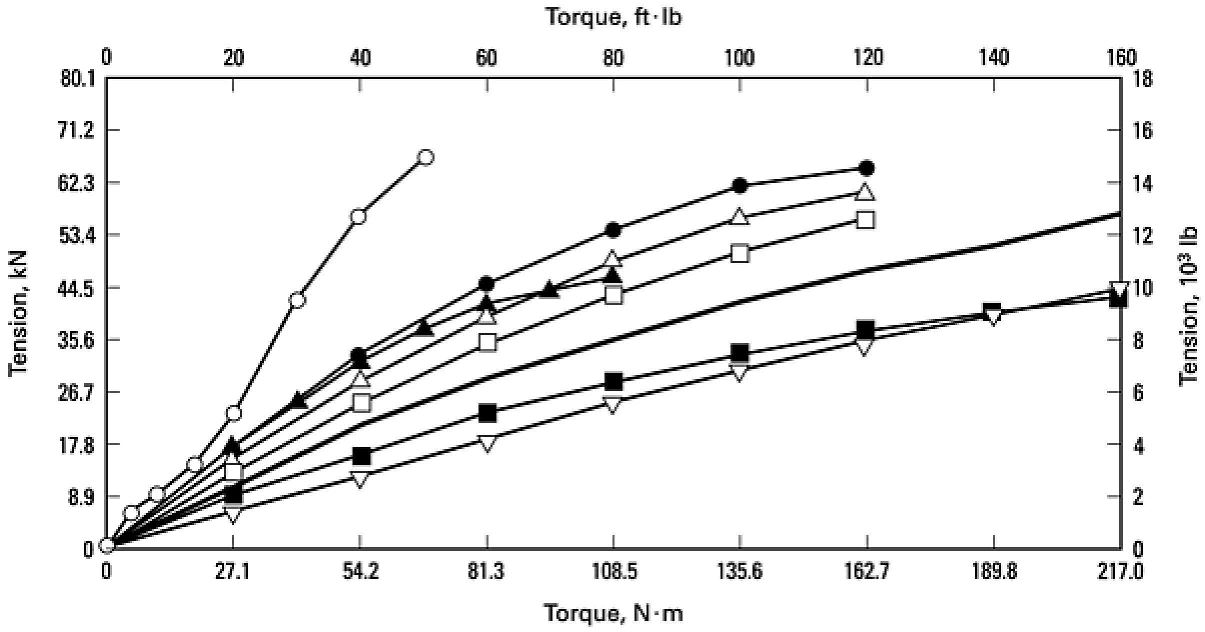

Fig. 6 Average torque-tension data from five replicate $\frac{1}{2}$-20-UNC grade 5 fasteners plated with cadmium, zinc-nickel, or zinc-nickel with lubricious topcoats. ○, dry film lubricant (MIL-L-56010); •, dry film lubricant (MIL-C-85614); △, organic sulfamate emulsion; ▲, aqueous polytetrafluoroethylene (PTFE)/phenolic; □, PTFE/phenolic A; ■, PTFE/phenolic B; ▽, zinc-nickel; thick line, cadmium. Source: Ref 24

Environmental and Worker Health Regulations. This column in Table 4 compares the environmental compliance risks and potential worker health hazards created by the replacement coatings. Of course, all of the replacements shown in Table 4 create far fewer environmental and worker health risks than cadmium. However, when applicable, there are comments about potential environmental and worker health issues that could affect replacement coatings.

For all plating processes described in Table 4, a comment is provided regarding the hazards posed by the chromate passivation treatment. Chromate passivation treatments based on hexavalent chromium-ion solutions are frequently used as a final step in the plating process and are subject to many of the same environmental and worker health regulations as cadmium. Although chromate passivation treatments do improve the corrosion-control performance of plating systems, the Table 4 data were developed using both chromated and nonchromated plating layers (Ref 3). Replacing cadmium with one of the replacement plating processes shown in Table 4, along with eliminating the chromate passivation process, minimizes hazardous materials handling and disposal costs and simplifies regulatory compliance.

Cost and Performance Factors. This column in Table 4 compares the application costs for the replacement processes to those for cadmium. The summaries are based on numerous analyses. Some of the data were inconsistent or contradictory, and as such, specific cost estimates must be developed on a case-by-case basis before any cadmium replacements are used.

Table 4 shows that the costs of using solid alloy components are higher than those for cadmium-coated parts. Although the costs for solid stainless steel or nickel alloy components are typically higher than those for cadmium-plated items, the life cycle costs (i.e., the costs associated with recurring maintenance and repair) for these solid alloy parts may be lower than those for cadmium or other replacement plating processes. The costs for IVD aluminum coatings are also shown to be higher than those for cadmium plating, primarily because the IVD aluminum application process is conducted in a vacuum chamber under the influence of an electric field. The significant investment in sophisticated equipment makes the IVD aluminum coating process approximately 33% more costly than QQ-P-416 cadmium plating on a per-part basis (Ref 23).

Other comments in this column relate to issues that might affect the cadmium replacement selection process. A key noneconomic issue that could affect cadmium replacement selection is the in-service appearance of the sacrificial layer. Zinc coatings are known to develop voluminous white corrosion products while sacrificially corroding (Ref 16). These corrosion products may interfere with the function of precision components, or they may simply be cosmetically unappealing. Decisions about whether these products might affect the performance of individual components should be made by engineering staff.

Chromium Elimination in Surface Engineering

Barry Meyers and Stephen Lynn, The MITRE Corporation; Elwin Jang, United States Air Force, Sacramento Air Logistics Center

---

Introduction

CHROMIUM has been widely used in surface finishing of metals because of the favorable properties it imparts to substrates and because the processes used are relatively mature, well understood, widely specified, and cost-effective. In recent years, however, the use and emission of hexavalent chromium has come under increased scrutiny by various regulatory bodies due to its adverse health and environmental effects. Indications are that regulatory agencies will continue to require significant reductions in the emissions of chromium in the future. Typical solutions to this problem range from the addition of emissions control devices, to a change in the method of application of a material, to the complete re-engineering of the surface finishing process through process and material substitution.

Major uses of hexavalent chromium in surface finishing are in chromium plating and chromate conversion coating. Chromium plating is electrolytically applied to steel parts and can be either hard (engineering) plating, which is applied relatively thickly to impart desirable wear and abrasion resistance, or decorative plating, which, as the name implies, is for aesthetic purposes. (See the articles "Industrial (Hard) Chromium Plating" and "Decorative Chromium Plating" in this Volume.) Chromate conversion coating is a nonelectrolytic process in which the conversion coating is applied to light metals (aluminum, magnesium, cadmium plate) and alloys for corrosion resistance and/or as a paint base. (See the article "Chromate Conversion Coatings" in this Volume.) To a lesser extent, chromium is used in chromic acid anodizing, which also imparts corrosion resistance and paint adhesion properties to aluminum but, unlike conversion coating, is an electrolytic process.

This article focuses on alternatives to chromium in both hard chromium plating and chromate conversion coating. It addresses material and process substitutions that can be used to eliminate the use or emissions of chromium in the industrial processes described above. Other uses of chromium, such as in paints, are not covered. The focus of the article is on comparing the physical characteristics of each coating and the economics, environmental impact, advantages, and disadvantages of alternative processes.

Alternatives to Hard Chromium Plating

Hard chromium plating is the most widely used application of chromium in surface finishing. It is routinely used for applications that require hard, wear-resistant coatings on either new or refurbished parts. The coating applied is relatively thick (as opposed to decorative chrome), generally between 0.25 and 0.76 mm (10 and 30 mils), which makes it good for dimensional restoration. In aerospace applications, chromium plating is the preferred wear-resistant coating for hydraulics, landing gear, rotating shafts, gears, and surfaces subjected to sliding or rolling wear. The plating characteristics of chromium plating are shown in Table 1. The thickness buildup, coating adhesion, hardness, and abrasion resistance properties are especially favorable.

Table 1 Plate characteristics of hard chromium plating and prospective alternative processes

Characteristic	**Chromium electrodeposition**	**Low-phosphorus electroless nickel (generic)**	**Ni-W-B electrodeposition (Amplate)**	**Ni-W-SiC electrodeposition (Takada)**	**Plasma spray (general)**	**High-velocity oxyfuel (general)**

Fatigue loss, %	As high as 60	Less than for chromium(a)	Less than for chromium(a)	Less than for chromium(a)	Less than for chromium(a)	Less than for chromium(a)

RHR, roughness height rating.

(a) Needs additional testing

The chromium plating process is inexpensive, well understood (it has been widely used for many years), and easy to perform. The process involves degreasing, masking, and cleaning prior to plating. The parts are then racked and immersed in the plating bath for up to 24 h, depending on the desired thickness. Following the plating step, the parts are removed from the bath, masking is removed from the part, the part is baked for embrittlement relief, and finishing (such as grinding, lapping, polishing) is completed.

Several disadvantages of chromium plating are its high fatigue life debit, marginal corrosion resistance due to microcracking, high power consumption, nonuniform coverage, poor penetration into holes and tube bores, and the evolution of hydrogen in the process. As a result of the hydrogen evolution, misting occurs, which leads to high air emission rates and associated adverse health, safety, and environmental risks.

Potential process substitutions for hard chromium plating are discussed below. These include electroless nickel in certain applications, several nickel-tungsten composite plating options, and spray applications such as plasma spray coatings. (There are other possible substitutions, such as vacuum deposition processes and cobalt alloys, that are not discussed.) None of these has exhibited all of the desirable qualities of chromium plating. Certain tradeoffs, such as somewhat poorer physical properties, increased process time, and increased costs, are to be expected. Clearly, no one alternative should be viewed as a "drop-in" replacement for the elimination of all chromium in hard chromium plating.

Electroless nickel (EN) plating has been in existence for several decades. In this autocatalytic process, nickel ions are reduced to metal by the action of chemical reducing agents, without the need for an electric current. A commonly used reducing agent is sodium hypochlorite, which donates electrons to the metal ions with the substrate acting as a catalyst for the reaction.

The use of EN as an alternative to chromium plating is severely limited by its somewhat poorer physical properties. As is evident from Table 1, the hardness and abrasion resistance of low-phosphorus EN are good but lower than those of chromium plating. In addition, the wear rate and galling resistance are poorer than those of chromium plating (Ref 1).

One advantage of EN is that the deposit follows all of the contours of the substrate without the excessive buildup at the edges and corners that is common with chromium plating. Sharp edges and blind holes receive the same plating thickness. The process bath, however, is more sensitive to impurities than the chromium plating bath, and it must be closely monitored to maintain the proper concentrations and balance of the metal ions and reducing agents. In addition, the bath life is finite and less than that of chromium plating, which means that periodically it must be "dumped" and a fresh bath prepared. Deposition rate and coating properties are affected by temperature, pH, and metal ion/reducing agent concentration.

Electroless nickel plating can be used as a chromium plating alternative in limited applications, such as for very well lubricated conditions. It cannot be cost-effectively plated as thick as chromium, but because it plates more evenly, the need for substantial overplating can often be eliminated. The main drawback with EN is that the coating is not as hard as chromium plate. However, a postplating heat-treatment step can improve its hardness significantly. Although EN does not wear as well as chromium plating and is more susceptible to galling wear, on a positive note, it imparts greater corrosion protection than chromium plate and should not result in significant fatigue life debit.

Nickel-Tungsten Composite Electroplating. Two separate nickel-tungsten composite electroplating processes are available as potential alternatives to chromium plating: nickel-tungsten-boron (Ni-W-B) composite electroplate (Ref 2) and nickel-tungsten-silicon carbide (Ni-W-SiC) composite electroplate (Ref 3, 4). The two processes are similar in that they are both electrolytic and deposit a composite of nickel and tungsten onto the substrate. Both have been developed relatively recently and are not yet widely used. Each coating exhibits many of the desirable properties of chromium plating, but additional testing is required before the processes can be widely used in critical applications. The processes use less energy than chromium plating, so the platings are more uniform than chromium and can result in cost savings by allowing greater throughput and a minimal amount of overplating. In addition, the applications are tank-based, which makes a transition from chromium plating relatively straightforward.

Ni-W-B composite electroplating deposits a coating that is approximately 59.5% Ni, 39.5% W, and 1% B (Ref 2). The coating has a bright silver-white, highly lustrous appearance at thicknesses of up to 0.25 mm (10 mils), above which it becomes matte in appearance. The physical properties of the coating are listed in Table 1. The coating has favorable chemical and abrasion resistance, high ductility, a low coefficient of friction, and plates very uniformly and smoothly. However, as compared with chromium, Ni-W-B is less hard; postplating heat treatment raises the hardness significantly to a level that is equal to or slightly greater than that of chromium plate.

Ni-W-SiC composite plating is similar to Ni-W-B except that it uses silicon carbide interspersed in the matrix to relieve internal stresses and improve the coating hardness. The resulting deposit is roughly 46.3% Ni, 46.1% W, 4.3% Si, and 3.2% C (Ref 4). The appearance of the coating is similar to that of Ni-W-B, with the silicon carbide causing a nearly indiscernible darkening. The coating properties, which are also listed in Table 1, indicate favorable chemical resistance, abrasion resistance, and coefficient of friction. The hardness of the coating is somewhat greater than that of Ni-W-B, and with heat treatment it can exceed that of chromium plating.

The major disadvantages associated with these two nickel-tungsten processes are their lack of maturity, their potential increased costs over chromium, and, to a lesser extent, their reliance on nickel. Besides not having been scaled up to production, additional testing, which is ongoing at various locations, will be required to qualify these coatings for particular applications. The qualification process is not easy; engineers rightly err on the conservative side in approving such sweeping changes in potentially critical situations. Also, while no hard numbers exist, it has been estimated that these processes will cost considerably more than for chromium plating (Ref 5). However, these estimates do not consider the potential liability costs associated with the continued use of chromium. It is true that the use of nickel, and to a lesser extent the use of tungsten, may become more tightly regulated, but even so, there is much less nickel in these plating baths than there is chromium in a chromium bath, resulting in lower risk.

Spray Coating Applications. Several spray coating applications have shown promise as potential alternatives to chromium plating. Variations on this application include arc spray, flame spray, plasma spray, and high-velocity oxygen fuel (HVOF) spray. From a materials standpoint, the one having the best coating properties is HVOF spray, which is the type addressed in this section.

HVOF coatings are presently used in many industrial applications because they develop very hard, wear-resistant surfaces that have comparable performance requirements to those of chromium plating. HVOF spray is based on the detonation gun (D-gun) process developed by Union Carbide (Praxair). In HVOF coating application, an explosive gas mixture ignites in the barrel of the spray gun, which melts a powdered coating material and propels it (with a carrier gas) at supersonic speeds toward the substrate. The superior coating properties are a result of the high velocities that are reached in the process--the higher the velocity, the greater the force of impact at the substrate, resulting in fewer voids in the coating and more desirable properties.

There are presently numerous manufacturers of HVOF equipment and coating materials, each having a somewhat different design; the system and coating material selected contributes to the resulting coating properties. Table 2 lists the coating properties of some typical HVOF coatings that may be applicable to chromium plating elimination. Note that many HVOF coatings are chromium-base, so the use of the HVOF system would not necessarily result in chromium *elimination.* However, the HVOF process emits significantly less chromium than chromium plating, and recovered metal powders can be recycled.

Table 2 Physical characteristics of high-velocity oxyfuel spray deposited coatings

Characteristic	Tungsten carbide-	Cobalt-chromium-	Nickel-chromium-	Chromium carbide-	Iron-nickel-

	cobalt	**nickel-tungsten**	**molybdenum**	**Nichrome**	**chromium**
Thickness buildup, mm (mils)	>1.3 (>50)	>1.3 (>50)	>2.5 (>100)	>0.6 mm (>25)	>1.5 (>60) max

Alternatives to Chromate Conversion Coating

Chromate conversion coating is a nonelectrolytic application to light metals, generally aluminum and its alloys, for the purpose of imparting corrosion protection and paint adhesion properties. The process is widely used in the aerospace industry and can be applied by brush, spray, wipe, or immersion. Chromate conversion coating offers numerous advantages over the potential alternatives:

- Greatly improved wet and dry paint adhesion
- Self-healing corrosion protection in case of scratched parts
- Simple application process and easy-to-maintain bath chemistry
- Mature process; in many applications has been the preferred coating for years

Presently, there are no drop-in substitutes to chromate conversion coating that adequately address each of its advantages.

The major disadvantage of chromate conversion coating is simply its use of hexavalent chromium. The tank-based process does not have the misting emission problem typical of chromium plating, but in applying the coating to entire aircraft, the subsequent rinse process can generate large quantities of chromium-containing wastes.

Several tests are routinely used to quantify the characteristics of conversion coatings. Paint adhesion can be measured using the wet tape adhesion method, scrape adhesion method, knife scribe test, crosshatch adhesion test, and others. Corrosion resistance is typically measured using the salt spray corrosion resistance test, ASTM B117, which is conducted on either unpainted or painted specimens. Examples of the performance of chromate conversion coatings in these tests are included in Table 3, which also shows the performance of alternatives.

Table 3 Coating characteristics of chromate conversion coating and prospective alternative processes

Characteristic	**Chromate conversion coating**	**Cobalt/ molybdenum-base coating**	**Oxide layer growth coating**	**Sulfuric acid boric acid anodizing**

Electrical resistance, MΩ	<5,000	<5,000	>5,000	>5,000
	<10,000 after salt spray	<10,000 after salt spray	>10,000 after salt spray	>10,000 after salt spray

Potential alternatives to chromate conversion coating are discussed below. These include a proprietary cobalt and molybdenum-based process, a multistep process that grows a corrosion-resistant oxide layer, and various others.

Cobalt/molybdenum-base conversion coating is a project of a major aerospace company and a supplier of conversion coatings, Parker-Amchem. It is a developmental process that uses cobalt and molybdates rather than chromates. Laboratory tests have shown that the coating is capable of meeting the important corrosion resistance and paint adhesion characteristics (Table 3), but the process has not been scaled up to production levels.

The cobalt/molybdenum process requires one additional process tank and rinse step for sealing, which could have considerable cost impact. In addition, it requires heated baths, resulting in increased energy usage. This makes the estimated cost associated with the process about twice as much as that of chromate conversion coating (Ref 6), keeping in mind that liability costs, which could be significant, are not factored into the costs of chromate conversion coating. Although this is a significant increase, the cost is not as much as for the oxide layer growth process described below. Probably the greatest disadvantage of the cobalt/molybdenum-base process is that it is still developmental and has not been scaled up to production levels.

Advantages of this coating process are that it would be universally applicable to parts that are presently chromate conversion coated. It is still a tank-based process for immersion application (it is also being developed for spray, brush, and wipe applications), and it requires only slightly more time than the present coating process.

Oxide layer growth in high-temperature deionized water was developed and refined within the past decade (Ref 7, 8, 9), and this process is somewhat more mature than the cobalt/molybdenum process. Several variations are in different stages of development. This process uses a series of steps, including immersion in boiling distilled water, to build a corrosion-resistant paint base on aluminum. Following the growth of the corrosion-resistant oxide layer, several proprietary baths are used to seal and enhance the properties of the coating. The coating meets the corrosion protection and paint adhesion requirements of a conversion coating (see Table 2) and has been tested extensively by the Navy (Ref 10).

The major drawback of the oxide layer growth process is its cost. It requires many additional steps, involving numerous tanks of chemicals at various elevated temperatures. Consequently, the energy costs and processing times, as well as capital costs, increase substantially. In fact, it is estimated that the tank-based process may cost up to ten times as much as the present chromate conversion coating process (Ref 6).

A variation on the process involves spray application within a cabinet coater, a chamber large enough to handle the applicable parts. The various solutions are then applied sequentially using a steam generator. The concept is a joint venture of the developer of the process and another company, Electrosteam Generator Corporation. It saves on heating costs and reduces the volume of chemical required, but it is still in the developmental stage.

Other chromate conversion coating alternatives may prove to be of use in eliminating chromium from conversion coatings. These include sulfuric acid/boric acid anodizing (SBAA), various phosphate treatments, and other emergent technologies.

SBAA was developed by a major aerospace company to replace chromic acid anodizing (Ref 11). The process imparts exceptional paint adhesion and corrosion protection at a cost comparable to that of chromate conversion coating, and it may prove valuable as a replacement for chromate conversion coatings on some parts. However, SBAA is an anodic process, so it is not universally appropriate to all parts, especially parts with steel inserts or those having sharp edges, welds, crevices, and other areas that entrap fluids. This problem severely limits the applicability of SBAA as a chromate conversion coating alternative.

Phosphate coatings do not provide as high a quality of coating as the present process. However, in applications where the conversion coating/primer/topcoat is treated as a "system" for testing purposes (i.e., the *bare* salt spray corrosion resistance is not considered important), this type of coating could be an appropriate substitute. It is in use within the automotive industry, but it has the disadvantages of additional process steps, long process cycle time, and increased energy consumption.

Table 4 lists several experimental and developmental technologies that may lead to breakthroughs with respect to replacement of chromium in conversion coatings in some applications. Another developmental technology is the "no-rinse" conversion coating, which, although not a chromium-eliminating technology, has the capability to reduce the amount of chromium discharged. The Navy and Air Force have worked to develop a conversion coating that can be applied to an entire aircraft with no rinse step, which is where the majority of the chromium emissions occur during brush or wipe applications of the conversion coating.

Table 4 Emergent alternative conversion coat technologies

Process description	**Status**
Trivalent chromium conversion coatings	Meets no corrosion in 500 h requirement (ASTM B 117 salt spray test)
	Still contains chromium
	Electrolytic process
Hydrated alumina coating	Poor paint adhesion
	Meets no corrosion in 500 h requirement (ASTM B 117 salt spray test)
Hydrated metal salt coating (Mg, Ni, Mn, Sn, Ti, Fe, Ba, Cu, Co, Ca)	Does not meet salt spray requirement
	Poor adhesion
Peroxide oxidant coating	Does not meet salt spray requirement
	Poor adhesion
	Unstable chemical baths
Oxyanion analogs (molybdates, tungstates, vanadates, and permanganates)	Moderate corrosion resistance
	Poor paint adhesion
	Molybdates with borate seem best
	Expensive

Potassium permanganate coating	Moderate corrosion protection (168 h)
	Poor wet tape adhesion
	Does not work well on 2024 or 7075
	Requires boiling deionized water
	Multistep process, expensive
Rare earth metal salts (cerium)	Corrosion protection close to that of chromium
	Good paint adhesion
	Unstable chemical bath
	Expensive
	Has good future potential
Zirconium oxide/yttrium oxide in aqueous polymeric solution	Good paint adhesion
	Moderate salt spray protection (100 h)
	Commercially used for >10 years
	One step
	Expensive
Silanes or titanates	Good adhesion
	Moderate corrosion resistance
	Contain flammable solvents
	Thickness dependent, must be cured
	Difficult to dispose of
	Good corrosion protection on 1000-, 3000-, and 6000-series

	alloys
	Poor wet paint adhesion
	Single process bath
	Environmentally benign
	Very promising

Vapor Degreasing Alternatives

Dennis Zupan, Brulin Corporation; Tony L. Green, Lockheed Aeronautical Systems Company; Donald W. Benjamin, AlliedSignal Aerospace; Bruce Hooke, Boeing Commercial Airplane Group; Calvin Fong, Northrop Corporation

Introduction

VAPOR DEGREASING has been widely used for many years in the automotive, aerospace, and other manufacturing and processing industries to degrease and clean parts prior to chemical processing, bonding, painting, and other treatments. The chemicals traditionally used for this process are trichloroethylene (TCE) and perchloroethylene (PCE); however, these compounds have proven to be serious health and environmental hazards. Concern about these hazards led to the use of alternate chemicals: chlorofluorocarbons (CFC) and 1,1,1-trichloroethane (TCA). These compounds are less toxic and appeared, at least initially, to have no adverse effects on the environment.

Since the early 1980s, however, there has been mounting evidence that the ozone layer is being depleted, and the release into the atmosphere of CFC and TCA from their use in various industrial operations and consumer products has been identified as a contributor to this problem. CFC and TCA are classified by federal law as class 1 ozone depleting chemicals (ODC).

The traditional vapor degreasing process is described in the article "Solvent Cold Cleaning and Vapor Degreasing" in this Volume. This present article discusses the regulatory mandates that affect the use of industrial degreasing methods and describes several of the modified and alternative processes that are being used in place of traditional vapor degreasing.

Regulatory Constraints

Industry has used vapor degreasing with either a volatile organic compound (VOC) or an ODC as the solvent for many years, and the process has gained widespread acceptance. However, many laws have been put into place to regulate or restrict the use of traditional vapor degreasing, and many new regulations are pending. As these laws come into effect, it becomes increasingly more expensive to operate and maintain these systems and to dispose of the waste they generate. Aqueous degreasing techniques (see the section "Aqueous Systems" in this article) have been developed that offer industry an attractive alternative because they are less expensive to operate and maintain, they allow for easier disposal of waste, and they are also subject to fewer regulations. This section addresses many of the regulations in the United States that affect traditional and alternative degreasing systems. Additional information is available in the article "Environmental Regulation of Surface Engineering" in this Volume.

Environmental Protection Agency (EPA) Regulations. In 1967, the U.S. Congress enacted the Clean Air Act, which made provisions for the attainment and maintenance of ambient air quality. The passage of the Clean Air Act, which is administered by the EPA, marked the start of major regulatory initiatives to control the emissions of VOC from industrial processes. In 1977, Congress passed the Clean Water Act to maintain and ensure the quality of water that is used for recreation and consumption. Both of these acts contain language that requires monitoring and control of emissions to the air and water. The Clean Air Act also requires the EPA to promulgate a National Emission Standard for Hazardous Air Pollutants (NESHAP). The NESHAP standard limits the amount of hazardous air pollutants that can be released to the environment and requires the use of the maximum achievable control technology (MACT) to control the emissions. Both TCE and TCA are included as pollutants on the NESHAP list.

Because of these regulations, TCE and PCE have become costly to use for vapor degreasing applications. The higher costs are due to the limits on emissions and the controls required to capture these emissions, plus the restrictions on the disposal of waste materials. In the face of these rising costs, many industries switched to using CFC and TCA as vapor degreasing solvents. However, in 1990 the EPA amended the Clean Air Act to adopt the Montreal Protocol, which calls for worldwide cessation of the production of ozone-depleting chemicals. This step had the effect of making CFC and TCA as costly to use as TCE and PCE, and eventually they will be unavailable for use.

The primary alternatives to ODC and VOC materials are aqueous degreasing systems. Because the components are solids and soluble in water, compliance with the Clean Air Act can be easily achieved. It is compliance with the Clean Water Act that is the key regulatory issue with aqueous degreasers. Users of these systems should select component materials with great care. Some materials that are currently considered to be essentially nonhazardous (such as phosphates and glycol ethers) could be restricted in the future.

The Occupational Health and Safety Administration (OSHA) is a U.S. government agency that provides guidelines to employers to ensure the workplace safety of their employees. Through a variety of tests by OSHA and other organizations, OSHA has established safe 8-h exposure levels of 50 ppm for TCE and 25 ppm for PCE. When CFC and TCA replaced TCE and PCE as vapor degreasing solvents, the permissible exposure limits for CFC and TCA were set at 350 ppm. In other words, the ODC are seen as being less toxic to workers than either TCE and PCE.

The new aqueous degreasing materials have exposure limits that are, for the most part, higher than those for the ODC or VOC materials. The routes of exposure for ODC and VOC materials are inhalation, ingestion, and adsorption. For aqueous materials, inhalation is generally not an issue, and thus the primary routes of entry are limited to ingestion and adsorption. For these reasons, the aqueous degreasers are generally considered to be safer to work with than the ODC and VOC materials.

The Superfund Amendments and Reauthorization Act (SARA), enacted in 1986, deals with communities' "right-to-know." The right-to-know encompasses everything from where a toxic waste site may be located to what type and how much of certain chemicals are being used and/or stored at manufacturing facilities in the area that could cause problems should they be released into the environment.

The ODC and VOC materials used for vapor degreasing are on the list of chemicals that must be reported to the state in order to comply with the right-to-know law. Most materials used for aqueous degreasing do not appear on this list and have no reporting requirements.

The Resource Conservation and Recovery Act (RCRA) of 1976 requires that hazardous waste be disposed of in a manner that will not cause any adverse environmental or health effects. The RCRA also established that industrial manufacturers and processors must have plans for hazardous waste and solid waste management. Recycling of materials plays an important part in these plans.

Aqueous degreasing techniques offer the potential for easier and less expensive recycling as compared to vapor degreasing. In addition, the waste generated by aqueous degreasing does not cause the adverse environmental and health effects associated with VOC and ODC waste.

Aqueous Systems

Aqueous degreasing can be accomplished by hot tank or dip tank systems. Ultrasonic cleaning and spray cleaning are system options.

Hot Tank Systems

Heated, aqueous degreasing systems have been designed to replace vapor degreasers of various capacities. The equipment and processes described in this section have successfully replaced vapor degreasers in many applications within the aerospace industry, primarily to remove forming lubricants from detail parts prior to heat treatment, inspection, or finishing operations.

Advantages. The main advantage to these aqueous systems is that they are in regulatory compliance for air emissions. These systems are generally safer to operate and maintain than those using vaporized chlorinated solvents. They can remove many hydrocarbon-based oils, salts, and water-based materials. Treatment of spent aqueous solutions and rinse water can also often be accomplished on site.

Disadvantages. These systems generally require wash, rinse, and dry stages as a minimum. This often means that additional floor space is required as a vapor degreaser provides a clean, dry part using a single tank. Some utilities costs may be higher because heat must be provided to at least two liquid tanks and sometimes to a forced-air drier. More attention must be paid to racking considerations in an aqueous process because more space for solution flow is needed around the part surface. Process cycle times for aqueous degreasing are several times longer than for vapor degreasing due to the multiple steps required.

Equipment / Materials. In general, at least two tanks will be required: one to contain the wash solution and at least one to contain the rinse water. Additional rinse stages will significantly reduce water usage, but this advantage must be weighed against the additional capital cost and floor space required. The preferred material of construction for these tanks is stainless steel. Cost, compatibility with the cleaning solution, and life expectancy of the tanks are considerations when specifying tank material. When retrofitting a vapor degreaser tank with sufficient freeboard, a fresh water spray rinse or mist above the immersion wash or rinse tanks can improve rinsing, reduce overall water usage, and compensate for evaporative losses from the immersion tank(s).

Agitation of the fresh and rinse solutions is required. The flow of fresh solution past the part surface aids in cleaning and rinsing. A solution-recirculation system powered by centrifugal pumps is commonly used. The pumps are protected by a strainer and followed by cartridge or bag filters. These pumps deliver solution to a manifold that feeds an array of nozzles located near the tank walls. These nozzles should be oriented to maximize solution flow past the parts. Air sparging is not acceptable with many aqueous solutions due to the potential for foaming. When air sparging is used on the first (dirty) rinse stage, unacceptable levels of foaming may also be observed. This is due to carryover of soap solution. If agitation is vigorous, cleaning can also be enhanced by the mechanical scrubbing effect of the impinging fluid. This is often difficult to achieve in large tanks. Ultrasonic agitation also may be impractical on these larger systems, although the feasibility of using ultrasonic equipment ultimately depends on part geometry, economic factors, and other application requirements. Controllers should be used to maintain a constant temperature within the tank to ensure uniform cleaning.

Level controllers can be used in both the wash and rinse stages to add fresh water automatically to make up for evaporative losses. A conductivity meter can also be used to determine when the rinse needs to be freshened due to soap carryover. If the cleaning solution will foam, the pipe providing this make-up water should feed into the tank at a point below the surface to prevent foaming due to air entrainment and splashing. This should also be considered in the plumbing layout of the wash tank drainage system. A free fall of degreasing solution into a waste holding tank can quickly fill the tank with foam and create a severe maintenance problem. Electrically isolating the parts or basket from the tank walls may be required to prevent galvanic corrosion resulting from the formation of an electrolytic cell within the wash tank.

If parts must be dry and ambient evaporation rates are unacceptable, a forced-air drier may be required. High volumes of heated air are used. Flow rates and temperatures can be as high as practical while preventing part damage. The material handling system will probably have to disengage from the parts basket to allow for an airtight seal to improve drying and to minimize humidity in the shop area. High-pressure air (air knives) can be used to blow the water off the parts. These are most useful if the part and basket geometry allows the air knife apertures to get consistently within a few inches of the parts. The noise generated by these air knives should be considered if their use is intended.

Process Description. Parts are washed, rinsed, and dried conventionally. First, the parts must be placed in the basket or rack that supports and moves the work through the various processing stages. More spacing between parts is often required when racking for an aqueous process than with a vapor degreaser due to the greater reliance on liquid flow past the part surface. More consideration must also be given to part movement and/or part flotation when racking, due to the large increase in density of the cleaning medium. Special racking schemes or agitation systems may also be required for parts with hidden surfaces such as tubing. Tumblers or rotating baskets sometimes improve cleaning for small parts. When the load is racked for processing, the cleaning cycle is initiated. An automated material-handling system can be incorporated to move the basket through the wash, rinse, and dry stages, thus allowing the operator to perform other activities such as loading or unloading another basket.

The primary variables affecting cleaning performance in the wash stage are the solution temperature and concentration, the immersion time, the thickness and composition of the soil layer to be removed, and the level of agitation. Agitation is an especially important factor.

Higher temperatures generally result in better cleaning. Sometimes the bulk melting point of a paste or grease must be achieved for good cleaning. Temperatures above 65 to 70 °C (150 to 160 °F) can cause excessive wear of equipment, however, and increase the possibility of drying the soap solution onto the parts while transferring to the rinse stage(s).

The chemical supplier recommendations and engineering requirements developed through testing will help determine the concentration of soap required in the wash stage. This can vary between 3 and 20% by volume. Although higher concentration may improve cleaning, it will also result in more burden on the rinse stage and on waste treatment. Titration methods are often used to determine the soap concentration, and incremental additions of concentrated soap are often used to maintain the bath at its concentration set point. Eventually (after 3 to 12 mo), spent baths must be dumped and replaced with fresh solutions due to the buildup of emulsified oils and general degradation of the bath effectiveness. Cleaning performance of previous baths under similar conditions is often the best indicator for predicting bath life.

Immersion times of 15 to 30 min in the wash stage are standard. Increasing the wash stage time beyond this adds little in terms of cleaning benefits and often results in a cleaning cycle that is too long.

Agitation levels are usually fixed once the equipment is installed but should be designed to achieve solution flow rates as high as practical while considering issues such as equipment and utility costs, solution foaming, and part damage.

An often overlooked factor in improving cleaning performance is the soil that must be removed. Parts are sometimes grossly overcontaminated during prior operations and improved performance can often be achieved by reducing the amount of soil to be removed. In some cases, it is possible to eliminate a superfluous cleaning step entirely. Replacement of a hard-to-clean lubricant is another approach. The use of specific forming lubricants in many shops has evolved over the years in part because of the presence of the vapor degreaser. Lubricants that were compatible with the vapor degreaser solvents were preferred over water-based products that would not clean or that promoted acid formation within the solvent. For many applications, an aqueous cleanable lubricant can be just as successful in the upstream operation as the vapor degreasable one was.

After washing is complete, the basket is moved to the rinse stage(s). If soap drying onto the parts is a problem, a fine mist of warm fresh water or rinse water directed at the parts above the wash stage may be helpful. The parts are immersed in the rinse stage(s) for at least 5 min. Multiple rinse stages help conserve water but require more floor space and utilities. If a final spray rinse of fresh water is available above the immersion rinse stage, this should also be utilized. Temperatures above 65 °C (150 °F) can cause excessive wear on equipment and can produce mineral deposits on the tank walls.

After rinsing is complete, the basket is moved to the forced-air drier. Drying time will depend on the design of the system and the amount of parts and water going in. Parts with geometries that trap solution may need to be tilted or blown off with air knives to dry. Fifteen minutes is a reasonable length of time for a drying cycle.

Parts are generally unracked after the wash, rinse, and dry steps are complete. If parts are to be re-racked for the next operation (i.e., heat treatment), consideration may be given to a common rack that could be used by both operations. This could allow the elimination of a racking and unracking step.

Regeneration of aqueous cleaners is performed by removing the soils or contaminants (oils) from the cleaning solution. Oils that float to the surface of a wash tank can often be removed by manual or automatic skimming. Parts being pulled up through a floating oil or foam patch run the risk of having the soil redeposited. Agitation systems can be designed to create a surface flow that propels these floaters over a knife-edged weir. The weir can feed a more sophisticated device such as a coalescer, centrifuge, or ultrafilter to effect a more complete separation. The oil can be captured and the cleaner returned to the bath. Pumps used in conjunction with these systems should be of a low shear type design (i.e., diaphragm pumps) to minimize mixing of the oil and cleaner. Emulsifying-type cleaners are more difficult to regenerate using equipment than surfactant-type cleaners. Aqueous cleaners that strongly emulsify the soils often require nothing more elaborate than the cartridge filtration mentioned in the "Equipment/Materials" section above. When the bath becomes saturated with soils, cleaning performance will become unacceptable and dumping the spent bath and replacing it with fresh solution will be required.

Maintenance. Equipment should be designed with maintainability in mind. Pumps should be protected by strainers. They should have valves on either side for isolating. Pumps and motors should be easy to access and replace. Seals, pumps, piping, and other components should be compatible with the temperatures and chemistries of the solutions. Heat exchangers should also be accessible for replacement in the event of failure. Temperature, level, and conductivity sensors should be located in the body of the tank and should be easily accessible. Regeneration equipment should be easy to maintain, or it runs the risk of being turned off.

Example. A 1,1,1-trichloroethane vapor degreaser was being used to degrease detail aluminum aircraft parts prior to air furnace heat treatment. These parts are contaminated with forming lubricants from blanking and brake press operations. The original tank was 8 m (27 ft) long, 1.5 m (5 ft) wide, and 8 m (27 ft) deep. Very few of the parts going through this system were more than 3.5 m (12 ft) long, and other larger degreasing systems were available within the same building. To retrofit this vapor degreaser to an aqueous system, the tank was modified with the addition of a dividing wall down the center. This structural wall created two 4 m (13.5 ft) long, 1.5 m (5 ft) wide by 8 m (27 ft) deep tanks. Tanks were also modified by adding recirculating agitation systems as described above. Additional heating capacity was required, which was added via steam heat exchangers in the recirculation system. Heat transfer through the dividing wall was found to limit the maximum temperature difference achievable between these two tanks to about -12 °C (10 °F).

A steam-heated, forced-air drier was placed at the factory-floor level adjacent to the tanks and within reach of the overhead crane. A drying cart was used to allow the parts basket to be side loaded into the dryer after being disengaged from the crane. The parts basket and overhead crane system was modified for the smaller working envelope. Multiple-parts baskets and racks are available that are compatible with the adjacent heat-treat furnace material handling system. One load can be processed through the wash and rinse stages, while another is in the drier.

Dip Tank Systems

Dip tank cleaning systems are effective for many applications. Part configuration is a factor: the shape of the part must allow excess cleaning fluid and rinse water to drain away when the parts are removed from the tank. If these fluids do not drain away properly, it could lead to corrosion of ferrous metals and excessive depletion of the cleaning chemical from the wash tank. The proper racking of parts will help to eliminate this possibility.

Arrangement of parts in the dip basket is very important. The parts should not overlap and there should be space between each part to allow the cleaning solution to circulate. The most common reason for unsatisfactory results is failing to follow these requirements.

Ultrasonic dip tank methods are mostly used for small parts on a relatively small scale because the equipment is very expensive. This method is able to remove much heavier contamination than a simple dip tank can accomplish. Ultrasonic cleaning is also effective where partially hidden recesses (i.e., blind holes) are present in the part configuration.

It must be pointed out that an ultrasonic tank that has been configured for solvent cleaning is not suitable for aqueous cleaning. The sonic frequencies need to be changed from 25 to 40 kHz or higher for aqueous cleaning. Once the frequency (transducer) modification has been made, meaningful cleaning evaluations can proceed. Additional information on ultrasonic cleaning and equipment is available in the article "Ultrasonic Cleaning" in this Volume.

Spray washer methods are recommended when production requires very high throughput, or when parts have irregular surfaces. This method will remove very heavy oils and greases and other contaminants.

Contaminant Removal. After being removed from the parts, some oil and grease will end up floating (because they are lighter than water) in the wash tank. These contaminants must be removed from the wash tank so that they do not interfere with the efficiency of the cleaning solution.

Skimming is the most practical method for removing these contaminants. Devices for this purpose are readily available from industrial supply companies. They feature an oil attractive surface that rejects water; the oil is removed from the skimming surface by wiper blades and is collected for disposal.

Ultrafiltration may be a viable option for large tank systems. A great deal of experimentation has taken place involving ultrafiltration of aqueous cleaning chemicals. It has been found that with either polymeric or ceramic membranes, a filter pore size of 0.3 to 0.5 μm with a 500,000 molecular weight cutoff is the most efficient at removing oil, grease, and other contaminants while still allowing the cleaning chemical and the water to pass through. Ultrafiltration equipment is very expensive, but it can be cost effective in situations where waste disposal is severely restricted.

Cleaning tank maintenance is an important consideration. It must be remembered that the major losses from the cleaning tank will be water due to evaporation. Actual cleaning chemical losses will depend on part configurations and their effect on dragout (process chemical loss).

With all aqueous cleaning methods, maintenance of recommended solution concentrations is very important. The manufacturer of the process chemical is best able to provide the methods for maintaining process chemical concentrations.

Rinse Water Quality. The quality of the rinse water has a significant impact on the cleanliness of the part. Tap water will effectively rinse a surface but often will leave a residue that has nothing to do with the cleaner used. The type of rinse water that should be used depends on the cleanliness requirements of the part. Those with strict requirements should be rinsed with the highest quality water, namely distilled water. Next cleanest is deionized water, then soft water (water treated with Zeolite resin), and finally tap water.

Converting an Existing Vapor Degreaser

Converting an existing vapor degreaser to an aqueous cleaning system can enhance the cleaning process and costs less than purchasing entirely new equipment. Figure 1 is a schematic drawing of a vapor degreasing system converted for aqueous cleaning; see the article "Solvent Cold Cleaning and Vapor Degreasing" in this Volume for schematics of conventional vapor degreasers. In some cases, only minimal modifications are needed. Depending on thickness of tank walls, reinforcement may be required to accommodate the increased weight and volume of cleaner in the tank. The refrigerant freeboard coils can be disconnected because they will no longer be required.

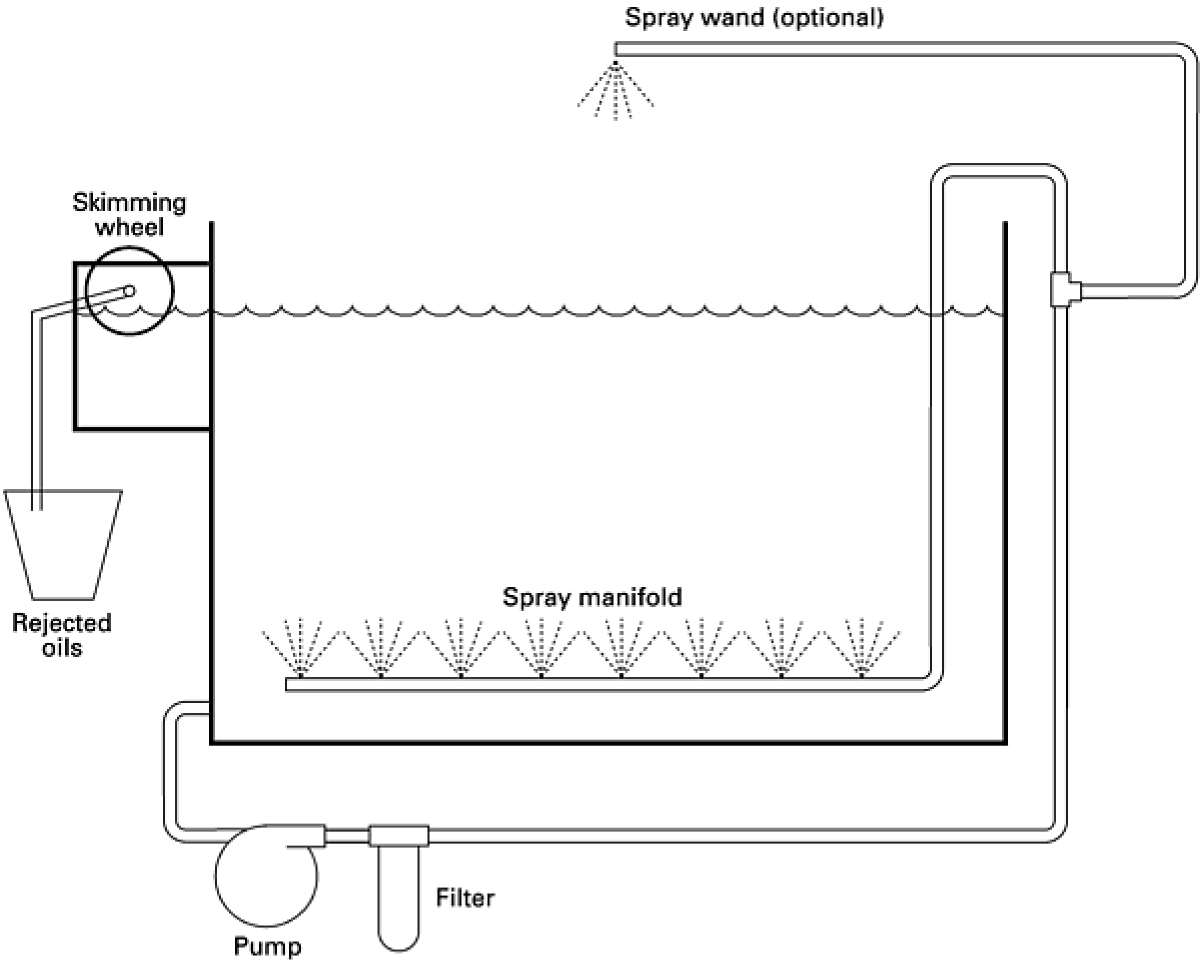

Fig. 1 Schematic of a vapor degreasing system converted for aqueous cleaning

A circulation system will be needed for effective aqueous cleaning. This can consist of a circulation pump and spray manifolds (under solution level), a "lightening" tank mixer, air sparging (not recommended for some alkaline cleaners, which can foam), and even ultrasonic agitation. If the degreaser has a hand spray wand, this can still be used for more aggressive cleaning (again, this would not be recommended for some alkaline cleaners, which can foam).

For alkaline cleaners that reject oils (as opposed to emulsification-type cleaners), some type of oil removal device will be necessary. There are several options available to accomplish this. Skimming devices such as belts or wheels work well. Coalescers, separation tanks, and microfiltration are also effective at removing oils.

Filtering is another option for prolonging the life of the cleaner. Filter media such as fabric and paper cartridges, bags, or ceramic can be used. Selection of proper filter size depends on the molecular size of the contaminants and the molecular size of the cleaning agent ingredients.

A series of rinse tanks to remove the cleaner will need to be added to the cleaning area as well as some type of drying device to remove the rinse water from the workpieces.

Advanced Vapor Degreasing Systems

Another option to traditional vapor degreasing is the so-called advanced vapor degreasing system (Fig. 2). This system is quite different from a conventional vapor degreaser. Instead of using a single vapor degreasing step, the advanced vapor degreaser is a three-stage system involving the use of a solvating chemical (aliphatic esters), a rinsing agent (perfluoro hexane), and a vapor rinse.

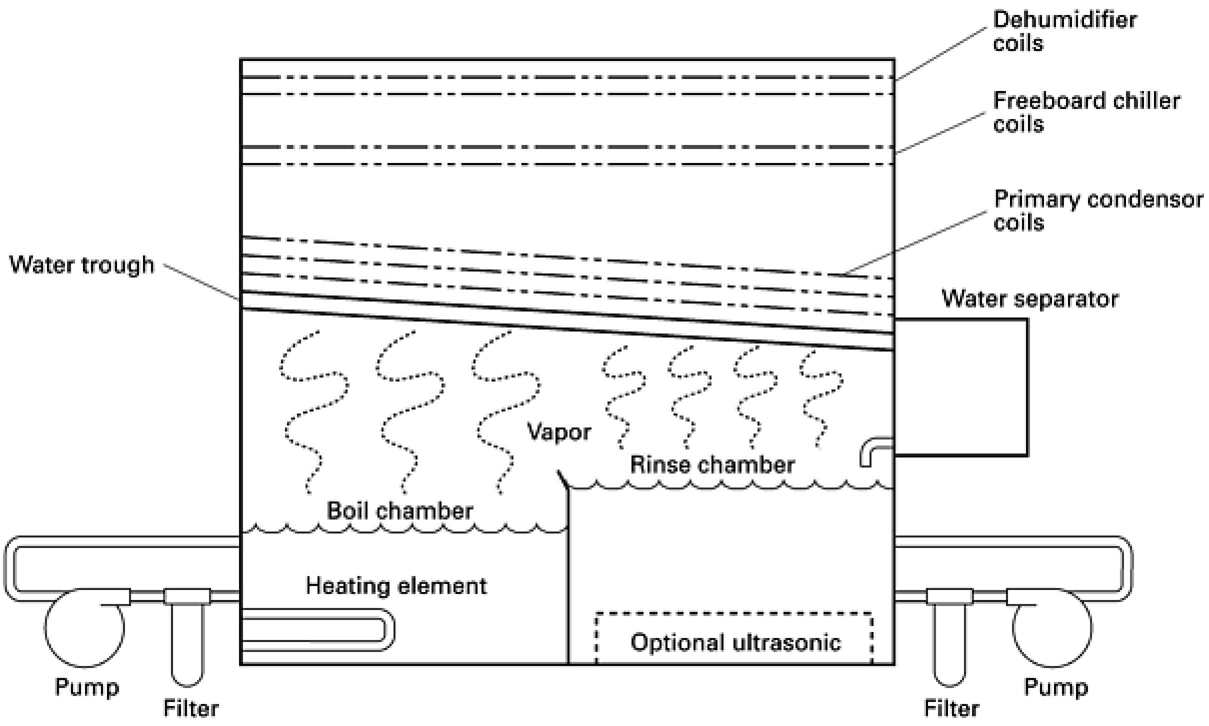

Fig. 2 Schematic of an advanced vapor degreasing system

Equipment for an advanced vapor degreasing system consists of a boil chamber containing a solvating chemical, a rinse chamber containing the rinsing agent, a pump and filter system for both chambers, primary condenser coils, freeboard chiller coils, dehumidifier coils, a water separator, and a freon compressor. Some systems include an optional ultrasonic unit.

The boil chamber generates vapors that rise to the point where the primary condenser coils suppress the vapor column. Distillate generated from this vapor rinse is collected through a trough system and then funneled into a water separator and finally into the rinse chamber. The added rinse solution from this process overflows into the boil chamber (which is already combined with the solvating agent), completing the process cycle.

Parts to be cleaned are first immersed into the boiling solvating chemical/rinse agent mixture. They are then immersed into the rinse agent, which displaces the remaining solvating chemical; the use of an ultrasonic unit at this stage enhances the removal of solvating chemical. Finally, the parts are raised into the vapor column where they are rinsed with condensate vapor and then dried.

Compliant Organic Coatings

Thomas E. Kearney, Courtaulds Aerospace

Introduction

THE FEDERAL CLEAN AIR ACT requires the Environmental Protection Agency (EPA) to establish a set of health-related standards for air pollutants. One of these pollutants is ozone, which is the primary component of the condition known as smog. Because smog is caused in part by the photochemical oxidation of solvent vapors from coating application sources, this regulation has had a profound impact on how coatings are formulated and applied. A whole new class of products has been developed, compliant coatings, that contain lower amounts of organic solvents. This article discusses the compliant coating products available for use in the aerospace industry, including their characteristics and their limitations compared to conventional noncompliant materials.

As of this writing, the use of compliant coatings is not universally required. The National Ambient Air Quality Standard defines the maximum amount of ozone that can be present in an area in order to maintain the air quality required. States with nonattainment regions (regions where the amount of ozone exceeds the maximum) are required to develop a state implementation plan (SIP) that demonstrates how the state will achieve the standard. A SIP usually requires the use of compliant coatings. In attainment areas (regions that meet the air quality standard), compliant coatings are not required. However, the EPA is currently developing control technique guidelines for the aerospace industry that will standardize these organic emission regulations across regions.

Rule 1124

The most stringent regulations within the United States have been implemented by California because of its severe air quality problems. The South Coast Air Quality Management District (SCAQMD) has issued a regulation, Rule 1124, that generally has been the bellwether document for the aerospace industry. As a result, coatings suppliers have concentrated on developing products to meet this rule. Its method of control is to designate the maximum allowable specific weight of volatile organic compounds (VOCs) per unit volume of material. In Rule 1124 the limits are expressed in grams per liter; other regulations may use pounds per gallon. Following are the definitions used in this rule:

- *Primer* is applied directly to an aerospace component for the purposes of corrosion prevention, protection from the environment, functional fluid resistance, and/or adhesion of subsequent coatings.
- *Topcoat* is applied over a primer for purposes such as improved appearance, identification, or maximum corrosion protection of exterior surfaces.
- *Flight test coating* is applied to an aircraft or missile prior to flight testing to protect the aircraft from corrosion and provide required marking during flight test evaluation.
- *Impact-resistant coating* protects aerospace components such as aircraft landing gear, landing gear components, and other surfaces subject to erosion, abrasion, or impact from runway debris.
- *Maskant for chemical milling* is applied directly to an aerospace component during chemical milling of that component.
- *Fuel tank coating* is applied to the interior of integral fuel cells of an aircraft to protect it from corrosion and/or bacterial growth.

Table 1 presents the Rule 1124 requirements in condensed form. It includes the products that require, or will require in the near future, substantially reduced VOC contents. The bulk of VOC emissions from the aerospace industry are from primers, topcoats, and chemical milling maskants. This paper addresses the methods most commonly used to bring these products into compliance: waterborne coatings, exempt-solvent-based coatings, high-solids coatings, powder coating, and electrodeposition, along with the application equipment used.

Table 1 Maximum allowable volatile organic compound contents

Coating	**Pre-1985**	**Current**	**As of 1 Jan 1996**
Primer	650	350	350
Topcoat	600	420	420
Flight test coating used on missiles or single-use aircraft	840	420	420
Impact-resistant coating	600	420	420
Maskant for chemical milling	1200	250	250

Fuel tank coating	720	720	420

Note: All values are given in grams per liter of coating.

Waterborne Coatings

Water can be used in organic coatings to form either emulsions or solutions. However, polymers that can be solubilized in water usually form films with poor moisture resistance, which makes them unsuitable for aerospace environments. The most successful approach has been to use emulsions in which water is the major carrier but is not a solvent for the resins in the coating. These materials are not free from VOC, however. Some organic solvents must be included to control evaporation and flow and to provide film coalescence.

The VOC content in waterborne coatings is determined on a basis that excludes water from the calculation:

$$g/L = \frac{W_s - W_w}{V_m - V_w}$$

where g/L is the grams of VOC per liter of coating, W_s is the weight of VOC in grams, W_w is the weight of water in grams, V_m is the volume of material in liters, and V_w is the volume of water in liters.

Waterborne Primers. The compliant waterborne primers used in the aerospace industry have been based on epoxy resins and polyamine or polyamide curing agents. There are two approaches to formulating these primers. One is to supply the product as an emulsion that can be mixed and applied in a manner similar to that used for solvent-based primers. The second method is to provide a very-high-solids material that can be dispersed in water to form an emulsion just prior to application. A pre-emulsified product is easier for the user to handle, but the water-reducible high-solids material may be preferred for its shipping and storage properties.

Following are some of the characteristics of waterborne primers:

- These products require a scrupulously clean substrate for proper adhesion. They are not forgiving of imperfect surface preparation.
- Drying time can be substantially slower when humidity is high. Drying can be assisted by increasing the air flow across the wet primer.
- Surfactants and water-miscible cosolvents may cause water sensitivity if the primer is exposed to harsh environments before it is completely cured.
- When a waterborne primer is supplied as an emulsion, viscosity may be substantially higher than with a solvent-based primer. However, this is a false body and the applied film will be smooth and uniform.
- The higher density of water, compared to that in most organic solvents, results in less overspray and improves transfer efficiency. (Transfer efficiency is discussed in the section "Application Equipment" in this article.)

Primers supplied for military and commercial applications differ in that the latter must be resistant to the phosphate ester hydraulic fluid used in these aircraft. The densely cross-linked surface that is usually required for resistance to phosphate esters is difficult to achieve with an emulsion, so these products have been primarily used for military aircraft. The specification for military aircraft primers is MIL-P-85582. However, products have recently been developed that will meet some commercial requirements for phosphate ester resistance. Boeing Aircraft Company has qualified a waterborne product to their specification BMS10-11 for commercial use, which requires phosphate ester resistance.

Implementation of waterborne epoxy primers has been successful. In general, their adhesion properties, corrosion protection, and service life have been comparable to those of conventional solvent-based materials.

Waterborne Topcoats. To date, waterborne topcoats have been limited to single-package emulsions, which are most often used as replacements for solvent-based lacquers. However, one manufacturer has developed a two-package aliphatic urethane resin system that shows promise. Coatings made with this material are now under evaluation.

Waterborne Chemical Milling Maskant. In chemical milling, metal is removed by chemical etching rather than by mechanical methods. The maskant is a coating of any kind that defines which areas on the part are to remain unetched (it protects those areas from the action of the etchant). Chemical mill masking has historically been the largest contributor of VOC emissions in the aerospace industry. The solvents used have been toluene, a combination of aromatic solvents, and more recently perchloroethylene. Perchloroethylene is attractive because it has been classified as an exempt solvent in many states. However, it is being considered for reclassification as an air toxin, which would restrict its use.

Prior to July 1993, the VOC emissions limit for chemical milling maskant in Rule 1124 was 1200 g/L (10 lb/gal). The current regulation is 250 g/L (2 lb/gal). This VOC reduction can be achieved by collecting solvent emissions with air pollution control equipment, such as carbon absorption beds, or by using water-based products.

Water-based chemical milling maskants have been available for several years. Two approaches have been used.

The anode dipping process takes its name from the fact that the emulsified particles are attracted to the part to be masked in much the same way that metallic ions are attracted to the anode in electroplating. It is similar to the method used to produce rubber latex gloves. The part to be masked is immersed in a solution of a multivalent salt. After flashoff, the part is dipped into a bath of a latex rubber. The salt on the surface causes the latex to coagulate on the part to an even film thickness of 200 to 250 μm (8 to 10 mils). This must be cured at a low bake (85 to 90 °C, or 190 to 200 °F) for about 1 h. As the water leaves the film, some porosity may remain, and usually a third dip in a seal coat is required. This process provides excellent edge protection and an even film over the part. It also lends itself very well to automation because all parts, regardless of size, can be handled in the same manner. The disadvantage is that it is a three-tank process that requires extra floor space and substantial expenditure on capital equipment.

The single tank method uses a chemically resistant emulsion polymer, formulated with fillers and additives to control the film thickness and adhesion properties. Multiple dips are usually required to achieve the necessary film thickness. The parts are rotated between dips to eliminate variation in film thickness from top to bottom ("wedging"). A bake between coats and after completion is required. The single-tank process can usually be installed in the existing facility, and shop personnel may adapt to it more easily because it more closely approximates the procedure for solvent-based material. The disadvantages are that it may be difficult to achieve coverage on edges and complex parts, and that a longer force-dry at lower temperatures is usually required to avoid entrapment of water.

In both processes, the emulsion bath should be closely monitored to control tank stability. The viscosity and pH should be checked at least weekly.

Exempt-Solvent-Based Coatings

Exempt solvents are a class of organic materials that are nonphotochemically reactive and therefore are not precursors to the formation of ozone. Chemically, these are chlorinated hydrocarbons and chlorofluorocarbons (CFCs). The exempt solvents that have been most commonly used in coating formulations are 1,1,1-trichloroethane (TCA, also known as methyl chloroform) and methylene chloride.

Although these compounds are not smog producers, they have been shown to deplete the ozone layer in the upper atmosphere. Therefore, their use will be restricted in the future. The SCAQMD has established a policy to phase out CFCs on or before December 31, 1995. The Montreal protocol, to which the United States is a signatory, is an international agreement that requires the use of ozone-depleting compounds to be discontinued by the year 2000. However, because these products are still widely used in compliant coating formulations, they may be used for a year or two more, and they are included in this discussion.

The calculation for determining the VOC content of exempt-solvent-based materials is similar to that used for waterborne coatings:

$$g / L(VOC \text{ less exempt}) = \frac{W_s - W_{es}}{V_m - V_{es}}$$

where g/L (VOC less exempt) is the grams of VOC per liter of coating, less exempt compounds, W_s is the weight of the nonexempt volatile compound in grams, W_{es} is the weight of the exempt compound in grams, V_m is the volume of material in liters, and V_{es} is the volume of the exempt compound in liters.

Exempt-Solvent-Based Primers. TCA is the exempt solvent that is most generally used in primers. It is compatible with most organic resins, but it has a lower solubility parameter and a faster evaporation rate than other solvents used in formulating aerospace materials. TCA has been successfully used to formulate epoxy primers for both the military and commercial markets. The military specification is MIL-P-23377F, Class 3. The commercial specifications include Boeing Aircraft BMS10-11; McDonnell Douglas DMS2104, Composition B; and Gulfstream GMS5004. TCA has been popular because it requires no modification of existing procedures or equipment.

Following are some characteristics of exempt-solvent-based primers:

- These products have a tendency to dry spray because of the fast evaporation rate. Additional TCA may be required to ensure a sufficiently wet film.
- The commercially available TCA usually contains 3 to 5% of a stabilizer to prevent the formation of corrosive chloride compounds. This stabilizer is classified as a VOC.
- Because of the high density of chlorinated solvents, there tends to be less overspray than with conventional primers.
- Care must be taken to avoid the use of aluminum pressure vessels with these primers. A violent reaction with aluminum can occur under some circumstances.

Exempt-Solvent-Based Topcoats. There are no exempt-solvent-based topcoats currently in use in the aerospace industry. Until recently, Grumman Aerospace had a specification in use (GM4209) that was based on this technology, but this material has been discontinued because of the restrictions on the use of chlorinated solvents.

High-Solids Coatings

Coatings may be made compliant simply by reducing the amount of organic solvent in the formula. However, to produce the high-performance epoxies and urethanes required for the aerospace industry at a sprayable viscosity, suppliers must use much lower-molecular-weight resins and curing agents than in the past. These are typically liquid resins, and the drying time is strongly dependent on the cross-linking rate and the buildup in molecular weight. The result is a much longer tack-free time than with conventional noncompliant materials. In addition, this reaction causes the molecular weight to increase, which increases the viscosity and shortens the usable work life. In spite of these difficulties, coating suppliers have been able to produce materials that meet the needs of the industry.

High-Solids Primers. High-solids primers have proven to be a viable alternative to waterborne primers and exempt-solvent-based primers for achieving VOC compliance. They are usually low-molecular-weight epoxies reacted with low-viscosity polyamides or polyamines. These primers have a VOC content of 340 g/L or less.

Following are some of the characteristics of high-solids primers:

- These products normally require up to 4 h of drying before topcoating and 12 h or more to dry hard.
- The usable pot life is 4 h or less because of the comparatively rapid buildup in viscosity.
- Care must be taken to avoid applying a wet film that is overly heavy. Higher solids cause the film thickness to increase very quickly.

Compared to waterborne primers, high-solids primers offer:

- Better chemical and fluid resistance
- Less sensitivity to surface contamination
- Better compatibility with high-solids topcoats

The military specification for high-solids aerospace primers is MIL-P-23377F, Class 2. Commercial high-solids primer candidates are now in the qualification phase.

High-Solids Urethane Topcoats. High-solids has been the method most often selected for meeting the VOC requirements for topcoats. Development in this area has been concentrated primarily on aliphatic urethanes. Coatings formulated with these materials have the desirable properties of weatherability, durability, and flexibility. Low-molecular-weight polyesters and acrylics have become generally available that can be cross-linked with aliphatic isocyanate prepolymers to form urethanes. For instances where the use of isocyanates is limited, or greater chemical or fluid resistance is required, topcoats have been formulated with an epoxy resin base.

The low-molecular-weight components necessary to achieve a sprayable viscosity present difficulties similar to those experienced with high-solids primers. The drying time is again related to the increase in molecular weight, and there is a tradeoff between drying time and usable work life. Formulators attempt to balance these properties by using catalysts for the isocyanate-hydroxyl reaction. Increasing the amount of catalyst shortens the tack-free time but also results in a more rapid increase in viscosity. Conversely, less catalyst means a longer drying time and a longer pot life. Depending on the needs of the user, a satisfactory compromise of properties usually can be achieved.

Following are some of the characteristics of high-solids urethanes:

- Complete drying may require 8 to 12 h or more. However, a second coat, if required, can be applied after the film takes on an initial set, and most of the solvent is released in about 2 h.
- The usable pot life is typically 4 h or less.
- Hot humid weather may result in blistering or "solvent pop" if the film thickness is not properly controlled. Under colder conditions there may be a greater tendency to sag or run.

The specification covering high-solids urethanes for military applications is MIL-C-85285. Type I is 420 g/L (3.5 lb/gal) for aircraft applications, and type II is 340 g/L (2.8 lb/gal) for ground support equipment. An example of a commercial high-solids specification is BMS10-60 TY II, Grade B, which has a maximum VOC content of 420 g/L (3.5 lb/gal).

High-Solids Self-Priming Urethane Topcoat. The self-priming topcoat was developed by the Naval Air Warfare Center. The specification is TT-P-2756. The self-priming topcoat combines the functions of a primer and those of a topcoat into a single product that is environmentally compliant. In addition, the corrosion inhibitors incorporated in the formula are chromate-free. This product, commonly known as Unicoat, has been in use for several years at Navy and Air Force depots. In general, its performance has been satisfactory; it works best when applied over a chromated conversion coating such as MIL-C-5541. The use of self-priming topcoats should be avoided if the aircraft will be exposed to harsh environmental conditions over a long period of time.

High-Solids Epoxy Topcoats. The use of epoxy topcoats is indicated when exposure to ultraviolet light is not a factor and good fluid resistance is required, as in the interior of commercial aircraft. Sample specifications are Boeing Aircraft BMS10-11, type II or McDonnell Douglas DPM110. These products have a VOC content of 420 g/L (3.5 lb/gal). The Navy has issued a specification MIL-C-22750E for a high-solids epoxy that can be used where the use of urethanes is restricted, as on shipboard. This specification requires a VOC content of 340 g/L (2.8 lb/gal). These epoxy topcoats have the short pot life and longer drying time of most high-solids materials.

Powder Coatings

Powder coatings are not yet in general use in the aerospace industry, but there is a great deal of interest because of the benefits they offer in terms of VOC content reduction and efficiency of application. Further development may overcome some of the limitations of these coatings. As the name implies, these coatings are applied as powder to a given surface. The solid ingredients, resin pigments, extenders, and so forth are melted together to produce a completely homogenous plastic mass. This is cooled to room temperature and ground to a powder.

The powders that have been considered for use in the aerospace industry are thermoset, meaning that the components react at elevated temperatures to form a cured film. The powder is applied electrostatically (i.e., the electrically charged particles are sprayed on the part to be coated, which is grounded) and is held in place by electrostatic attraction. The coating is then fused together and cured at temperatures from 135 to 200 °C (275 to 400 °F). The types of thermoset powders available fall into the general categories of epoxies, polyesters, polyurethanes, and acrylics. Many of the aerospace applications are on aluminum or aluminum-alloy substrates, which are sensitive to changes in strength properties when exposed to high temperatures. For this reason the principal types used have been epoxy-resin-based materials that can be cured at temperatures as low as 120 °C (250 °F). Powders based on other polymers usually require temperatures of 175 to 200 °C (350 to 400 °F) to achieve optimum properties.

The advantages of powder coatings are that no VOCs are present, up to 98% of the powder can be deposited on the part, application is easy, and minimal rework is required. The disadvantages for aerospace applications are that powder coatings cannot be used on assemblies or aircraft exteriors that cannot be heated, and that epoxy-resin-based products have poor ultraviolet stability and so cannot be used on exterior surfaces.

Electrodeposition

Electrodeposition (electrocoating) is similar to electroplating but deposits organic materials rather than metal ions. It uses the principle of *electrophoresis*, the movement of charged suspended particles under the influence of an applied voltage. This process may be either *anodic*, in which the anode is the coated part, or *cathodic*, in which the organic coating is deposited on the cathode (Fig. 1). Because of problems associated with coating-substrate interaction in anodic systems, the cathodic process is chosen for aerospace applications. The types of materials deposited by electrocoating are epoxies, acrylics, or polyesters cross-linked with melamines or blocked isocyanates. A bake of 135 to 230 °C (275 to 450 °F) is required to cure the deposited film.

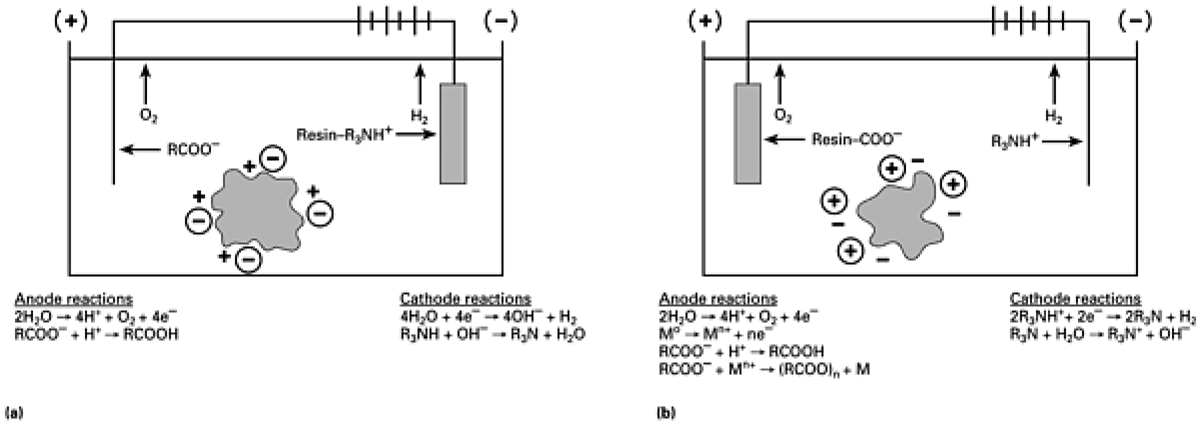

Fig. 1 Electrodeposition process. (a) Cathodic deposition (resin deposits on the negative electrode). (b) Anodic deposition

The advantages of electrodeposition are that:

- The process emits very low levels of VOC.
- The coating film is deposited at a uniform thickness so that the total film weight can be controlled.
- The deposited film has superior adhesion and film density.

The disadvantages of electrodeposition in the aerospace industry are that:

- The initial equipment cost is high.
- The large variation in the sizes of parts to be coated makes it difficult to determine an optimum bath size.
- Electrocoat baths are sensitive to degradation, so turnover at fairly frequent intervals is important. If the bath components are not depleted and replenished at a sufficient rate, it may be necessary to discard the aged product and recharge with fresh material.
- The heat required for curing can affect the temper of aluminum alloys. Careful monitoring of the time

and temperature of the bake is necessary.

Electrodeposition seems to have enough advantages to ensure that it will be used in many applications in the aerospace industry, such as the coating of small parts.

Application Equipment

The regulations for VOC compliance often dictate the transfer efficiency of the spray equipment used to apply the coatings. Transfer efficiency is defined as the percentage of material actually applied to the object out of the total nonvolatile material sprayed. Rule 1124 requires that the transfer efficiency be a minimum of 65% or that the excess overspray be collected by air pollution control equipment. The types of spray equipment commonly used are described below.

Air-atomized spray equipment is the conventional equipment that has been in use for many years. The coating is broken into very fine particles by an air flow at a pressure of 200 to 480 kPa (30 to 70 psi). This method usually results in the best appearance because of the excellent breakup. However, air-atomized spray equipment has a transfer efficiency of only 20 to 30%.

Airless spray equipment forces the coating through a small orifice (diameter of 0.22 to 0.53 mm, or 0.009 to 0.021 in.) under high pressure (6200 to 11,700 kPa, or 900 to 1700 psi). This atomizes the liquid paint into fine particles, but even so the particles are much larger than those produced by air atomization. The transfer efficiency is better than that of air atomization, about 45%, but because of the comparatively large particle size it is difficult to achieve a satisfactory film appearance.

Air-assisted airless spray equipment is similar to airless spray equipment, except that compressed air under low pressure is introduced at the top and the bottom of the fan pattern to break up the tails of the large particles. This produces a better appearance than airless spray. In addition, because lower hydraulic pressures are used (700 to 2750 kPa, or 100 to 400 psi), the transfer efficiency is somewhat better.

High-volume, low-pressure spray equipment is similar to that used for conventional air atomization. The difference is that the guns are constructed with special air and fluid nozzles that allow the coating to be atomized at low air pressures and velocities. This creates a soft spray effect that produces higher transfer efficiencies, usually 60 to 70%.

Electrostatic spray equipment charges the atomized particles so that they are electrically attracted to the grounded metallic part. The resulting "wrap effect" greatly reduces overspray and improves transfer efficiency to 60 to 90%. This technique is effective only if the resistivity of the liquid coating is at least 0.05 MΩ · m. The more highly polar solvents used in aerospace coatings, such as methyl ethyl ketone, are very conductive and result in low resistivities. Some solvents with high resistivity, such as aromatics or esters, must be included in the formula to achieve the desired transfer efficiency.

Compliant Wipe Solvent Cleaners

Mark T. Carroll, Lockheed Fort Worth Company

Introduction

WIPE SOLVENTS are used to remove contaminants from a workpiece before it undergoes manufacturing operations that require clean surfaces, such as bonding, sealing, painting, welding, plating, specialized surface treatment procedures, and others. Traditional wipe solvent cleaners include:

- Methyl ethyl ketone
- Methyl isobutyl ketone
- Trichloroethene (trichloroethylene)
- Tetrachloroethylene (perchloroethylene)

- 1,1,1-trichloroethane (methyl chloroform)
- Acetone
- Toluene
- Dichloromethane (methylene chloride)
- Tetrachloromethane (carbon tetrachloride)
- Benzene
- Xylene
- Ethylene glycol ethers
- Diethylene glycol ethers
- 1,1,2-trichloro-1,2,2-trifluoroethane (CFC-113)
- Combinations of these materials

The U.S. Environmental Protection Agency (EPA) has classified these materials as being either hazardous air pollutants or ozone layer depleting substances. Some relevant regulations are identified in Table 1, along with a curtailment schedule that will either limit or prohibit the use of certain materials in the future. The article "Solvent Cold Cleaning and Vapor Degreasing" in this Volume provides additional information about these cleaners.

Table 1 U.S. regulations related to curtailment in the use of solvent materials

U.S. Regulation	Material	Curtailment schedule
Clean Air Act Amendments of 1990, Hazardous Air Pollutants	190 chemicals, including benzene, chloroform, methyl ethyl ketone, methyl isobutyl ketone, toluene, xylene, trichloroethylene, ethylene glycol ethers, and diethylene glycol ethers	Discontinue use by late 1997
EPA Industrial Toxics (33/50) Program (voluntary)	17 toxic chemicals,including benzene,carbon tetrachloride, chloroform, methyl ethyl ketone, methyl isobutyl ketone, toluene, 1,1,1-trichloroethane, trichloroethylene, and xylene	33% reduction of use by end of 1992; 50% reduction by end of 1995 (from 1988 levels)
Presidential Directive to Accelerate Phase-Out of Ozone Layer Depleting Substances, Feb 1992	Chlorofluorocarbons, halons, 1,1,1-trichloroethane, and carbon tetrachloride	Production phase-out: 50% beginning Jan 1993, 100% by Jan 1996. (Air Force will ban purchases after April 1994)

Alternate Materials

Innovative methods will be required to develop wipe solvent materials that will meet EPA requirements for the emission of volatile organic compounds, the reduction or elimination of hazardous air pollutants, and the elimination of ozone layer depleting substances. Besides meeting EPA requirements, the alternate wipe solvents must be effective in their required applications.

Frequently, the contaminating materials that need to be removed from a surface are actually a combination of materials, and therefore the use of mixed solvents is required to remove them. For example, one of the most widely used wipe solvent cleaners is the MIL-C-38736 formulation (Ref 1), which contains solvents that remove oil-and water-soluble contaminants (Table 2). Particulate materials that are insoluble are removed by the wiping action during cleaning. Some of the solvents in this formulation are classified as hazardous air pollutants. This cleaner also has a very high vapor pressure, which contributes to volatile organic compound emissions, and a low flash point, which warrants it a classification as a flammable material.

Table 2 Compositions of MIL-C-38736 wipe solvent cleaners

Solvent	Concentration,%
Type I	
Aromatic naphtha	50
Ethyl acetate	20
Methyl ethyl ketone	20
Isopropyl alcohol	10
Type II (nonphotochemically reactive)[a]	
Toluene	18.5
Ethyl acetate	35.5
Methyl ethyl ketone	36
Isopropyl alcohol	10

(a) A nonphotochemically reactive solvent is any solvent or solvent combination with an aggregate of less than 20% of its total volume composed of the chemical compounds listed in (1),(2), or (3) below and which does not exceed the individual volume percentage composition limitations. (1) A combination of hydrocarbons, alcohols, aldehydes, esters, ethers, or ketones having an olefinic or cycloolefinic type unsaturation, not to exceed 5% of the total volume. (2) A combination of aromatic compounds with eight or more carbon atoms to the molecule, except ethylbenzene, not to exceed 8% of the total volume. (3) A combination of ethylbenzene, ketones having branched hydrocarbon structures, trichloroethylene, or toluene, not to exceed 20% of the total volume.

Alternate nonhazardous air pollutants and higher vapor pressure materials that can be used to formulate a cleaner that is as efficient as the MIL-C-38736 formulation are available. A series of naphtha-type hydrocarbon materials with a variety of flash points and vapor pressures is available from one manufacturer, whereas naphtha-type hydrocarbons and blends of them that contain dibasic esters are produced by another producer (Table 3). In many cases, glycol ethers (carbon chain >8) can be substituted for methyl ethyl ketone, because they are not classified as hazardous air pollutants and can be selected with low vapor pressures and high flash points.

Table 3 Characteristics of isoparaffins

Commercial name[a]	Flash point		Distillation range		Evaporation rate[b]	Vapor pressure[c]	
	°C	°F	°C	°F		kPa	mm Hg
Isopar C	-7.2	19	97-103	207-217	560	13.1	98

Isopar E	7.2	45	117-137	243-279	155	6.9	52
Isopar G	41.1	106	160-174	320-345	27	1.9	14
Isopar H	53.3	128	179-189	354-372	9	0.83	6.2
Isopar K	52.7	127	177-197	351-387	8	0.76	5.7
Isopar L	62.2	144	191-201	376-405	4	0.69	5.2
Isopar M	88.9	192	223-251	433-484	0.5	0.41	3.1
Isopar V	136.1	277	273-317	523-592	<0.1	0.03	0.26
Axarel 9100	93.3	200	. . .	. . .	<0.1	<0.01	<0.1

(a) Isopar is a registered tradename of Exxon Chemical Co.; Axarel is a registered tradename of DuPont Chemical Co.

(b) Based on butyl acetate = 1.

(c) Vapor pressure determined at 25 °C (77 °F).

Another solvent to consider is ethyl lactate, which is completely miscible with water and most organic solvents. This material, which has a flash point higher than 37.8 °C (100 °F), is reported to be an excellent wipe solvent cleaner for many applications. It is approved by the U.S. Federal Drug Administration for use as a food additive and, therefore, is considered relatively nontoxic.

The terpene hydrocarbon materials also can be used as alternate solvent materials. They include naturally occurring organic compounds, such as *d*-limonene, dipentene, α-terpinene, terpinolene, α-terpineol, and other proprietary terpene hydrocarbons. A major objection to these materials is their odor, which can become overwhelming with prolonged use. Other objections include their instability (auto-oxidation and decomposition), their reactivity with certain polymers and elastomers, and the presence of nonvolatile residue upon evaporation. However, a new class of these materials with low odor and flash points higher than 93.3 °C (200 °F) have been developed (Ref 2). These newer formulations also claim to be low in nonvolatile residue content.

A nonflammable, noncombustible material that is widely used as a wipe solvent cleaner is 1,1,1-trichloroethane (methyl chloroform). Because it is classified as a Class I ozone layer depleting substance, its manufacture will be discontinued in 1994. Reported substitutes listed in the EPA Significant New Alternatives Program (SNAP) are tetrachloroethylene (perchloroethylene), trichloroethene (trichloroethylene), and dichloromethane (methylene chloride), which are all highly toxic materials, and some of the fluorochlorohydrocarbons, which are classified as Class II ozone layer depleting substances. The use of the latter materials will be severely limited by the EPA after 1994. It should be noted, however, that the SNAP alternatives are for vapor degreasing and cold cleaning operations, rather than wipe solvent cleaning operations.

One company manufactures a series of perfluorocarbons that are nonflammable, noncombustible solvents (Table 4). However, the cleaning efficiency of these materials is very poor, and they are only being considered at this time as rinsing and drying agents in new degreasing systems, in combination with either isopropyl alcohol or terpene hydrocarbons. It is also likely that the EPA will ban their use in the near future.

Table 4 Characteristics of perfluorocarbons

Commercial name[(a)]	**Chemical name**	**Flash point**	**Boiling point**		**Vapor pressure**[(b)]

(a) Products of 3M Co.

(b) Vapor pressure determined at 25 °C (77 °F).

Aqueous cleaners, including the newer enzyme cleaning materials, are another class of materials that should be considered as wipe solvent cleaner candidates. These materials have been used previously in wipe solvent cleaning operations and are currently replacing the use of vapor degreasing operations in many manufacturing facilities. Objections to using these materials in wipe solvent cleaning operations include a slow evaporation rate, an unacceptable amount of residue, an inability to remove uncured polymers, such as fuel tank sealant materials encountered in manufacturing operations and carbonaceous soils encountered in the exterior cleaning of aircraft and support equipment during operation and maintenance.

Water-soluble, oil-soluble, and insoluble materials are all encountered in production operations. Wipe solvent cleaners have been developed that combine several of the solvents already discussed (Table 5). These cleaners have low vapor pressures and flash points higher than 37.8 °C (100 °F), which means they are classified as nonflammable. Evaluation tests have shown that these wipe solvent cleaners are very efficient in general-purpose wipe solvent cleaning operations.

Evaluation of Wipe Solvent Cleaners

The specific procedure for using wipe solvent cleaners involves wetting a clean cloth with the solvent, wiping the surface to be cleaned, and removing the residual solvent from the surface with a clean, dry cloth. The wipe solvent must either dissolve the contaminants or keep them in suspension until they can be removed from the surface with the clean, dry cloth. If the solvent evaporates too quickly, then the contaminants are merely redeposited on the surface. Because a wipe solvent cleaner is likely to be used as a general-purpose cleaner in production operations, it would need to clean all types of surfaces, such as metals, including those that have been chemically treated, anodized, or plated; primers; paints; coatings; rubbers; plastics, and others. It is actually unlikely that a single wipe solvent cleaner would be suitable for all cleaning operations. It is also obvious that extensive evaluations would be required to ensure the applicability of the wipe solvent cleaner to the cleaning processes under consideration.

An initial evaluation should include a literature review to determine the properties of the selected wipe solvent cleaner materials, such as toxicity, flash point, vapor pressure, and corrosion potential. Consultation with an industrial hygienist and an environmental professional is also recommended to ensure the acceptability of the candidate material.

Laboratory screening tests can then be conducted to determine the general cleaning efficiency properties of the candidate material, as well as its compatibility with the surface materials to be cleaned. These tests can include a simple water-break test and adhesion tests using an adhesive material that is representative of those that will be applied in production operations. Compatibility tests can consist of exposing the materials to be cleaned to the wipe solvent cleaner and then observing deterioration and other deleterious effects that might occur.

Evaluation Parameters by Property. After selecting the potential candidates, based on screening test results, extensive evaluation tests must be conducted. For general-purpose wipe solvent cleaner operations, the properties summarized in Table 6 and described below should be determined.

Table 6 Tests for wipe solvent cleaners

Attribute	Test method
Cleaning efficiency	Contaminate substrate with standard contaminant. Expose to 48.9 °C (120 °F) for 24 h. Clean with candidate cleaner. Perform mechanical property test simulating subsequent operations.
Compatibility	Expose substrates to candidate cleaners. Observe for deterioration of substrates.

Corrosion potential	Immersion corrosion, ASTM F 483; sandwich corrosion, ASTM F 1110; hydrogen embrittlement, ASTM F 519; and stress cracking, ASTM G 38
Vapor pressure	Calculate using Eq 1 (described in text)
Volatile organic compounds	ASTM D 3960
Flash point	ASTM D 3278
Odor	ASTM D 1296 or subjective evaluation using operators performing cleaning operations in open and confined areas
Dry residue	Apply candidate cleaners to a cleaned reflective surface. Allow to evaporate. Observe for residue and/or streaking.
Composition	Chromatography, ASTM D 3545; infrared analysis, ASTM E 1252
Water content	ASTM D 1364
Acidity	ASTM D 1613
Refractive index	ASTM D 1218
Density	ASTM D 1475

The cleaning efficiency property of the wipe solvent cleaner will determine if subsequent operations can be satisfactorily performed. The surfaces to be cleaned should be contaminated with a solution such as that described in AMS 3166 (Ref 3) and shown in Table 7, followed by cleaning with the candidate wipe solvent cleaner. After the contaminating material is applied to the test substrate, it should be exposed to a temperature of 48.9 °C (120 °F) for 24 h, in order to ensure that crevices and imperfections in the substrate are sufficiently contaminated. Next, the test substrate should be cleaned with the proposed wipe solvent material. Because the laboratory tests listed in Table 6 do not guarantee that the wipe solvent will in fact be suitable for use in actual manufacturing operations, physical property tests, such as sealant adhesion, adhesive strength, paint and primer application and adhesion, and subsequent chemical surface treatments and processing should be conducted to determine if the wipe solvent is effective in removing the contaminant. It is also important to ensure that subsequent manufacturing operations will not be compromised.

Table 7 Standard contaminant for testing the cleaning efficiency of wipe solvent cleaners

Ingredient	**Parts by weight**
Glycerol monostearate	3.0
Glycerol trioleate	9.0

Caprylic acid	3.0
Lauryl alcohol	1.3
Cholesterol	1.2
Mineral oil	2.7
Petrolatum	3.0
Lecithin	0.3
Water	70.0

Heat and blend and add 0.5 wt% lamp black. Do not heat above 93.3 °C (200 °F).

It should be noted that new compliant wipe solvent cleaner formulations may not be as efficient in preparing some substrates as the wipe solvent cleaner formulations that are currently used. Therefore, it may be necessary to use additional techniques to obtain a satisfactory surface for the intended purpose. For example, evaluation tests have revealed that some substrates cleaned with the wipe solvent cleaners listed in Table 5 required the application of an adhesion promoter to ensure the adhesion of fuel tank sealants.

Compatibility tests will determine the effects of the wipe solvent cleaner on the substrates being cleaned and adjacent materials that the cleaner may contact. The materials should be exposed to the wipe solvent cleaner for a typical time period. After exposure, the materials should be observed for etching, staining, and oxidation in metals; deterioration, softening, and swelling in elastomers; cracking or crazing in plastics; and loss of adhesion for any coated surfaces. Whether these changes are permanent or transitory should also be determined. These test results should indicate which substrates will require different wipe solvent cleaners.

Compatibility tests that were conducted on the formulations given in Table 5 indicated that these cleaners were satisfactory for use on most of the substrates investigated. However, they could not be used in cleaning operations involving most elastomers (specifically, the silicone, natural, neoprene, butyl, and nitrile rubbers) and some plastic materials, such as acrylics, polycarbonates, polystyrene, and polyurethane. Alternate cleaners, such as diluted isopropyl alcohol and, in some cases, acetone, were required for the wipe solvent cleaning of these substrates.

The corrosion potential of the wipe solvent cleaner is an extremely important property that must be determined for metal-cleaning operations. In some cases, the wipe solvent cleaner contacts the metals for a short period of time, whereas in cases such as assembly cleaning, it can become trapped in the faying surfaces of joints, which would allow long-term contact with metal surfaces. Numerous corrosion tests are available to indicate potential problems in these applications.

The most simple test is the total immersion corrosion test, described in ASTM F 483. In applications where entrapment of the wipe solvent cleaner may occur, the sandwich corrosion test described in ASTM F 1110 is satisfactory. If the metals being cleaned are subject to hydrogen embrittlement or stress-corrosion cracking, then corrosion tests such as these described in ASTM F 519 and ASTM G 38 should be conducted. Other corrosion tests are available and should be selected if they better simulate the requirements of the wipe solvent cleaner operation in question.

Vapor pressure is directly related to evaporation rate for a given solvent type, such as alcohols or ketones. Generally, the lower the vapor pressure, the lower the evaporation rate. Because the EPA tends to require a maximum pressure of 6 kPa (45 mm Hg) for wipe solvent cleaners, it is obvious that the evaporation rate of new wipe solvent cleaners will be much slower than that experienced traditionally. This is beneficial in that less cleaner will be required for a given cleaning operation. A potential hazard, however, is that there is a greater chance of the wipe solvent cleaner being trapped in the faying surfaces of manufactured assemblies. In addition, areas that are hard to reach will be more difficult to wipe dry during wipe cleaning operations. The vapor pressure of candidate wipe solvent cleaners can be calculated using Eq 1:

$$VP = \sum_j^i \frac{(VP)_i (W)_i /(MW)_i}{\sum_i \left[(W)_i /(MW)_i + \sum_j \left[(W)_j /(MW)_j \right] \right]} \qquad \textbf{(Eq 1)}$$

where VP is the composite vapor pressure of the volatile organic compound in the solvent cleaner, $(VP)_i$ is the vapor pressure at 20 °C (68 °F) of the "i"th component in the solvent cleaner, $(W)_{i \text{ or } j}$ is the weight in grams of the "i"th (or "j"th) component in the solvent cleaner, $(MW)_{i \text{ or } j}$ is the molecular weight of the "i"th (or "j"th) component in the solvent cleaner, i is the volatile organic compound component(s) in the solvent cleaner, and j is the exempt component(s) in the solvent cleaner, as defined by appropriate federal, state, and local regulations.

Volatile organic compounds are contained in many of the new wipe solvent cleaners. The emission of these compounds must be minimized to meet most established clean-air requirements. Because wipe solvent cleaners are normally used in all areas of production operations, unique methods must be developed to conform to these emission requirements.

To control the emissions from the solvents listed in Table 5, which have very low vapor pressures that result in reduced evaporation rates, one company immediately places the used wiping cloths that are wet with wipe solvent into an aluminum-coated plastic bag. The bags are then collected at the end of each shift and compacted into sealed drums for later disposal. This method reduces volatile organic compound emissions by approximately 75%. The drums of compacted cloths can be used as high-energy, supplemental fuel in cement manufacturing and incinerated in permitted hazardous waste incinerators. Volatile organic compound content is determined using the test method described in ASTM D 3960.

Flash Points. Wipe solvent cleaners with flash points higher than 37.8 °C (100 °F) are classified by the Occupational Safety and Health Administration (OSHA) as combustible materials, whereas those cleaners with flash points below that temperature are classified as flammable materials. The former type of cleaner is preferred because of safety concerns. In cases where nonflammable, noncombustible materials are required, only a limited number of compliant materials are available, and their cleaning efficiency may not suffice for the specific operation. If this is the case, alternate cleaning procedures, such as providing an inert atmosphere or establishing cleaning areas where ignition sources can be eliminated, should be investigated. Flash point is determined using the procedure described in ASTM D 3278.

Odor is a rather subjective property of wipe solvent cleaners. In addition to conducting a standard test, as defined in ASTM D 1295, other tests should be conducted under the conditions of actual production environments. These environments should include open-area cleaning, as well as confined-space cleaning. A number of different operators should be used to obtain a general consensus on the odor of the wipe solvent cleaner. This odor should be mild and not objectionable to personnel engaged in the cleaning operations. Methods of minimizing odor include an increase in ventilation and the use of respirators.

Dry Residue. The wipe solvent cleaner must evaporate without leaving residue on the surface that could interfere with subsequent manufacturing operations. This property can be determined by applying the candidate cleaner to a test substrate, allowing it to evaporate, and then observing the resulting surface for evidence of residue and streaking. Optimally, the test substrate should be a cleaned, reflective surface.

Other properties to evaluate include composition, water content, acidity, refractive index, and density. It is useful to determine these properties by conducting receiving inspection-type tests to ensure that the wipe solvent cleaner has the same composition as when evaluated. These tests will also indicate if accidental contamination of the cleaner has occurred. The relevant test methods are identified in Table 6.

Industrial hygiene and safety is another important aspect of the wipe solvent cleaner that must be evaluated. The cleaner should not contain components listed by OSHA as being hazardous materials, which are toxic under use conditions. It is also important to not exceed threshold limit value, which is typically a minimum of 150 parts per million for a wipe solvent cleaner, although lower values may be satisfactory if suitable protection techniques are incorporated. To determine the protection methods required to limit the exposure of cleaning personnel to the wipe solvent cleaners, monitoring tests should be conducted on the air near those personnel. Depending on the cleaning operation (open or confined areas) and area ventilation, it may be necessary to use respirators while conducting cleaning activities. Eye and skin protection should also be investigated and the necessary devices made available to personnel.

3. "Solvents, Cleaning, for Cleaning Prior to Application of Sealing Compounds," AMS 3166, Society of Automotive Engineers

- **A**
- **abrasion**
  - (1) A process in which hard particles or protuberances are forced against and moved along a solid surface. (2) A roughening or scratching of a surface due to abrasive wear . (3) The process of grinding or wearing away a surface through the use of abrasives.
- **abrasive**
  - (1) A hard substance used for grinding , honing , lapping , superfinishing , polishing, pressure blasting, or barrel finishing . Abrasives in common use are alumina, silicon carbide, boron carbide, diamond, cubic boron nitride, garnet, and quartz. (2) Hard particles, such as rocks, sand, or fragments of certain hard metals, that wear away a surface when they move across it under pressure. See also superabrasives .
- **abrasive blasting**
  - A process for cleaning or finishing by means of an abrasive directed at high velocity against the workpiece. Abrasive blasting methods include grit blasting , sandblasting , and shotblasting .
- **abrasive disk**
  - (1) A grinding wheel that is mounted on a steel plate, with the exposed flat side being used for grinding. (2) A disk-shaped, coated abrasive product.
- **abrasive flow machining**
  - Removal of material by a viscous abrasive media flowing under pressure through or across a workpiece.
- **abrasive jet machining**
  - Material removal from a workpiece by impingement of fine abrasive particles that are entrained in a focused, high-velocity gas stream.
- **abrasive machining**
  - A machining process in which the points of abrasive particles are used as machining tools. Grinding is a typical abrasive machining process.
- **abrasive wear**
  - The removal of material from a surface when hard particles slide or roll across the surface under pressure. The particles may be loose or may be part of another surface in contact with the surface being abraded. Compare with adhesive wear .
- **abrasive wheel**
  - A grinding wheel composed of an abrasive grit and a bonding agent.
- **abrasivity**
  - The extent to which a surface, particle, or collection of particles will tend to cause abrasive wear when forced against a solid surface under relative motion and under prescribed conditions.
- **accelerated aging**
  - A process by which the effects of aging are accelerated under extreme and/or cycling temperature and humidity conditions. The process is meant to duplicate long-time environmental conditions in a relatively short space of time.
- **acicular ferrite**
  - A highly substructured nonequiaxed ferrite formed upon continuous cooling by a mixed diffusion and shear mode of transformation that begins at a temperature slightly higher than the transformation temperature range for upper bainite. It is distinguished from bainite in that it has a limited amount of carbon available; thus, there is only a small amount of carbide present.
- **acicular ferrite steels**
  - Ultralow carbon (<0.08%) steels having a microstructure consisting of either acicular ferrite or a mixture of acicular and equiaxed ferrite .
- **acid cleaning**
  - Process in which a solution of mineral acid, organic acid, or acid salt, in combination with a wetting agent and detergent, is used to remove oxide, shop soil, oil, grease, and other contaminants from metal surfaces, with or without the use of heat.
- **acrylic**
  - A coating based on a polymer containing short-chain esters of acrylic and methacrylic acid. Their physical properties can be controlled in part by the choice of the alcohol used to make the ester.

- **activation**
  - (1) The changing of a passive surface of a metal to a chemically active state. Contrast with passivation . (2) The (usually) chemical process of making a surface more receptive to bonding with a coating or an encapsulating material.
- **active**
  - The negative direction of electrode potential . Also used to describe corrosion and its associated potential range when an electrode potential is more negative than an adjacent depressed corrosion rate (passive) range.
- **active metal**
  - A metal ready to corrode, or being corroded.
- **actual contact area**
  - In tribology, the total area of contact formed by summing the localized asperity contact areas within the apparent area of contact . Also known as real area of contact.
- **addition agent**
  - See additive .
- **additive**
  - (1) A material added in small quantities to a solution to modify its characteristics. For example, additives may be added to a plating solution to modify the character of the deposit. (2) In lubrication, a material added to a lubricant for the purpose of imparting new properties or of enhancing existing properties. Main classes of additives include anticorrosive, antifoam, antioxidant , antiwear, detergent , dispersant , extreme-pressure lubricant , and VI improver additives. (3) In polymer engineering, a substance added to another substance, usually to improve properties, such as plasticizers , initiators, light stabilizers, and flame retardants.
- **adherend**
  - A body held to another body by an adhesive. See also substrate .
- **adhesion**
  - The attractive force that exists between a deposit and its substrate that can be measured as the force required to separate a deposit and its substrate. Contrast with cohesion .
- **adhesion promoter**
  - A coating applied to a substrate , before it is coated with an adhesive, to improve the adhesion of the substrate. Also called primer .
- **adhesive**
  - A substance capable of holding materials together by surface attachment. Adhesive is a general term and includes, among others, cement, glue, mucilage, and paste. These terms are loosely used interchangeably. Various descriptive adjectives are applied to the term adhesive to indicate certain physical characteristics: hot-melt adhesives, pressure-sensitive adhesives, structural adhesives, ultraviolet/electron-beam cured adhesives, and water-based adhesives.
- **adhesive bond**
  - Attractive forces, generally physical in character, between an adhesive and the base materials. Two principal interactions that contribute to the adhesion are van der Waals bonds and dipole bonds.
- **adhesive film**
  - A synthetic resin adhesive, with or without a film carrier fabric, usually of the thermosetting type, in the form of a thin film of resin, used under heat and pressure as an interleaf in the production of bonded structures.
- **adhesive strength**
  - The strength of the bond between an adhesive and an adherend .
- **adhesive wear**
  - (1) Wear by transference of material from one surface to another during relative motion due to a process of solid-phase welding. Particles that are removed from one surface are either permanently or temporarily attached to the other surface. (2) Wear due to localized bonding between contacting solid surfaces leading to material transfer between the two surfaces or loss from either surface. Compare with abrasive wear .
- **adsorption**
  - The adhesion of the molecules of gases, dissolved substances, or liquids to the surfaces of solids or liquids with which they are in contact.
- **aerated bath nitriding**

  - A type of liquid nitriding in which air is pumped through the molten bath creating agitation and increased chemical activity.
- **AFS 50-70 test sand**
  - A rounded quartz sand specified for use as an abrasive in the dry sand-rubber wheel test (ASTM G 65). Using the U.S. Sieve Series, none of this sand will be retained on Sieve No. 40, 5% maximum will be retained on Sieve No. 50, 95% minimum will be retained on Sieve No. 70, and none will pass Sieve No. 100. This places all the particle diameters between 425 and 150 µm. See also sieve analysis .
- **age hardening**
  - (1) Hardening by aging (heat treatment) usually after rapid cooling or cold working. (2) (of grease). The increasing consistency of a lubricating grease with time of storage.
- **age softening**
  - Spontaneous decrease of strength and hardness that takes place at room temperature in certain strain hardened alloys, especially those of aluminum.
- **agglomerate**
  - The clustering together of a few or many particles, whiskers, or fibers, or a combination thereof, into a larger solid mass.
- **aging**
  - (1) The storage of porcelain enamel slips or powders before use. (2) The change occurring in porcelain enamel slips or powders with the lapse of time. (3) In heat treatment, a change in the properties of certain metals and alloys that occurs at ambient or moderately elevated temperatures after hot working or a heat treatment (quench aging in ferrous alloys, natural or artificial aging in ferrous and nonferrous alloys) or after cold working (strain aging). The change in properties is often, but not always, due to a phase change (precipitation), but never involves a change in chemical composition of the metal or alloy.
- **air cap**
  - A device for forming, shaping, and directing an air pattern for the atomization of wire or ceramic rod.
- **air feed**
  - A thermal spraying process variation in which an air stream carries the powdered material to be sprayed through the gun and into the heat source.
- **air gap**
  - In extrusion coating, the distance from the die opening to the nip formed by the pressure roll and the chill roll.
- **air hole**
  - A hole in a casting caused by air or gas trapped in the metal during solidification.
- **air setting**
  - The characteristic of some materials, such as refractory cements, core pastes, binders , and plastics, to take permanent set at normal air temperatures.
- **alclad**
  - Composite wrought product comprised of an aluminum alloy core having one or both surfaces a metallurgically bonded aluminum or aluminum alloy coating that is anodic to the core and thus electrochemically protects the core against corrosion .
- **aliphatic solvent**
  - A type of solvent comprised mainly of straight-chain hydrocarbons. Examples are gasoline, kerosene, hexane, and naphtha.
- **alkaline cleaner**
  - A material blended from alkali hydroxides and such alkaline salts as borates, carbonates, phosphates, or silicates. The cleaning action may be enhanced by the addition of surface-active agents and special solvents.
- **alkyd**
  - A coating based on a polyester binder . The polyester binders are chemical combinations of molecules that contain more than one acid or alcohol group. Alkyds are widely used in water-based house paints and automotive primers.
- **alligatoring**
  - (1) Pronounced wide cracking over the entire surface of a coating having the appearance of alligator hide. (2) The longitudinal splitting of flat slabs in a plane parallel to the rolled surface. Also called fishmouthing.

- **allowance**
  - (1) The specified difference in limiting sizes (minimum clearance or maximum interference) between mating parts, as computed arithmetically from the specified dimensions and tolerances of each part. (2) In a foundry, the specified clearance. The difference in limiting sizes, such as minimum clearance or maximum interferences between mating parts, as computed arithmetically. See also tolerance .
- **aluminizing**
  - Forming of an aluminum or aluminum alloy coating on a metal by hot dipping, hot spraying, or diffusion .
- **amorphous**
  - Not having a crystal structure; noncrystalline.
- **Amsler wear machine**
  - A wear and traction-testing machine consisting of two disk-shaped specimens oriented such that their axes are parallel and whose circumferential, cylindrical surfaces are caused to roll or roll and slide against one another. The rotation rates of each disk may be varied so as to produce varying degrees of sliding and rolling motion.
- **anchorite**
  - A zinc-iron phosphate coating for iron and steel.
- **anchor pattern**
  - A pattern made by blast cleaning abrasives on an adherend surface in preparation for adhesive application prior to bonding. Pattern is examined in profile.
- **angle of attack**
  - In tribology, the angle between the direction of motion of an impinging liquid or solid particle and the tangent to the surface at the point of impact.
- **angle of incidence**
  - In tribology, the angle between the direction of motion of an impinging liquid or solid particle stream and the plane of the surface.
- **angle-ply laminate**
  - A laminate having fibers of adjacent plies, oriented at alternating angles.
- **anion**
  - A negatively charged ion.
- **anionic detergent**
  - A detergent that produces aggregates of negatively charged ions with colloidal properties.
- **anneal to temper**
  - A final partial anneal that softens a cold-worked nonferrous alloy to a specified level of hardness or tensile strength.
- **anode**
  - The electrode in electrolysis at which negative ions are discharged, positive ions are formed, or other oxidizing reactions occur. Contrast with cathode .
- **anode corrosion**
  - The dissolution of a metal acting as an anode .
- **anode film**
  - (1) The layer of solution in contact with the anode that differs in composition from that of the bulk of the solution. (2) The outer layer of the anode itself consisting of oxidation or reaction products of the anode metal.
- **anodic cleaning**
  - Electrolytic cleaning in which the work is the anode . Also called reverse-current cleaning.
- **anodic coating**
  - A protective, decorative, or functional coating, formed by conversion of the surface of a metal in an electrolytic oxidation process.
- **anodic etching**
  - Method of revealing microstructure by selective dissolution of the polished surface under application of a direct current. Variation with layer formation: anodizing.
- **anodic inhibitor**
  - A chemical substance or mixture that prevents or reduces the rate of the anodic or oxidation reaction. See also inhibitor .
- **anodic pickling**
  - Electrolytic pickling in which the work is the anode.

- **anodic protection**
    - (1) A technique to reduce the corrosion rate of a metal by polarizing it into its passive region, where dissolution rates are low. (2) Imposing an external electrical potential to protect a metal from corrosive attack. (Applicable only to metals that show active-passive behavior.) Contrast with cathodic protection .
- **anodic reaction**
    - Electrode reaction equivalent to a transfer of positive charge from the electronic to the ionic conductor. An anodic reaction is an oxidation process. An example common in corrosion is Me $\mathrm{Me}^{n+} + ne^{-}$
- **anodizing**
    - An electrolytic oxidation process in which the surface of a metal, when anodic, is converted to a coating having desirable protective, decorative, or functional properties.
- **anolyte**
    - The portion of electrolyte in the vicinity of the anode; in a divided cell, the portion of electrolyte on the anode side of the diagram.
- **antioxidant**
    - Any additive for the purpose of reducing the rate of oxidation and subsequent deterioration of a material.
- **antipitting agent**
    - An additive for electroplating solutions to prevent the formation of pits or large pores in the electrodeposit.
- **antiskinning agents**
    - Chemicals added to a paint to help prevent the formation of a surface film on the paint.
- **apparent area of contact**
    - In tribology, the area of contact between two solid surfaces defined by the boundaries of their macroscopic interface.
- **arc of contact**
    - The portion of the circumference of a grinding wheel or cutter touching the work being processed.
- **aromatic**
    - A type of solvent based on benzene ring molecules. Aromatics are often used as diluents in acrylic lacquers. Typical examples are benzene, xylol, and toluol.
- **asperity**
    - In tribology, a protuberance in the small-scale topographical irregularities of a solid surface.
- **atmospheric corrosion**
    - The gradual degradation or alteration of a material by contact with substances present in the atmosphere, such as oxygen, carbon dioxide, water vapor, and sulfur and chlorine compounds.
- **atomic replica**
    - A thin replica devoid of structure on the molecular level. It is prepared by the vacuum or hydrolytic deposition of metals or simple compounds of low molecular weight. See also replica .
- **atomization**
    - In thermal spraying, the division of molten material at the end of the wire or rod into fine particles.
- **attack-polishing**
    - Simultaneous etching and mechanical polishing.
- **attrition**
    - Removal of small fragments of surface material during sliding contact.
- **attritor**
    - A high-intensity ball mill whose drum is stationary and whose balls are agitated by rotating baffles, paddles, or rods at right angle to the drum axis.
- **attritor grinding**
    - The intensive grinding or alloying in an attritor. Examples: milling of carbides and binder metal powders and mechanical alloying of hard dispersoid particles with softer metal or alloy powders.
- **austempering**
    - A heat treatment for ferrous alloys in which a part is quenched from the austenitizing temperature at a rate fast enough to avoid formation of ferrite or pearlite and then held at a temperature just above M_s, the martensite start temperature, until transformation to bainite is complete. Although designated as bainite in both austempered steel and austempered ductile iron (ADI), austempered

steel consists of two-phase mixtures containing ferrite and carbide, while austempered ductile iron consists of two-phase mixtures containing ferrite and austenite .

- **austenite**
  - A solid solution of one or more elements in face-centered cubic iron (gamma iron). Unless otherwise designated (such as nickel austenite), the solute is generally assumed to be carbon.
- **austenitizing**
  - Forming austenite by heating a ferrous alloy into the transformation range (partial austenitizing) or above the transformation range (complete austenitizing). When used without qualification, the term implies complete austenitizing.
- **autocatalytic plating**
  - Deposition of a metal coating by a controlled chemical reduction, catalyzed by the metal or alloy being deposited.
- **average grain diameter**
  - The mean diameter of an equiaxed grain section whose size represents all the grain sections in the aggregate being measured. See also grain size .
- **B**
- **babbitting**
  - The process by which a babbitt metal is mechanically or chemically bonded to a shell or stiffener, which supports the weight and torsion of a rotating, oscillating, or sliding shaft. The babbitt metal, being softer than the support and having excellent antifrictional properties, prevents galling and/or scoring of the shaft over long periods of use.
- **babbitt metal**
  - A nonferrous bearing alloy originated by Isaac Babbitt in 1839. Currently, the term includes several tin-base alloys consisting mainly of various amounts of copper, antimony, tin, and lead. Lead-base babbitt metals are also used.
- **back emission**
  - The electrical breakdown of air resulting from an excessive charge buildup in porcelain enamel powder film during powder application. This reaction is due to the self-limiting characteristic of electrostatic powders. Also known as back ionization.
- **backing**
  - (1) In grinding, the material (paper, cloth, or fiber) that serves as the base for coated abrasives . (2) In welding, a material placed under or behind a joint to enhance the quality of the weld at the root. It may be a metal backing ring or strip; a pass of weld metal; or a nonmetal such as carbon, granular flux or a protective gas atmosphere . (3) In plain bearings, that part of the bearing to which the bearing alloy is attached, normally by a metallurgical bond .
- **backing film**
  - A film used as auxiliary support for the thin replica or specimen-supporting film.
- **back ionization**
  - See back emission .
- **bainite**
  - A metastable aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures below the pearlite range but above M_s, the martensite start temperature. Upper bainite is an aggregate that contains parallel lath-shape units of ferrite, produces the so-called "feathery" appearance in optical microscopy, and is formed above approximately 350 °C (660 °F). Lower bainite, which has an acicular appearance similar to tempered martensite , is formed below approximately 350 °C (660 °F).
- **bainitic hardening**
  - Quench-hardening treatment resulting principally in the formation of bainite .
- **Bakelite**
  - A proprietary name for a phenolic thermosetting resin used as a plastic mounting material for metallographic samples.
- **ball milling**
  - In porcelain enameling, a method of grinding and mixing ceramic materials, with or without liquid, in a dense, ceramic-lined rotating cylinder or conical mill partially filled with grinding media such as pebbles or porcelain balls.
- **bark**
  - The decarburized layer just beneath the scale that results from heating steel in an oxidizing atmosphere.

- **barrel burnishing**
    - The smoothing of surfaces by means of tumbling the work in rotating barrels in the presence of metallic or ceramic shot, and in the absence of abrasive. In ball burnishing, the shot consists of hardened steel balls.
- **barrel finishing**
    - Improving the surface finish of workpieces by processing them in rotating equipment along with abrasive particles that may be suspended in a liquid. The barrel is normally loaded about 60% full with a mixture of parts, media, compound, and water. See also tumbling .
- **barrel plating**
    - (or cleaning). Plating articles in a rotating container, usually a perforated cylinder that operates at least partially submerged in a solution.
- **barrier coat**
    - An exterior coating applied to a composite filament-wound structure to provide protection. In fuel tanks, a coating applied to the inside of the tank to prevent fuel from permeating the side wall.
- **barrier film**
    - The layer of film used during cure to permit removal of air and volatiles from a reinforced plastic or a composite lay-up while minimizing resin loss.
- **barrier layer**
    - In anodizing aluminum, the thin, pore-free, semiconducting aluminum oxide region nearest the metal surface and distinct from the main anodic oxide coating, which has a pore structure.
- **base metal**
    - (1) The original metal to which one or more coatings are applied. Also known as basis metal. (2) The metal present in the largest proportion in an alloy; brass, for example, is a copper-base alloy. (3) A metal that readily oxidizes, or that dissolves to form ions. Contrast with noble metal .
- **basis metal**
    - See base metal .
- **beads**
    - Defects in porcelain enamel caused by coarse enamel particles, spitting of guns, or falloff of accumulation on guns. Also known as lumps.
- **Beilby layer**
    - The altered surface layer formed on a crystalline solid during a wear process or by mechanical polishing that, according to a theory by Sir George Beilby, consists of a material in an amorphous state. It is now generally accepted that an amorphous layer is not formed at a surface except possibly in some special cases; however, the term is still used to denote a surface altered by wear, without any implication as to its actual structure.
- **bending**
    - The straining of material, usually flat sheet or strip metal, by moving it around a straight axis lying in the neutral plane. Metal flow takes place within the plastic range of the metal, so that the bent part retains a permanent set after removal of the applied stress. The cross section of the bend inward from the neutral plane is in compression; the rest of the bend is in tension.
- **bend test**
    - A test for determining relative ductility of metal that is to be formed (usually sheet, strip, plate, or wire) and for determining soundness and toughness of metal (after welding, for example). The specimen is usually bent over a specified diameter through a specified angle for a specified number of cycles. There are four general types of bend test, named according to the manner in which the forces are applied to the specimen to make the bend: free bend, guided bend, semiguided bend, and wrap-around bend. Bend tests can also be used to test the adhesion of metallic or organic coatings.
- **beta rays**
    - Beams of electrons that can be used to cure certain kinds of paints.
- **binder**
    - The paint material that forms the film, so called because it binds the pigment and any additives present into a solid durable film. Also referred to as the resin.
- **bisque**
    - A coating of wet process porcelain enamel that has been dried, but not fired.
- **black annealing**
    - Box annealing or pot annealing ferrous alloy sheet, strip, or wire impart a black color to the oxidized surface. See also box annealing .

- **black carburizing**
  - Simulating the carburizing operation without introducing carbon. This is usually accomplished by using an inert material in place of the carburizing agent, or by applying a suitable protective coating to the ferrous alloy.
- **black oxide**
  - A black finish on a metal produced by immersing it in hot oxidizing salts or salt solutions.
- **black specking**
  - Same as specking .
- **blank nitriding**
  - Simulating the nitriding operation without introducing nitrogen. This is usually accomplished by using an inert material in place of the nitriding agent or by applying a suitable protective coating to the ferrous alloy.
- **blasting or blast cleaning**
  - A process for cleaning or finishing metal objects with an air blast or centrifugal wheel that throws abrasive particles against the surface of the workpiece. Small, irregular particles of metal are used as the abrasive in grit blasting ; sand, in sandblasting ; and steel, in shotblasting .
- **blister**
  - (1) A raised area, often dome shaped, resulting from loss of adhesion between a coating or deposit and the base metal . (2) In porcelain enamel , a defect caused by gas evolution, consisting of a bubble that forms during fusion and remains when the porcelain enamel solidifies. (3) A casting defect, on or near the surface of the metal, resulting from the expansion of gas in a subsurface zone. It is characterized by a smooth bump on the surface of the casting and a hole inside the casting directly below the bump.
- **blistering**
  - The development during firing of enclosed or broken macroscopic vesicles or bubbles in a body, or in a glaze or other coating.
- **bloom**
  - (1) A visible exudation or efflorescence on the surface of an electroplating bath. (2) A bluish fluorescent cast to a painted surface caused by deposition of a thin film of smoke, dust, or oil. (3) A loose, flowerlike corrosion product that forms when certain metals are exposed to a moist environment.
- **blow hole**
  - A void produced by the outgassing of trapped air during cure. (2) A void in a solder connection caused by outgassing or a void in a fired dielectric.
- **blue annealing**
  - Heating hot-rolled ferrous sheet in an open furnace to a temperature within the transformation range, then cooling in air to soften the metal. A bluish oxide surface layer forms.
- **blue brittleness**
  - Brittleness exhibited by some steels after being heated to some temperature within the range of about 205 to 370 °C (400 to 700 °F), particularly if the steel is worked at the elevated temperature. Killed steels are virtually free of this kind of brittleness.
- **blue dip**
  - A solution containing a mercury compound, once widely used to deposit mercury on a metal by immersion, usually prior to silver plating .
- **blue enamel**
  - (1) In dry-process enameling , an area of enamel coating so thin that it appears blue in color. (2) In wet-process enameling , a cover coat applied too thinly to hide the substrate.
- **bluing**
  - (or blueing). Subjecting the scale-free surface of a ferrous alloy to the action of air, steam, or other agents at a suitable temperature, thus forming a thin blue film of oxide and improving the appearance and resistance to corrosion. This term is ordinarily applied to sheet, strip, or finished parts. It is used also to denote the heating of springs after fabrication to improve their properties.
- **blushing**
  - (1) Whitening and loss of gloss of a usually organic coating caused by moisture. Also called blooming. (2) The condensation of atmospheric moisture at the adhesive bond line interface.
- **bobbing compound**
  - A compound used for heavy buffing that usually contains some form of coarse silica such as flint or quartz. Considerably more abrasive than tripoli compound .

- **boiling**
    - A defect visible in fired porcelain enamel that is caused by gas evolution and that results in the formation of blisters , pinholes , specking , dimples , or a spongy surface.
- **bond**
    - (1) In grinding wheels and other relatively rigid abrasive products, the material that holds the abrasive grains together. (2) In an adhesive bonded or diffusion bonded joint, the line along which the faying surfaces are joined together. (3) In thermal spraying, the junction between the material deposited and the substrate , or its strength. See also adhesive bond , mechanical bond , and metallic bond .
- **bond coat**
    - In thermal spraying, a preliminary (or prime) coat of material which improves adherence of the subsequent thermal spray deposit.
- **boriding**
    - Thermochemical treatment involving the enrichment of the surface layer of an object with borides. This surface-hardening process is performed below the Ac_1 temperature (the temperature at which austenite begins to form during heating). Also referred to as boronizing.
- **box annealing**
    - Annealing a metal or alloy in a sealed container under conditions that minimize oxidation. In box annealing a ferrous alloy, the charge is usually heated slowly to a temperature below the transformation range, but sometimes is above or within it, and is then cooled slowly; this process is also called close annealing or pot annealing. See also black annealing .
- **breakout**
    - Fiber separation or break on surface plies at drilled or machined composite material edges.
- **bright annealing**
    - Annealing in a protective medium to prevent discoloration of the bright surface.
- **bright dip**
    - A solution that produces, through chemical action, a bright surface on an immersed metal.
- **brightener**
    - An agent or combination of agents added to an electroplating bath to produce a lustrous deposit.
- **bright finish**
    - A high-quality finish produced on ground and polished rolls. Suitable for electroplating.
- **bright nitriding**
    - Nitriding in a protective medium to prevent discoloration of the bright surface. Compare with blank nitriding .
- **bright plate**
    - An electrodeposit that is lustrous in the as-plated condition.
- **bright-throwing power**
    - The measure of the ability of a plating solution or a specified set of plating conditions to deposit uniformly bright electroplate on an irregularly shaped cathode .
- **Brinelling**
    - (1) Indentation of the surface of a solid body by repeated local impact or impacts, or static overload. Brinelling may occur especially in a rolling-element bearing. (2) Damage to a solid bearing surface characterized by one or more plastically formed indentations brought about by overload. See also false Brinelling .
- **brittle**
    - Permitting little or no plastic deformation prior to fracture.
- **brittle erosion behavior**
    - Erosion behavior having characteristic properties (e.g., little or no plastic flow, the formation of cracks) that can be associated with brittle fracture of the exposed surface. The maximum volume removal occurs at an angle near 90°, in contrast to approximately 25° for ductile erosion behavior .
- **brittle fracture**
    - Separation of a solid accompanied by little or no macroscopic plastic deformation . Typically, brittle fracture occurs by rapid crack propagation with less expenditure of energy than for ductile fracture . Brittle tensile fractures have a bright, granular appearance and exhibit little or no necking. A chevron pattern may be present on the fracture surface, pointing toward the origin of the crack, especially in brittle fractures in flat platelike components. Examples of brittle fracture include transgranular cracking and intergranular cracking .

- **brittleness**
  - The tendency of a material to fracture without first undergoing significant plastic deformation . Contrast with ductility .
- **broaching**
  - Cutting with a tool that consists of a bar having a single edge or a series of cutting edges (teeth) on its surface. The cutting edges of multiple-tooth, or successive single-tooth, broaches increase in size and/or change in shape. The broach cuts in a straight line or axial direction when relative motion is produced in relation to the workpiece, which may also be rotating. The entire cut is made in single or multiple passes over the workpiece to shape the required surface contour.
- **bronzing**
  - (1) Applying a chemical finish to copper or copper-alloy surfaces to alter the color. (2) Plating a copper-tin alloy on various materials.
- **brush plating**
  - A method of plating in which the plating solution is applied with a pad or brush, within which is an anode that is moved over the cathode to be plated. Also called selective plating.
- **brush polishing (electrolytic)**
  - A method of electropolishing in which the electrolyte is applied with a pad or brush in contact with the part to be polished.
- **bubble structure**
  - Size and spatial distribution of voids within fired porcelain enamel .
- **buckle**
  - (1) Bulging of a large, flat face of a casting; in investment casting, caused by dip coat peeling from the pattern. (2) An indentation in a casting, resulting from expansion of the sand, can be termed the start of an expansion defect. (3) A local waviness in metal bar or sheet, usually transverse to the direction of rolling.
- **buffer**
  - A compound or mixture that, when contained in solution, causes the solution to resist change in pH. Each buffer has a characteristic limited range of pH over which it is effective.
- **buffing**
  - Developing a lustrous surface by contacting the work with a rotating buffing wheel .
- **buffing wheel**
  - Buff sections assembled to the required face width for use on a rotating shaft between flanges. Sometimes called a buff.
- **buff sections**
  - Fabric, paper, or leather disks with concentric center holes held together by various types of sewing to provide degrees of flexibility or hardness. These sections are assembled to make wheels for polishing or buffing .
- **building up**
  - Electroplating for the purpose of increasing the dimensions of a workpiece.
- **built-up edge**
  - (1) Chip material adhering to the tool face adjacent to the cutting edge during cutting. (2) Material from the workpiece, especially in machining, which is stationary with respect to the tool. See also wedge formation .
- **bull's-eye structure**
  - The microstructure of malleable or ductile cast iron when graphite nodules are surrounded by a ferrite layer in a pearlitic matrix.
- **burned-in sand**
  - A defect consisting of a mixture of sand and metal cohering to the surface of a casting.
- **burned-on sand**
  - A misnomer usually indicating metal penetration into sand, resulting in a mixture of sand and cast metal adhering to the surface of a casting.
- **burning**
  - (1) Permanently damaging a metal or alloy by heating to cause either incipient melting or intergranular oxidation. (2) During subcritical annealing, particularly in continuous annealing, production of a severely decarburized and grain-coarsened surface layer that results from excessively prolonged heating to an excessively high temperature. (3) In grinding, getting the work hot enough to cause discoloration or to change the microstructure by tempering or

hardening. (4) In sliding contacts, the oxidation of a surface due to local heating in an oxidizing environment. See also metallurgical burn .

- **burnishing**
  - Finish sizing and smooth finishing of surfaces (previously machined or ground) by displacement, rather than removal, of minute surface irregularities with smooth point or line-contact, fixed or rotating tools.
- **burnoff**
  - (1) The unintentional removal of an autocatalytic deposit from a nonconducting substrate, during subsequent electroplating operations, owing to the application of excessive current or a poor contact area. (2) In porcelain enamel , a condition caused by thin application resulting in a black or yellow-green color. The enamel layer may appear transparent. Lack of bubble structure and shinier scale may be associated with this condition.
- **burnt deposit**
  - A rough, noncoherent or otherwise unsatisfactory deposit produced by the application of an excessive current density and usually containing oxides or other inclusions.
- **burr**
  - An undesirable projection of material that results from a cutting, forming, blanking, or shearing operation, especially a rough edge left on sheet steel after stamping or punching.
- **burr hardness**
  - Hardness of the burr in the vicinity of the base of the burr .
- **burr height**
  - The distance a burr projects above the surface of the workpiece.
- **burring**
  - (1) The process of removing burrs (preferred word is deburring). (2) The intentional production of a small flange around holes in a pressworking operation (preferred word is flanging). (3) The act of burr formation.
- **bus (bus bar)**
  - A rigid conducting section, for carrying current to the anode and cathode bars.
- **butler finish**
  - A semilustrous metal finish composed of fine, uniformly distributed parallel lines, usually produced with a soft abrasive buffing wheel ; similar in appearance to the traditional hand-rubbed finish on silver.
- **buttering**
  - A form of surfacing in which one or more layers of weld metal are deposited on the groove face of one member (for example, a high-alloy weld deposit on steel base metal that is to be welded to a dissimilar base metal). The buttering provides a suitable transition weld deposit for subsequent completion of the butt weld (joint).
- **C**
- **calcareous coating or deposit**
  - A layer consisting of a mixture of calcium carbonate and magnesium hydroxide deposited on surfaces being cathodically protected against corrosion , because of the increased pH adjacent to the protected surface.
- **calender**
  - The passing of plastic sheet material between sets of pressure rollers to produce a smooth finish and a desired thickness.
- **calomel half cell (calomel electrode)**
  - A half cell containing a mercury electrode in contact with a solution of potassium chloride of specified concentration that is saturated with mercurous chloride (calomel).
- **calorizing**
  - Imparting resistance to oxidation to an iron or steel surface by heating in aluminum powder at 800 to 1000 °C (1470 to 1830 °F).
- **canning**
  - (1) A dished distortion in a flat or nearly flat sheet metal surface, sometimes referred to as oil canning. (2) Enclosing a highly reactive metal within a relatively inert material for the purpose of hot working without undue oxidation of the active metal.
- **capillary attraction**

  - (1) The combined force of adhesion and cohesion that causes liquids, including molten metals, to flow between very closely spaced and solid surfaces, even against gravity. (2) In powder metallurgy, the driving force for the infiltration of the pores of a sintered compact by a liquid.
- **carbide tools**
  - Cutting or forming tools, usually made from tungsten, titanium, tantalum, or niobium carbides, or a combination of them, in a matrix of cobalt, nickel, or other metals. Carbide tools are characterized by high hardnesses and compressive strengths and may be coated to improve wear resistance.
- **carbon edges**
  - Carbonaceous deposits in a wavy pattern along the edges of a steel sheet or strip; also known as snaky edges.
- **carbonitriding**
  - A case hardening process in which a suitable ferrous material is heated above the lower transformation temperature in a gaseous atmosphere of such composition as to cause simultaneous absorption of carbon and nitrogen by the surface and, by diffusion, create a concentration gradient. The heat-treating process is completed by cooling at a rate that produces the desired properties in the workpiece.
- **carbon restoration**
  - Replacing the carbon lost in the surface layer from previous processing of a steel by carburizing this layer to substantially the original carbon level. Sometimes called recarburizing.
- **carburizing**
  - Absorption and diffusion of carbon into solid ferrous alloys by heating, to a temperature usually above Ac_3, in contact with a suitable carbonaceous material. A form of case hardening that produces a carbon gradient extending inward from the surface, enabling the surface layer to be hardened either by quenching directly from the carburizing temperature or by cooling to room temperature, then reaustenitizing and quenching.
- **carrier gas**
  - In thermal spraying, the gas used to carry the powdered materials from the powder feeder or hopper to the gun.
- **case**
  - In heat treating, that portion of a ferrous alloy, extending inward from the surface, whose composition has been altered during case hardening . Typically considered to be the portion of an alloy (a) whose composition has been measurably altered from the original composition, (b) that appears light when etched, or (c) that has a higher hardness value than the core.
- **case hardening**
  - A generic term covering several processes applicable to steel that change the chemical composition of the surface layer by absorption of carbon, nitrogen, or a mixture of the two and, by diffusion, create a concentration gradient. The processes commonly used are carburizing and quench hardening , cyaniding , nitriding , and carbonitriding . The use of the applicable specific process name is preferred.
- **cast film**
  - A film made by depositing a layer of liquid plastic onto a surface and stabilizing this form by the evaporation of solvent, by fusing after deposition, or by allowing a melt to cool. Cast films are usually made from solutions or dispersions .
- **cast replica**
  - In metallography, a reproduction of a surface in plastic made by the evaporation of the solvent from a solution of the plastic or by polymerization of a monomer on the surface. See also replica .
- **catalyst**
  - A chemical used to change the rate of a chemical reaction. Differs from a curing agent in that the catalyst is not itself chemically consumed in the reaction, while a curing agent is. Technically, catalysts that increase reaction rates are called accelerators; those that decrease reaction rates are called inhibitors or retarders.
- **catastrophic wear**
  - Sudden surface damage, deterioration, or change of shape caused by wear to such an extent that the life of the part is appreciably shortened or action is impaired.
- **cathode**

    - The electrode in electrolysis at which positive ions are discharged, negative ions are formed, or other reducing actions occur. Contrast with anode .
- **cathode film**
    - The layer of solution in contact with the cathode that differs in composition from that of the bulk of the solution.
- **cathodic cleaning**
    - Electrolytic cleaning in which the work is the cathode . Also called direct-current cleaning.
- **cathodic corrosion**
    - Corrosion resulting from a cathodic condition of a structure usually caused by the reaction of an amphoteric metal with the alkaline products of electrolysis .
- **cathodic disbondment**
    - The destruction of adhesion between a coating and its substrate by products of a cathodic reaction .
- **cathodic pickling**
    - Electrolytic pickling in which the work is the cathode .
- **cathodic protection**
    - The prevention of corrosion of a metal by electrically connecting it to a sacrificial anode . The anode is itself decomposed, and the object of interest is protected. The sacrificial anode must be replaced periodically. Contrast with anodic protection .
- **cathodic reaction**
    - Electrode reaction equivalent to a transfer of negative charge from the electronic to the ionic conductor. A cathodic reaction is a reduction process. An example common in corrosion is: $\mathrm{Ni}^{2+} + 2e^-$ Ni.
- **catholyte**
    - The portion of the electrolyte in the vicinity of the cathode ; in a divided cell the portion of the cathode side of the diaphragm.
- **cation**
    - A positively charged ion that migrates through the electrolyte toward the cathode under the influence of a potential gradient. See also anion and ion .
- **cationic detergent**
    - A detergent that produces aggregates of positively charged ions with colloidal properties.
- **caul**
    - In adhesive bonding, a sheet of material employed singly or in pairs in the hot or cold pressing of assemblies being bonded. A caul is used to protect either the faces of the assembly or the press platens, or both, against marring and staining in order to prevent sticking, facilitate press loading, impart a desired surface texture or finish, and provide uniform pressure distribution. A caul may be made of any suitable material such as aluminum, stainless steel, hardboard, fiberboard, or plastic, the length and width dimensions generally being the same as those of the plates of the press where it is used.
- **caustic dip**
    - A strongly alkaline solution into which metal is immersed for etching, for neutralizing acid, or for removing organic materials such as greases or paints.
- **cavitation**
    - The formation and collapse, within a liquid, of cavities or bubbles that contain vapor or gas or both. In general, cavitation originates from a decrease in the static pressure in the liquid. It is distinguished in this way from boiling, which originates from an increase in the liquid temperature. There are certain situations where it may be difficult to make a clear distinction between cavitation and boiling, and the more general definition that is given here is therefore to be preferred. In order to erode a solid surface by cavitation, it is necessary for the cavitation bubbles to collapse on or close to that surface.
- **cavitation corrosion**
    - A process involving conjoint corrosion and cavitation .
- **cavitation erosion**
    - Progressive loss of original material from a solid surface due to continuing exposure to cavitation .
- **cell**
    - Electrochemical system consisting of an anode and a cathode immersed in an electrolyte . The anode and cathode may be separate metals or dissimilar areas on the same metal. The cell

includes the external circuit, which permits the flow of electrons from the anode toward the cathode.

- **cementite**
  - A hard (800 HV), brittle compound of iron and carbon, known chemically as iron carbide and having the approximate chemical formula Fe_3C. It is characterized by an orthorhombic crystal structure. When it occurs as a phase in steel, the chemical composition will be altered by the presence of manganese and other carbide-forming elements. The highest cementite contents are observed in white cast irons, which are used in applications where high wear resistance is required.
- **centerless grinding**
  - Grinding the outside or inside diameter of a cylindrical piece that is supported on a work support blade instead of being held between centers and that is rotated by a so-called regulating or feed wheel.
- **ceramic-metal coating**
  - A mixture of one or more ceramic materials in combination with a metallic phase applied to a metallic substrate that may or may not require heat treatment prior to service. This term may also be used for coatings applied to nonmetallic substrates, for example, graphite.
- **ceramic process**
  - The production of articles or coatings from essentially inorganic, nonmetallic materials, the article or coating being made permanent and suitable for utilitarian and decorative purposes by the action of heat at temperatures sufficient to cause sintering, solid-state reactions, bonding, or conversion partially or wholly to the glassy state.
- **chafing**
  - Repeated rubbing between two solid bodies that can result in surface damage and/or wear.
- **chafing fatigue**
  - Fatigue initiated in a surface damaged by rubbing against another body. See also fretting .
- **Charpy test**
  - An impact test in which a V-notched, keyhole-notched, or U-notched specimen, supported at both ends, is struck behind the notch by a striker mounted at the lower end of a bar that can swing as a pendulum. The energy that is absorbed in fracture is calculated from the height to which the striker would have risen had there been no specimen and the height to which it actually rises after fracture of the specimen. Contrast with Izod test .
- **chatter marks**
  - Surface imperfections on the work being ground, usually caused by vibrations transferred from the wheel-work interface during grinding.
- **checking**
  - The development of slight breaks in a coating that do not penetrate to the underlying surface. See also craze cracking .
- **chelating agent**
  - (1) An organic compound in which atoms form more than one coordinate bond with metals in solution. (2) A substance used in metal finishing to control or eliminate certain metallic ions present in undesirable quantities.
- **chemical conversion coating**
  - A protective or decorative nonmetallic coating produced in situ by chemical reaction of a metal with a chosen environment. It is often used to prepare the surface prior to the application of an organic coating and to provide some corrosion protection.
- **chemical deposition**
  - The precipitation or plating-out of a metal from solutions of its salts through the introduction of another metal or reagent to the solution.
- **chemical etching**
  - The dissolution of the material of a surface by subjecting it to the corrosive action of an acid or an alkali.
- **chemical milling**
  - A process for the selective and controlled removal of metal from a surface through the use of chemical etchants.
- **chemical polishing**
  - The improvement in surface smoothness of a metal by simple immersion in a suitable solution.
- **chemical vapor deposition (CVD)**

  - (1) A coating process, similar to gas carburizing and carbonitriding, whereby a reactant atmosphere gas is fed into a processing chamber where it decomposes at the surface of the workpiece, liberating one material for either absorption by, or accumulation on, the workpiece. A second material is liberated in gas form and is removed from the processing chamber, along with excess atmosphere gas. (2) Process used in manufacture of several composite reinforcements, especially boron and silicon carbide, in which desired reinforcement material is deposited from vapor phase onto a continuous core, for example, boron on tungsten wire (core).
- **chevron pattern**
  - A fractographic pattern of radial marks (shear ledges) that look like nested letters "V;" sometimes called a herringbone pattern. Chevron patterns are typically found on brittle fracture surfaces in parts whose widths are considerably greater than their thicknesses. The points of the chevrons can be traced back to the fracture origin.
- **chipping**
  - Fracturing and breaking away of fragments of a porcelain enamel surface.
- **chips**
  - Pieces of material removed from a workpiece by cutting tools or by an abrasive medium.
- **chlorinated lubricant**
  - A lubricant containing a chlorine compound that reacts with a rubbing surface at elevated temperatures to protect it from sliding damage. See also extreme-pressure lubricant , sulfochlorinated lubricant , and sulfurized lubricant .
- **chlorinated solvent**
  - A liquid organic compound of carbon, hydrogen, and chlorine such as methylene chloride, perchloroethylene, 1,1,1-trichloroethane, and trichloroethylene. These solvents are very effective for degreasing with a minimum fire hazard, but their use is heavily regulated due to their classification as ozone-depleting chemicals.
- **chromadizing**
  - Improving paint adhesion on aluminum or aluminum alloys, mainly aircraft skins, by treatment with a solution of chromic acid. Also called chromidizing or chromatizing. Not to be confused with chromating or chromizing .
- **chromate treatment**
  - A treatment of metal in a solution of a hexavalent chromium compound to produce a conversion coating consisting of trivalent and hexavalent chromium compounds.
- **chromating**
  - The process for producing a conversion coating containing chromium compounds.
- **chromium buffing compound**
  - A buffing compound consisting of fine unfused alumina. Originally developed to color buff chromium-plated parts that had been stained or frosted in the electroplating process.
- **chromium plating**
  - Electrodeposition of chromium on a substrate.
- **chromizing**
  - A surface treatment at elevated temperature, generally carried out in pack, vapor, or salt baths, in which an alloy is formed by the inward diffusion of chromium into the base metal .
- **cladding**
  - (1) A layer of material, usually metallic, that is mechanically or metallurgically bonded to a substrate . Cladding may be bonded to the substrate by any of several processes, such as roll-cladding and explosive forming. (2) A relatively thick layer (>1 mm, or 0.04 in.) of material applied by surfacing for the purpose of improved corrosion resistance or other properties. See also coating , surfacing , and hardfacing .
- **clad metal**
  - A composite metal containing two or more layers that have been bonded together. The bonding may have been accomplished by co-rolling, co-extrusion, welding, diffusion bonding, casting, heavy chemical deposition, or heavy electroplating.
- **cleaning**
  - The removal of grease, oxides, or other foreign material from a surface. See also types of cleaning: alkaline , anodic , cathodic , diphase , electrolytic , emulsion , immersion , soak , solvent , spray , ultrasonic .
- **cleaning-emulsifiable solvent**

    - Two-stage cleaning system wherein a concentrate containing organic solvents and surface-active agents is applied to a surface, subsequently emulsified, and removed along with the soil , by water rinsing.
- **clean surface**
    - A surface that is free of foreign material, both visible and invisible.
- **coarse grains**
    - Grains larger than normal for the particular wrought metal or alloy or of a size that produces a surface roughening known as orange peel or alligator skin.
- **coated abrasive**
    - An abrasive product (sandpaper, for example) in which a layer of abrasive particles is firmly attached to a paper, cloth, or fiber backing by means of glue or synthetic-resin adhesive.
- **coating**
    - A relatively thin layer (<1 mm, or 0.04 in.) of material applied by various processes for the purpose of corrosion prevention, resistance to high-temperature scaling, wear resistance, lubrication, or other purposes.
- **coating strength**
    - A measure of the cohesive bond within a coating, as opposed to coating-to-coating substrate bond; the tensile strength of a coating.
- **coating stress**
    - The stresses in a coating resulting, for example, from rapid cooling of molten or semimolten particles as they impact the substrate or from differential thermal expansion.
- **cocoa**
    - In fretting wear , a powdery form of debris, usually consisting of iron oxides, that is expelled from a ferrous metal joint near the location where fretting wear is occurring. Also known as red mud.
- **coefficient of friction**
    - The dimensionless ratio of the friction force (F) between two bodies to the normal force (N) pressing these bodies together: (or f) = (F/N).
- **cohesion**
    - (1) The state in which the particles of a single substance are held together by primary or secondary valence forces. As used in the adhesive field, the state in which the particles of the adhesive (or adherend) are held together. (2) Force of attraction between the molecules (or atoms) within a single phase. Contrast with adhesion .
- **coil breaks**
    - Creases or ridges in sheet or strip that appear as parallel lines across the direction of rolling and that generally extend the full width of the sheet or strip. Most commonly seen in as-annealed carbon steels.
- **cold etching**
    - Etching to reveal microstructure conducted at room temperature and below.
- **cold lap**
    - Wrinkled markings on the surface of an ingot or casting from incipient freezing of the surface and too low a casting temperature.
- **cold rolled sheets**
    - A metal mill product produced from a hot rolled pickled coil that has been given substantial cold reduction at room temperature. The resulting product is usually annealed and temper rolled to make it suitable for most common applications. The usual end product is characterized by improved surface, greater uniformity in thickness, and improved mechanical properties compared with hot rolled sheet.
- **cold shut**
    - (1) A discontinuity that appears on the surface of cast metal as a result of two streams of liquid meeting and failing to unite. (2) A lap on the surface of a forging or billet that was closed without fusion during deformation. (3)Freezing of the top surface of an ingot before the mold is full.
- **cold treatment**
    - Exposing steel to suitable sub-zero temperatures (-85 °C, or -120 °F) for the purpose of obtaining desired conditions or properties such as dimensional or microstructural stability. When the treatment involves the transformation of retained austenite, it is usually followed by tempering.
- **cold-worked structure**

  - A microstructure resulting from plastic deformation of a metal or alloy below its recrystallization temperature.
- **collodion replica**
  - In metallography, a replica of a surface cast in nitrocellulose.
- **colloidal particle**
  - An electrically charged particle, generally smaller in size than 200 μm, dispersed in a second continuous phase.
- **colloids**
  - Aggregates of molecules in solution (dispersion) resulting in particles having dimensions in the 0.001 millimicron to 1000 micron range.
- **colonial finish**
  - A surface finish achieved by selectively buffing an oxidized surface, thereby producing lustrous highlights against the oxidized background.
- **color anodizing**
  - In anodizing of aluminum, formation of a colored coating on aluminum where the colored compound, pigment, or dye is incorporated after the coating has been formed and prior to sealing.
- **color buffing**
  - Producing a final high luster by buffing . Sometimes called coloring .
- **color etching**
  - Same as staining and tint etching .
- **coloring**
  - The production of desired colors on metal surfaces by appropriate chemical or electrochemical action. See also color buffing .
- **color oxide**
  - A material used to impart color to a porcelain enamel .
- **columnar structure**
  - A coarse structure of parallel elongated grains formed by unidirectional growth, most often observed in castings, but sometimes seen in structures resulting from diffusional growth accompanied by a solid-state transformation.
- **comet tails (on a polished surface)**
  - A group of comparatively deep unidirectional scratches that form adjacent to a microstructural discontinuity during mechanical polishing. They have the general shape of a comet tail. Comet tails form only when a unidirectional motion is maintained between the surface being polished and the polishing cloth.
- **complex ion**
  - An ion composed of two or more ions or radicals, both of which are capable or independent existence, for example, cuprocyanide $(Cu(CN)_3)^{2-}$.
- **composite coating**
  - A coating on a metal or non-metal that consists of two or more components, one of which is often particulate in form. Example: a cermet composite coating on a cemented carbide cutting tool. Also known as multilayer coating.
- **composite plate**
  - An electrodeposit consisting of layers of at least two different compositions.
- **compound zone**
  - The surface layer of diffusion-treated steels, which is made up of intermetallic compounds such as nitrides or carbides.
- **compressive burr**
  - The burr produced in blanking or piercing operations in which the slug separates from the stock in a compressive stress field. Burrs produced in this manner initially begin as tensile burrs and are typically identified as tensile-plus-compressive burrs .
- **conditioning**
  - The conversion of a surface on a plastic substrate to a suitable state for successful treatment in succeeding steps.
- **conductance**
  - The capacity of a medium, usually expressed in mhos, for transmitting electric current. The reciprocal of resistance.
- **conducting salt**
  - A salt added to the solution in order to increase its conductivity.

- **conformal coating**
  - A coating that covers and exactly fits the shape of the coated object.
- **contact plating**
  - A metal plating process wherein the plating current is provided by galvanic action between the work metal and a second metal, without the use of an external source of current.
- **contact potential**
  - In corrosion technology, the potential difference at the junction of two dissimilar substances.
- **continuity of coating**
  - The degree to which a porcelain enamel or ceramic coating is free of defects , such as bare spots, boiling , blisters , or copperheads , that could reduce its protective properties.
- **controlled cooling**
  - Cooling a metal or alloy from an elevated temperature in a predetermined manner to avoid hardening, cracking, or internal damage, or to produce desired microstructure or mechanical properties.
- **controlled etching**
  - Electrolytic etching with selection of suitable etchant and voltage resulting in a balance between current and dissolved metal ions.
- **controlled rolling**
  - A hot-rolling process in which the temperature of the steel is closely controlled, particularly during the final rolling passes, to produce a fine-grain microstructure.
- **conversion coating**
  - A coating consisting of a compound of the surface metal, produced by chemical or electrochemical treatments of the metal. Examples include chromate coatings on zinc, cadmium, magnesium, and aluminum, and oxide and phosphate coatings on steel. See also chromate treatment and phosphating .
- **copper-accelerated salt-spray (CASS) test**
  - An accelerated corrosion test for some electrodeposits and for anodic coatings on aluminum.
- **copperhead**
  - A reddish spot in a porcelain enamel coating caused by iron pickup during enameling, iron oxide left on poorly cleaned base metal , or burrs on iron or steel base metal that protrude through the coating and are oxidized during firing. Also called pull through.
- **coring**
  - (1) A condition of variable composition between the center and surface of a unit of microstructure (such as a dendrite, grain, carbide particle); results from nonequilibrium solidification, which occurs over a range of temperature. (2) A central cavity at the butt end of a rod extrusion, sometimes called extrusion pipe.
- **Corrodkote test**
  - An accelerated corrosion test for electrodeposits.
- **corrosion**
  - The chemical or electrochemical reaction between a material, usually a metal, and its environment that produces a deterioration of the material and its properties.
- **corrosion embrittlement**
  - The severe loss of ductility of a metal resulting from corrosive attack, usually intergranular corrosion and often not visually apparent.
- **corrosion fatigue**
  - The process in which a metal fractures prematurely under conditions of simultaneous corrosion and repeated cyclic loading at lower stress levels or fewer cycles than would be required in the absence of the corrosive environment.
- **corrosion protection**
  - Modification of a corrosion system so that corrosion damage is mitigated.
- **corrosion rate**
  - Corrosion effect on a metal per unit of time. The type of corrosion rate used depends on the technical system and on the type of corrosion effect. Thus, corrosion rate may be expressed as an increase in corrosion depth per unit of time (penetration rate, for example, mm/yr) or the mass of metal turned into corrosion products per unit area of surface per unit of time (weight loss, for example, $g/m^2/yr$). The corrosion effect may vary with time and may not be the same at all points of the corroding surface. Therefore, reports of corrosion rates should be accompanied by information on the type, time dependency, and location of the corrosion effect.

- **corrosion resistance**
    - The ability of a material to withstand contact with ambient natural factors or those of a particular, artificially created atmosphere, without degradation or change in properties. For metals, this could be pitting or rusting; for organic materials, it could be crazing .
- **corrosive wear**
    - Wear in which chemical or electrochemical reaction with the environment is significant. See also oxidative wear .
- **corrugations**
    - In metal forming, transverse ripples caused by a variation in strip shape during hot or cold reduction.
- **corundum**
    - A naturally occurring fused aluminum oxide (Al_2O_3) used as an abrasive.
- **coulomb**
    - The quantity of electricity that is transmitted through an electric circuit in 1 s when the current in the circuit is 1 A. The quantity of electricity that will deposit 0.0011180 g of silver.
- **cover coat**
    - A porcelain enamel finish applied to and then fused over a ground coat or applied directly to the metal substrate and then fused.
- **covering power**
    - (1) The ability of a solution to give satisfactory plating at very low current densities, a condition that exists in recesses and pits. This term suggests an ability to cover, but not necessarily to build up, a uniform coating, whereas throwing power suggests the ability to obtain a coating of uniform thickness on an irregularly shaped object. (2) The degree to which a porcelain enamel coating obscures the underlying surface. (3) The ability of a glaze to uniformly and completely cover the surface of the fired ceramic ware.
- **crack**
    - (1) A fracture type discontinuity characterized by a sharp tip and high ratio of length and width to opening displacement. (2) A line of fracture without complete separation.
- **cratering**
    - Depressions on coated surfaces caused by excess lubricant. Cratering results when paint is too thin and later ruptures, leaving pinholes and other voids. Use of less thinner in the coating can reduce or eliminate cratering, as can the use of less lubricant on the part.
- **crater wear**
    - The wear that occurs on the rake face of a cutting tool due to contact with the material in the chip that is sliding along that face.
- **crawling**
    - In porcelain enamel , a condition similar to tearing that occurs when firing a sprayed enamel coating over another coating already fired. It is characterized by the aggregation of the topcoat into balls or irregularly shaped islands during firing, thus exposing the base coat layer.
- **craze cracking**
    - Irregular surface cracking of a metal associated with thermal cycling. This term is used more in the United Kingdom than in the United States, where the term checking is used instead.
- **crazing**
    - (1) A network of fine hairline cracks in a coating. (2) Cracking that occurs in fired glazes or other ceramic coatings due to critical tensile stresses. (3) In porcelain enamel , almost-invisible lines in the finished surface that extend down to the base metal.
- **creep-feed grinding**
    - A subset of surface grinding , creep-feed grinding produces deeper (full) depths of cut at slow traverse rates.
- **crevice corrosion**
    - Localized corrosion of a metal surface at, or immediately adjacent to, an area that is shielded from full exposure to the environment because of close proximity between the metal and the surface of another material.
- **critical current density**
    - In an electrolytic process, a current density at which an abrupt change occurs in an operating variable or in the nature of an electrodeposit or electrode film.
- **critical pigment volume concentration (CPVC)**

  - The volume percent of pigment in a coating in which the pigment particles are surrounded by resin so that no free surface pigment exists.
- **cross rolling**
  - Rolling of metal or sheet or plate so that the direction of rolling is about 90° from the direction of a previous rolling.
- **cure**
  - The process by which paint is converted from the liquid to the solid state.
- **current density**
  - The current flowing to or from a unit area of an electrode surface.
- **current efficiency**
  - (1) The ratio of the electrochemical equivalent current density for a specific reaction to the total applied current density . (2) The proportion of current used in a given process to accomplish a desired result; in electroplating, the proportion used in depositing or dissolving metal.
- **curing temperature**
  - The temperature to which a paint film or adhesive is subjected to cure the paint or adhesive.
- **curtain coating**
  - A method of coating that may be employed with low-viscosity resins or solutions, suspensions, or emulsions of resins in which the substrate to be coated is passed through and perpendicular to a freely falling liquid curtain (or waterfall). The flow rate of the falling liquid and the linear speed of the substrate passing through the curtain are coordinated in accordance with the thickness of coating desired.
- **cutting down**
  - Polishing or buffing for the purpose of removing roughness or irregularities.
- **cutting fluid**
  - A fluid used in metal cutting to improve finish, tool life, or dimensional accuracy. On being flowed over the tool and work, the fluid reduces friction, the heat generated, and tool wear, and prevents galling . It conducts the heat away from the point of generation and also serves to wash the chips away.
- **cutoff burr**
  - A projection of material left when the workpiece falls from the stock before the separating cut has been completed.
- **cut wire blasting**
  - Blasting with short, cut lengths of metal wire. See also abrasive blasting .
- **cyaniding**
  - A case-hardening process in which a ferrous material is heated above the lower transformation temperature range in a molten salt containing cyanide to cause simultaneous absorption of carbon and nitrogen at the surface and, by diffusion, create a concentration gradient. Quench hardening completes the process.
- **cylindrical grinding**
  - Grinding the outer cylindrical surface of a rotating part.
- **D**
- **dealloying**
  - The selective corrosion of one or more components of a solid solution alloy. Also called parting or selective leaching . See also decarburization , decobaltification , denickelification , dezincification , and graphitic corrosion .
- **deburring**
  - The removal of burrs, sharp edges, or fins by mechanical, chemical or electrochemical means.
- **decalescence**
  - A phenomenon, associated with the transformation of alpha iron to gamma iron on the heating (superheating) of iron or steel, revealed by the darkening of the metal surface owing to the sudden decrease in temperature caused by the fast absorption of the latent heat of transformation. Contrast with recalescence .
- **decarburization**
  - Loss of carbon from the surface layer of a carbon-containing alloy due to reaction with one or more chemical substances in a medium that contacts the surface. See also dealloying .
- **decobaltification**
  - Corrosion in which cobalt is selectively leached from cobalt-base alloys, such as Stellite, or from cemented carbides. See also dealloying and selective leaching .

- **deep etching**
  - In metallography, macroetching , especially for steels, to determine the overall character of the material, that is, the presence of imperfections, such as seams, forging bursts, shrinkage-void remnants, cracks, and coring.
- **defect**
  - (1) A discontinuity whose size, shape, orientation, or location makes it detrimental to the useful service of the part in which it occurs. (2) A discontinuity or discontinuities which by nature or accumulated effect (for example, total crack length) render a part or product unable to meet minimum applicable acceptance standards or specifications. This term designates rejectability.
- **deflocculating**
  - Thinning the consistency of a slip by adding a suitable electrolyte .
- **degreasing**
  - The removal of grease and oils from a surface. Can be accomplished by immersion in liquid organic solvent, by solvent vapors condensing on the parts being cleaned (vapor degreasing), or by spraying the parts with solvent.
- **delayed fishscaling**
  - See fishscale .
- **delta iron**
  - Solid phase of pure iron that is stable from 1400 to 1539 °C (2550 to 2800 °F) and possesses the body-centered cubic lattice.
- **denickelification**
  - Corrosion in which nickel is selectively leached from nickel-containing alloys. Most commonly observed in copper-nickel alloys after extended service in fresh water. See also dealloying and selective leaching .
- **depletion**
  - Selective removal of one component of an alloy, usually from the surface or preferentially from grain-boundary regions. See also dealloying .
- **deposit corrosion**
  - Corrosion occurring under or around a discontinuous deposit on a metallic surface. Also called poultice corrosion.
- **deposition efficiency**
  - In thermal spraying, the ratio, usually expressed in percent, of the weight of spray deposit to the weight of the material sprayed.
- **deposition rate**
  - In thermal spraying, the weight of material deposited in a unit of time. It is usually expressed as kilograms per hour (kg/h) or pounds per hour (lb/h).
- **descaling**
  - A chemical or mechanical process for removing the thick layer of oxides formed on some metals at elevated temperatures.
- **detergent**
  - A surface active agent that possesses the ability to clean soiled surfaces. See also types of detergents: anionic , cationic , and nonionic .
- **detergent additive**
  - In lubrication technology, a surface-active additive that helps to keep solid particles suspended in an oil.
- **devitrification**
  - In porcelain enamel , a surface defect caused by crystallization of the enamel due to overfiring or contamination, resulting in the loss of the glassy, vitreous appearance of the surface.
- **dezincification**
  - Corrosion in which zinc is selectively leached from zinc-containing alloys leaving a relatively weak layer of copper and copper oxide. Most commonly found in copper-zinc alloys containing less than 85% copper after extended service in water containing dissolved oxygen. See also dealloying and selective leaching .
- **diamond**
  - A highly transparent mineral composed entirely of carbon (allotropic form of carbon) having a cubic structure. The hardest material known, it is used as a gemstone and as an abrasive in cutting and grinding applications. Natural diamonds are produced deep within the earth's crust at extremely high pressures and temperatures. Synthetic diamonds are synthesized by subjecting

carbon, in the form of graphite, to high temperatures and pressures using large special-purpose presses. See also superabrasives .

- **diamondlike film**
  - A hard, noncrystalline carbon film, usually grown by chemical vapor deposition or related techniques, that contains predominantly sp^2 carbon-carbon bonds.
- **diamond wheels**
  - A grinding wheel in which crushed and sized industrial diamonds are held in a resinoid, metal, or vitrified bond.
- **diaphragm**
  - A porous or permeable membrane separating anode and cathode compartments of an electrolytic cell from each other or from an intermediate compartment.
- **dichromate treatment**
  - A chromate conversion coating produced on magnesium alloys in a boiling solution of sodium dichromate.
- **dielectric shield**
  - In a cathodic protection system, an electrically nonconductive material, such as a coating, plastic sheet, or pipe, that is placed between an anode and an adjacent cathode to avoid current wastage and to improve current distribution, usually on the cathode.
- **die lines**
  - Lines or markings on formed, drawn, or extruded metal parts caused by imperfections in the surface of the die.
- **differential coating**
  - A coated product having a specified coating on one surface and a significantly lighter coating on the other surface (such as a hot dip galvanized product or electrolytic tin plate).
- **diffusion**
  - (1) Spreading of a constituent in a gas, liquid, or solid, tending to make the composition of all parts uniform. (2) The spontaneous movement of atoms or molecules to new sites within a material. (3) The movement of a material, such as a gas or liquid, in the body of a plastic. If the gas or liquid is absorbed on one side of a piece of plastic and given off on the other side, the phenomenon is called permeability. Diffusion and permeability are not due to holes or pores in the plastic but are caused by chemical mechanisms.
- **diffusion coating**
  - An alloy coating produced by applying heat to one or more coatings deposited on a base metal .
- **diluent**
  - A usually liquid inert substance added to some other substance or solution so that the volume of the latter substance is increased and its concentration per unit volume is decreased.
- **dimple**
  - In porcelain enamel , a cone-like depression defect in the fired enamel surface, somewhat larger than a pinhole . Also called flux pit.
- **dimpling**
  - (1) The stretching of a relatively small, shallow indentation into sheet metal. (2) In aircraft, the stretching of metal into a conical flange for a countersunk head rivet.
- **dip coating**
  - Applying a plastic coating by dipping the article to be coated into a tank of melted resin or plastisol , then chilling the adhering metal.
- **diphase cleaning**
  - Cleaning by means of solutions that contain a solvent layer and an aqueous layer. Cleaning is effected by both solvent and emulsifying action.
- **dipping**
  - In porcelain enameling, the process of coating a metal shape by immersion in slip, removal, and draining. In dry process enameling, the method of coating by immersing the heated metal shape for a short time in powdered frit .
- **dip plating**
  - Same as immersion coating .
- **direct cleaning**
  - Same as cathodic cleaning .
- **direct fire**

  - A method of maturing porcelain enamel so that the products of combustion come in contact with the ware.
- **disbondment**
  - The destruction of adhesion between a coating and the surface coated.
- **disk grinding**
  - Grinding with the flat side of an abrasive disk or segmented wheel. Also called vertical-spindle surface grinding.
- **dispersant additive**
  - In lubrication technology, an additive capable of dispersing cold oil sludge.
- **dispersing agent**
  - A material that increases the stability of a suspension of particles in a liquid medium.
- **dispersion**
  - To break big particles into small particles and suspend them in water so that they can be removed by rinsing. Alkaline silicates and phosphates are beneficial for dispersion.
- **dissolution etching**
  - Development of microstructure by surface removal.
- **divided cell**
  - A cell containing a diaphragm or other means for physically separating the anolyte from the catholyte .
- **double etching**
  - In metallography, use of two etching solutions in sequence. The second etchant emphasizes a particular microstructural feature.
- **drag-in**
  - The water or solution that adheres to the objects introduced into a bath.
- **drag-out**
  - The solution that adheres to the objects removed from a bath.
- **draining**
  - Part of the dipping or flow coating process during which the excess slip flows from suitably positioned ware.
- **drain time**
  - The time required for porcelain enamel slip applied by dipping, slushing, or flow coating to complete movement across the surfaces of a coated part.
- **dredge**
  - The sieve used to apply powdered porcelain enamel frit to the ware during dredging .
- **dredging**
  - In dry process enameling , the application of dry, powdered frit to hot ware by sifting.
- **dressing**
  - The process of eroding the bond matrix in a grinding wheel surface after truing or grinding in order to expose the abrasive grains and thereby improve grinding efficiency.
- **drier**
  - A catalyst added to speed the cure of oil-based paints. Driers are often metal salts of carboxylic acids.
- **drop etching**
  - In metallography, placing of a drop of etchant on the polished surface.
- **droplet erosion**
  - Erosive wear caused by the impingement of liquid droplets on a solid surface. See also erosion .
- **dross**
  - The scum that forms on the surface of molten metal largely because of oxidation but sometimes because of the rising of impurities to the surface.
- **dry etching**
  - In metallography, development of microstructure under the influence of gases.
- **drying cracks**
  - Irregular cracks in dry, unfired porcelain enamel caused by uneven or too rapid drying of the ware. The cracks may or may not heal over during the firing operation.
- **drying oil**
  - A water-insoluble liquid, usually obtained from a plant source, that reacts with oxygen (from the air) to form a cross-linked polymeric film.

- **dry process enameling**
    - A porcelain enameling process in which the metal article is heated to a temperature above the maturing temperature of the coating, usually 870 to 955 °C (1600 to 1750 °F). The coating materials are applied to the hot metal as a dry powder and fired.
- **dry-sand rubber wheel test**
    - In wear testing, a term used to describe a standard abrasive wear testing method in which a stream of dry quartz sand is passed between a rotating rubber wheel and a stationary test coupon that is held against it under specified normal force.
- **dry sliding wear**
    - Sliding wear in which there is no intentional lubricant or moisture introduced into the contact area. See also unlubricated sliding .
- **dry weight**
    - The weight per unit area of bisque .
- **ductile erosion behavior**
    - Erosion behavior having characteristic properties (i.e., considerable plastic deformation) that can be associated with ductile fracture of the exposed solid surface. A characteristic ripple pattern forms on the exposed surface at low values of angle of attack. Contrast with brittle erosion behavior .
- **ductile fracture**
    - Fracture characterized by tearing of metal accompanied by appreciable gross plastic deformation and expenditure of considerable energy. Contrast with brittle fracture .
- **ductility**
    - The ability of a material to deform plastically without fracturing.
- **dummy (or dummy cathode)**
    - A cathode in a plating solution that is not to be made use of after plating. Often used for removal or decomposition of impurities.
- **duplex microstructure**
    - A two-phase structure.
- **dynamic electrode force**
    - The electrode potential measured when current is passing between the electrode and the electrolyte .
- **E**
- **edge strain**
    - Transverse strain lines or Lüders lines ranging from 25 to 300 mm (1 to 12 in.) in from the edges of cold rolled steel sheet or strip. See also Lüders lines .
- **electrical discharge grinding**
    - Grinding by spark discharges between a negative electrode grinding wheel and a positive workpiece separated by a small gap containing a dielectric fluid such as petroleum oil.
- **electrical discharge machining (EDM)**
    - Metal removal by a rapid spark discharge between different polarity electrodes, one on the workpiece and the other the tool, separated by a gap distance of 0.013 to 0.9 mm (0.0005 to 0.035 in.). The gap is filled with dielectrical fluid and metal particles, which are melted, in part vaporized, and expelled from the gap.
- **electrical pitting**
    - The formation of surface cavities by removal of metal as a result of an electrical discharge across an interface.
- **electric arc spraying**
    - A thermal spraying process using as a heat source an electric arc between two consumable electrodes of a coating material and a compressed gas which is used to atomize and propel the material to the substrate.
- **electrochemical cell**
    - An electrochemical system consisting of an anode and a cathode in metallic contact and immersed in an electrolyte . The anode and cathode may be different metals or dissimilar areas on the same metal surface.
- **electrochemical (chemical) etching**
    - General expression for all developments of microstructure through reduction and oxidation (redox reactions).
- **electrochemical corrosion**

  - Corrosion that is accompanied by a flow of electrons between cathodic and anodic areas on metallic surfaces.
- **electrochemical discharge machining**
  - Metal removal by a combination of the processes of electrochemical machining and electrical discharge machining . Most of the metal removal occurs via anodic dissolution (i.e., ECM action). Oxide films that form as a result of electrolytic action through an electrolytic fluid are removed by intermittent spark discharges (i.e., EDM action).
- **electrochemical machining (ECM)**
  - Controlled metal removal by anodic dissolution. Direct current passes through a flowing film of conductive solution that separates the workpiece from the electrode/tool. The workpiece is the anode , and the tool is the cathode .
- **electrochemical polishing**
  - An attack-polishing method in which the chemical action of the polishing fluid is enhanced or controlled by the application of an electric current between the specimen and the polishing wheel.
- **electrocorrosive wear**
  - Wear of a solid surface which is accelerated by the presence of a corrosion-inducing electrical potential across the contact interface. This process is usually associated with wear in the presence of a liquid electrolyte in the interface. However, moisture from the air can also facilitate this type of wear when a galvanic wear couple exists and the contacting materials are sufficiently reactive.
- **electrode**
  - A conductor through which current enters or leaves an electrolytic cell , at which there is a change from conduction by electrons to conduction by dry particles of matter, or vice versa.
- **electrodeposition**
  - (1) The deposition of a conductive material from a plating solution by the application of electric current. (2) The deposition of a substance on an electrode by passing electric current through an electrolyte. Electrochemical plating, electroforming , electrorefining , and electrowinning result from electrodeposition.
- **electrode potential**
  - The difference in potential between an electrode and the immediately adjacent electrolyte referred to some standard electrode potential as zero. See also various types of electrode potentials: dynamic , equilibrium , static , and standard .
- **electroforming**
  - The production or reproduction of articles by electrodeposition upon a mandrel or mold that is subsequently separated from the deposit.
- **electrogalvanizing**
  - The electroplating of zinc upon iron or steel.
- **electroless plating**
  - Deposition of a metallic coating by a controlled chemical reduction that is catalyzed by the metal or alloy being deposited.
- **electrolysis**
  - Production of chemical changes by the passage of current through an electrolyte .
- **electrolyte**
  - (1) A conducting medium in which the flow of current is accompanied by movement of matter. Most often an aqueous solution of acids, bases, or salts, but includes many other media, such as fused salts, ionized gases, some solids, and so on. (2) A substance that is capable of forming a conducting liquid medium when dissolved or melted.
- **electrolytic cell**
  - A unit apparatus in which electrochemical reactions are produced by applying electrical energy, or which supplies electrical energy as a result of chemical reactions and which includes two or more electrodes and one or more electrolytes contained in a suitable vessel.
- **electrolytic cleaning**
  - A process of removing soil , scale , or corrosion products from a metal surface by subjecting it as an electrode to an electric current in an electrolytic bath.
- **electrolytic corrosion**
  - Corrosion by means of electrochemical or mechanical action.
- **electrolytic grinding**
  - A combination of grinding and machining wherein a metal-bonded abrasive wheel, usually diamond, is the cathode in physical contact with the anodic workpiece, the contact being made

beneath the surface of a suitable electrolyte. The abrasive particles that produce grinding act as nonconducting spacers permitting simultaneous machining through electrolysis .

- **electrolytic pickling**
  - Pickling in which electric current is used, the work being one of the electrodes.
- **electrolytic polishing**
  - An electrochemical polishing process in which the metal to be polished is made the anode in an electrolytic cell where preferential dissolution at high points in the surface topography produces a specularly reflective surface. Also referred to as electropolishing .
- **electromotive series**
  - A table that lists in order the standard electrode potentials of specified electrochemical reactions.
- **electron-beam curing**
  - A system for curing paint films using the energy of an electron beam. The process lends itself to high-speed curing of paint on flat surfaces. Special paints must be used and personal shielding is required.
- **electron-beam radiation**
  - Radiation generated from high-energy electrons that is used in cross-linking coating systems.
- **electrophoresis**
  - The movement of colloidal particles produced by the application of an electric potential.
- **electroplating**
  - The application of a metallic coating on a surface by means of electrolytic action.
- **electropolishing**
  - A technique commonly used to prepare metallographic specimens, in which a high polish is produced making the specimen the anode in an electrolytic cell , where preferential dissolution at high points smooths the surface. Also referred to as electrolytic polishing .
- **electrorefining**
  - The process of anodically dissolving a metal from a pure anode and depositing it cathodically in a purer form.
- **electrostatic spray**
  - The process by which paint particles are electrically charged and attracted to a substrate bearing an opposite charge.
- **electrowinning**
  - The production of metals by electrolysis with insoluble anodes in solutions derived from ores or other materials.
- **elongated grain**
  - A grain with one principal axis slightly longer than either of the other two.
- **embeddability**
  - The ability of a bearing material to embed harmful foreign particles and reduce their tendency to cause scoring or abrasion.
- **embedded abrasive**
  - Fragments of abrasive particles forced into the surface of a workpiece during grinding , abrasion, or polishing.
- **embossing**
  - (1) Technique used to create depressions of a specific pattern in plastic film and sheeting. Such embossing in the form of surface patterns can be achieved on molded parts by the treatment of the mold surface with photoengraving or another process. (2) Raising a design in relief against a surface.
- **embrittlement**
  - The severe loss of ductility or toughness or both, of a material, usually a metal or alloy. Many forms of embrittlement can lead to brittle fracture . Many forms can occur during thermal treatment or elevated-temperature service (thermally induced embrittlement). In addition, steels and other metals and alloys can be embrittled by environmental conditions (environmentally assisted embrittlement).
- **emery**
  - Naturally occurring abrasive containing 57 to 75% aluminum oxide and a remainder of iron oxide and impurities.
- **emulsifying agent**
  - A substance that increases the stability of an emulsion .
- **emulsion**

  - A class of collodial dispersions containing two or more immiscible liquids such as oil in water. Emulsions are usually unstable and will separate into their components unless a stabilizing agent is present.
- **emulsion cleaning**
  - Cleaning by means of solutions containing organic solvents, water, and emulsifying agents .
- **enamel**
  - A broad classification of free-flowing clear or pigmented varnishes, treated oils, or other forms of organic coatings that usually dry to a hard, glossy or semiglossy finish.
- **end-quench hardenability test**
  - Same as Jominy test .
- **entrance burr**
  - Burr formed on the surface at which the cutting tool or its teeth enters the workpiece.
- **environmental cracking**
  - Brittle fracture of a normally ductile material in which the corrosive effect of the environment is a causative factor. Environmental cracking is a general term that includes corrosion fatigue , high-temperature hydrogen attack , hydrogen blistering, hydrogen embrittlement , liquid metal embrittlement, solid metal embrittlement, stress-corrosion cracking , and sulfide stress cracking . The following terms have been used in the past in connection with environmental cracking, but are becoming obsolete: caustic embrittlement, delayed fracture, season cracking, static fatigue, stepwise cracking, sulfide corrosion cracking, and sulfide stress-corrosion cracking. See also embrittlement .
- **equiaxed grain structure**
  - A structure in which the grains have approximately the same dimensions in all directions.
- **equilibrium electrode potential**
  - A static electrode potential when the electrode and the electrolyte are in equilibrium with respect to a specified electrochemical reaction.
- **erosion**
  - (1) Loss of material from a solid surface due to relative motion in contact with a fluid that contains solid particles. Erosion in which the relative motion of particles is nearly parallel to the solid surface is called abrasive erosion. Erosion in which the relative motion of the solid particles is nearly normal to the solid surface is called impingement erosion or impact erosion. (2) Progressive loss of original material from a solid surface due to mechanical interaction between that surface and a fluid, a multicomponent fluid, and impinging liquid, or solid particles. (3) Loss of material from the surface of an electrical contact due to an electrical discharge (arcing). See also cavitation erosion , electrical pitting , and erosion-corrosion .
- **erosion-corrosion**
  - A conjoint action involving corrosion and erosion in the presence of a moving corrosive fluid, leading to the accelerated loss of material.
- **erosion (erosive) wear**
  - See erosion .
- **etch**
  - (1) A roughened surface produced by chemical or electrochemical means. (2) To dissolve unevenly a part of the surface of a metal.
- **etchant**
  - (1) A chemical solution used to etch a metal to reveal structural details. (2) A solution used to remove, by chemical reaction, the unwanted portion of material from a printed circuit board. (3) Hydrofluoric acid or other agent used to attack the surface of glass for marking or decoration.
- **etch cleaning**
  - Removing soil by dissolving away some of the underlying metal.
- **etch cracks**
  - Shallow cracks in hardened steel containing high residual surface stresses, produced by etching in an embrittling acid.
- **etching (pitting)**
  - The localized attack of metal surfaces. Controlled etching of metals improves the adhesion of organic coatings. By contrast, uncontrolled etching of metals by an acid can cause damage by weakening the crystal structure.
- **etch rinsing**

    - Pouring etchant over a tilted surface until the desired degree of attack is achieved. Used for etchants with severe gas formation.
- **eutectoid**
    - (1) An isothermal reversible reaction in which a solid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having the composition indicated by the eutectoid point on a phase diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectoid reaction.
- **evaporative deposition**
    - The techniques of condensing a thin film of material on a substrate. The entire process takes place in a high vacuum. The source material may be radioactively heated by bombardment with electrons (electron-beam radiation) or may be heated by thermal-conduction techniques.
- **exempt solvents**
    - Solvents that are not subject to air pollution legislation. Many alcohols, esters, some ketones, and mineral spirits are exempt. Aromatic and some ethylenic compounds are not exempt, and their use as solvents is therefore subject to regulation.
- **exit burr**
    - Burr formed on the surface at which the cutting tool or its teeth leaves the workpiece.
- **extreme-pressure lubricant**
    - A lubricant that imparts increased load-carrying capacity to rubbing surfaces under severe operating conditions. Extreme-pressure lubricants usually contain sulfur, halogens, or phosphorus. The term antiscuffing lubricant has been suggested as a replacement for extreme-pressure lubricant.
- **extrusion coating**
    - Using a resin to coat a substrate by extruding a thin film of molten resin and pressing it onto or into the substrate, or both, without the use of an adhesive.
- **extrusion pipe**
    - Same as coring (2).
- **F**
- **false Brinelling**
    - (1) Damage to a solid bearing surface characterized by indentations not caused by plastic deformation resulting from overload, but thought to be due to other causes such as fretting corrosion . (2) Local spots appearing when the protective film on a metal is broken continually by repeated impacts, usually in the presence of corrosive agents. The appearance is generally similar to that produced by Brinelling but corrosion products are usually visible. It may result from fretting corrosion. This term should be avoided when a more precise description is possible. False Brinelling (race fretting) can be distinguished from true Brinelling because in false Brinelling, surface material is removed so that original finishing marks are removed. The borders of a false Brinell mark are sharply defined, whereas a dent caused by a rolling element does not have sharp edges and the finishing marks are visible in the bottom of the dent.
- **fatigue**
    - The phenomenon leading to fracture under repeated or fluctuating stresses having a maximum value less than the ultimate tensile strength of the material.
- **fatigue striation**
    - Parallel lines frequently observed in electron microscope fractographs or fatigue fracture surfaces. The lines are transverse to the direction of local crack propagation; the distance between successive lines represents the advance of the crack front during the one cycle of stress variation.
- **fatigue wear**
    - (1) Removal of particles detached by fatigue arising from cyclic stress variations. (2) Wear of a solid surface caused by fracture arising from material fatigue. See also spalling .
- **feather burr**
    - A very fine or thin burr .
- **feather edge**
    - Same as feather burr except that feather edge can also refer to the ends of a lead-in or lead-out thread, which is a very thin machined ridge. Sometimes called a wire edge or whisker-type burr .
- **feed lines**
    - Linear marks on a machined or ground surface that are spaced at intervals equal to the feed per revolution or per stroke.

- **feed rate**
    - In thermal spraying, the rate at which material passes through the gun in a unit of time. A synonym for spray rate.
- **ferrite**
    - (1) A solid solution of one or more elements in body-centered cubic iron. Unless otherwise designated (for instance, as chromium ferrite), the solute is generally assumed to be carbon. On some equilibrium diagrams, there are two ferrite regions separated by an austenite area. The lower area is alpha ferrite; the upper, delta ferrite. If there is no designation, alpha ferrite is assumed. (2) An essentially carbon-free solid solution in which alpha iron is the solvent, and which is characterized by a body-centered cubic crystal structure. Fully ferritic steels are only obtained when the carbon content is quite low. The most obvious microstructural features in such metals are the ferrite grain boundaries.
- **ferrograph**
    - An instrument used to determine the size distribution of wear particles in lubricating oils of mechanical systems. The technique relies on the debris being capable of being attracted to a magnet.
- **filiform corrosion**
    - Corrosion that occurs under some coatings in the form of randomly distributed threadlike filaments.
- **film strength**
    - The relative resistance of a bisque to mechanical damage.
- **final polishing**
    - A polishing process in which the primary objective is to produce a final surface suitable for microscopic examination.
- **fine grinding**
    - See microgrinding .
- **fineness of enamel**
    - A measurement of the degree to which a frit has been milled in wet or dry form, usually expressed in grams residue retained on a certain type of mesh screen from a 50 cm^3 or a 100 g sample.
- **finish allowance**
    - (1) The amount of excess metal surrounding the intended final configuration of a formed part; sometimes called forging envelope, machining allowance, or cleanup allowance. (2) Amount of stock left on the surface of a casting for machining.
- **finish grinding**
    - The final grinding action on a workpiece, of which the objectives are surface finish and dimensional accuracy.
- **firing**
    - The controlled heat treatment of ceramic ware in a kiln or furnace to develop the desired final properties.
- **firing time**
    - The period during which the ware remains in the firing zone of the furnace to mature a ceramic or porcelain enamel coating.
- **fishscale**
    - A scaly appearance in a porcelain enamel coating in which the evolution of hydrogen from the base metal (iron or steel) causes loss of adhesion between the enamel and the base metal. Individual scales are usually small, but have been observed in sizes up to 25 mm (1 in.) or more in diameter. The scales are somewhat like blisters that have cracked part way around the perimeter but still remain attached to the coating around the rest of the perimeter. Delayed fishscaling occurs after the final porcelain enamel processing.
- **fixed-feed grinding**
    - Grinding in which the wheel is fed into the work, or vice versa, by given increments or at a given rate.
- **flaking**
    - (1) The removal of material from a surface in the form of flakes or scalelike particles. (2) A form of pitting resulting from fatigue. See also spalling .
- **flame cleaning**
    - Cleaning metal surfaces of scale , rust, dirt, and moisture by use of a gas flame.

- **flame hardening**
    - A process for hardening the surfaces of hardenable ferrous alloys in which an intense flame is used to heat the surface layers above the upper transformation temperature, whereupon the workpiece is immediately quenched.
- **flame spraying**
    - Thermal spraying in which a coating material is fed into an oxyfuel gas flame, where it is melted. Compressed gas may or may not be used to atomize the coating material and propel it onto the substrate. The sprayed material is originally in the form of wire or powder. Related terms are powder flame spraying and wire flame spraying . The term flame spraying is usually used when referring to a combustion-spraying process, as differentiated from plasma spraying .
- **flash coat**
    - A thin metallic coating usually less than 0.05 mm (0.002 in.) in thickness.
- **flash (or flash plate)**
    - A very thin electrodeposit, less than 2.5 µm (0.1 mil) thick. See also strike .
- **flash time**
    - The time between paint application and baking. Usually a considerable quantity of solvent is lost during this interval, and this solvent loss prevents popping problems in the oven.
- **flat honing**
    - A low-velocity abrading process, similar to honing , that uses a large, flat honing surface to simultaneously finish a large number of flat parts.
- **flocculate**
    - To aggregate into larger particles, to increase in size to the point where precipitation occurs.
- **flocculating**
    - In porcelain enameling, thickening the consistency of a slip by adding a suitable electrolyte .
- **flocking**
    - A method of coating by spraying finely dispersed textile powders or fibers.
- **floppers**
    - On metals, lines or ridges that are transverse to the direction of rolling and generally confined to the section midway between the edges of a coil as rolled.
- **flotation**
    - The rising of soil particles to the surface of cleaning baths for removal by skimming.
- **flow brightening**
    - (1) Melting of an electrodeposit, followed by solidification, especially of tin plate. See also reflowing . (2) Fusion (melting) of a chemically or mechanically deposited metallic coating on a substrate , particularly as it pertains to soldering.
- **flow coating**
    - The process of coating a metal shape by causing the slip to flow over its surface and then allowing the excess slip to drain.
- **flow lines**
    - (1) Texture showing the direction of metal flow during hot or cold working. Flow lines can often be revealed by etching the surface or a section of a metal part. (2) In mechanical metallurgy, paths followed by minute volumes of metal during deformation.
- **fluidized-bed coating**
    - A method of applying a thermoplastic or thermosetting resin coating to a heated article that is immersed in a dense-phase fluidized bed of powdered resin and thereafter heated in an oven to provide a smooth, pinhole -free coating.
- **fluorescent penetrant inspection**
    - Inspection using a fluorescent liquid that will penetrate any surface opening; after the surface has been wiped clean, the location of any surface flaws may be detected by the fluorescence, under ultraviolet light, of back-seepage of the fluid.
- **flux**
    - A substance that promotes fusion in a given ceramic mixture.
- **flux pit**
    - See dimple .
- **foam blanket**
    - An additive that forms a layer on the surface of electroplating baths that have poor anode /cathode efficiency and prevents any mist or spray from escaping.
- **foil**

  - Metal in sheet form less than 0.15 mm (0.006 in.) thick.
- **forged structure**
  - The macrostructure through a suitable section of a forging that reveals direction of working.
- **form grinding**
  - Grinding with a wheel having a contour on its cutting face that is a mating fit to the desired form.
- **Formvar replica**
  - A reproduction of a surface in a plastic Formvar film (used for the preparation of replicas or for specimen-supporting membranes).
- **free cyanide**
  - (1) True: The actual concentration of cyanide radical, or equivalent alkali cyanide, not combined in complex ions with metals in solution. (2) Calculated: The concentration of cyanide, or alkali cyanide, present in solution in excess of that calculated as necessary to form a specified complex ion with a metal or metals present in solution. (3) Analytical: The free cyanide content of a solution, as determined by a specified analytical method.
- **fretting**
  - A type of wear that occurs between tight-fitting surfaces subjected to cyclic relative motion of extremely small amplitude. Usually, fretting is accompanied by corrosion , especially of the very fine wear debris. Also referred to as fretting corrosion and false Brinelling (in rolling-element bearings).
- **fretting corrosion**
  - (1) The accelerated deterioration at the interface between contacting surfaces as the result of corrosion and slight oscillatory movement between the two surfaces. (2) A form of fretting in which chemical reaction predominates. Fretting corrosion is often characterized by the removal of particles and subsequent formation of oxides, which are often abrasive and so increase the wear. Fretting corrosion can involve other chemical reaction products, which may not be abrasive.
- **fretting wear**
  - Wear arising as a result of fretting .
- **friction**
  - The resisting force tangential to the common boundary between two bodies when, under the action of an external force, one body moves or tends to move relative to the surface of the other. The term friction is also used, incorrectly, to denote coefficient of friction . It is vague and imprecise unless accompanied by the appropriate modifiers, such as dry friction or kinetic friction. See also static coefficient of friction .
- **frit**
  - In porcelain enamel , the small friable particles produced by quenching a molten glassy material.
- **fused coating**
  - A metallic coating (usually tin or solder alloy) that has been melted and solidified, forming a metallurgical bond to the base metal .
- **fused spray deposit**
  - A self-fluxing spray deposit which is deposited by conventional thermal spraying and subsequently fused using either a heating torch or a furnace. The coatings are usually made of nickel and cobalt alloys to which hard particles, such as tungsten carbide, may be added for increased wear resistance.
- **fusing**
  - The melting of a metallic coating (usually electrodeposited) by means of a heat-transfer medium, followed by solidification.
- **fusion spray**
  - In thermal spraying, the process in which the coating is completely fused to the base metal , resulting in a metallurgically bonded, essentially void-free coating.
- **G**
- **galling**
  - (1) A condition whereby excessive friction between high spots results in localized welding with subsequent spalling and a further roughening of the rubbing surfaces of one or both of two mating parts. (2) A severe form of scuffing associated with gross damage to the surfaces or failure. Galling has been used in many ways; therefore, each time the term is encountered its meaning must be ascertained from the specific context of the usage. See also scoring and scuffing .

- **galvanic anode**
    - A metal which, because of its relative position in the galvanic series , provides sacrificial protection to metals that are more noble in the series, when coupled in an electrolyte . See also cathodic protection .
- **galvanic cell**
    - (1) An electrolytic cell capable of producing electrical energy by electrochemical action.
- **galvanic corrosion**
    - Corrosion associated with the current of a galvanic cell consisting of two dissimilar conductors in an electrolyte or two similar conductors in dissimilar electrolytes. Where the two dissimilar metals are in contact, the resulting reaction is referred to as couple action.
- **galvanic series**
    - A list of metals and alloys arranged according to their relative potentials in a given environment. Compare with electromotive series .
- **galvanizing**
    - Application of a coating of zinc to a metal surface using any of various processes.
- **galvanneal**
    - To produce a zinc-iron alloy coating on iron or steel by keeping the coating molten after hot-dip galvanizing until the zinc alloys completely with the base metal .
- **garnet**
    - A generic name for a related group of mineral silicates that have the general chemical formula $A_3B_2(SiO_4)_3$, where *A* can be calcium, magnesium, manganese, or ferrous iron, and *B* can be aluminum, ferric iron, chromium, or titanium. Garnet is used for coating abrasive paper or cloth, for bearing pivots in watches, for electronics, and the finer specimens for gemstones. The hardness of garnet varies from Mohs 6 to 8 (1360 Knoop), the latter being used for abrasive applications.
- **gas atomization**
    - An atomization process whereby molten metal is broken up into particles by a rapidly moving inert gas stream. The resulting particles are nearly spherical with attached satellites.
- **gaseous corrosion**
    - Corrosion with gas as the only corrosive agent and without any aqueous phase on the surface of the metal. Also called dry corrosion. See also hot corrosion and sulfidation .
- **gas holes**
    - Holes in castings or welds that are formed by gas escaping from molten metal as it solidifies. Gas holes may occur individually, in clusters, or throughout the solidified metal.
- **gas lubrication**
    - A system of lubrication in which the shape and relative motion of the sliding surfaces cause the formation of a gas film having sufficient pressure to separate the surfaces.
- **gas porosity**
    - Fine holes or pores within a metal that are caused by entrapped gas or by the evolution of dissolved gas during solidification.
- **gassing**
    - The occurrence of surface defects such as poor gloss or blisters on fired enamel ware caused by bubbles from contamination or poor firing conditions.
- **gear (form) grinding**
    - Removal of material to obtain correct gear tooth form by grinding . This is one of the more exact methods of finishing gears.
- **gelatin replica**
    - A reproduction of a surface prepared in a film composed of gelatin. See also replica .
- **general corrosion**
    - (1) A form of deterioration that is distributed more or less uniformly over a surface. (2) Corrosion dominated by uniform thinning that proceeds without appreciable localized attack. See also uniform corrosion .
- **ghost lines**
    - Lines running parallel to the rolling direction that appear in a sheet metal panel when it is stretched. These lines may not be evident unless the panel has been sanded or painted. Not to be confused with leveler lines .
- **glass**
    - A term sometimes used for porcelain enamel or frit .

- **glass electrode**
    - A half cell in which the potential measurements are made through a glass membrane.
- **glaze**
    - (1) A ceramic coating matured to the glassy state on a formed ceramic article, or the material or mixture from which the coating is made. (2) In tribology, a ceramic or other hard, smooth surface film produced by sliding.
- **glazing**
    - Dulling the abrasive grains in the cutting face of a wheel during grinding .
- **gloss**
    - The shine or luster of a porcelain enamel or a painted surface.
- **gold filled**
    - Covered on one or more surfaces with a layer of gold alloy to form a clad or composite material. Gold-filled dental restorations are an example of such materials.
- **gouging abrasion**
    - A form of high-stress abrasion in which easily observable grooves or gouges are created on the surface. See also abrasion , and low-stress abrasion .
- **graded abrasive**
    - An abrasive powder in which the sizes of the individual particles are confined to certain specified limits. See also grit size .
- **graded coating**
    - A thermal spray coating consisting of several successive layers of different materials; for example, starting with 100% metal, followed by one or more layers of metal-ceramic mixtures, and finishing with 100% ceramic.
- **grain**
    - An individual crystal in a polycrystalline material; it may or may not contain twinned regions and subgrains.
- **grain boundary**
    - A narrow zone in a metal or ceramic corresponding to the transition from one crystallographic orientation to another, thus separating one grain from another; the atoms in each grain are arranged in an orderly pattern.
- **grain-boundary etching**
    - In metallography, the development of intersections of grain faces with the polished surface. Because of severe, localized crystal deformation, grain boundaries have higher dissolution potential than grains themselves. Accumulation of impurities in grain boundaries increases this effect.
- **grain coarsening**
    - A heat treatment that produces excessively large austenitic grains in metals.
- **grain-contrast etching**
    - In metallography, the development of grain surfaces lying in the polished surface of the microsection. These become visible through differences in reflectivity caused by reaction products on the surface or by differences in roughness.
- **grain flow**
    - Fiber-like lines on polished and etched sections of forgings caused by orientation of the constituents of the metal in the direction of working during forging. Grain flow produced by proper die design can improve required mechanical properties of forgings. See also flow lines and forged structure .
- **grain growth**
    - (1) An increase in the average size of the grains in polycrystalline material, usually as a result of heating at elevated temperature. (2) In polycrystalline materials, a phenomenon occurring fairly close below the melting point in which the larger grains grow still larger while the smallest ones gradually diminish and disappear. See also recrystallization .
- **graining**
    - The process of vigorously stirring or agitating a partially solidified material to develop large grains having a thin oxide coating.
- **grain refinement**
    - The manipulation of the solidification process to cause more (and therefore smaller) grains to be formed and/or to cause the grains to form in specific shapes. The term refinement is usually used to denote a chemical addition to the metal but can refer to control of the cooling rate.

- **grain size**
  - (1) For metals, a measure of the areas or volumes of grains in a polycrystalline material, usually expressed as an average when the individual sizes are fairly uniform. In metals containing two or more phases, grain size refers to that of the matrix unless otherwise specified. Grain size is reported in terms of number of grains per unit area or volume, in terms of average diameter, or as a grain-size number derived from area measurements. (2) For grinding wheels, see preferred term grit size .
- **graphitic corrosion**
  - Corrosion of gray iron in which the iron matrix is selectively leached away, leaving a porous mass of graphite behind; it occurs in relatively mild aqueous solutions and on buried pipe and fittings.
- **graphitization**
  - The formation of graphite in iron or steel. Where graphite is formed during solidification, the phenomenon is termed primary graphitization; where formed later by heat treatment, secondary graphitization.
- **greaseless compounds**
  - A variety of buffing compounds in which the abrasive is blended with water and gelatin glue rather that tallow, wax, or oil.
- **green rot**
  - A form of high-temperature attack on stainless steels, nickel-chromium alloys and nickel-chromium-iron alloys subjected to simultaneous oxidation and carburization. Basically, attack occurs first by precipitation of chromium as chromium carbide, then by oxidation of the carbide particles.
- **grindability**
  - A value that represents the efficiency of the grinding process. Grindability = (G-ratio)/(specific energy), where G-ratio = (volume of material removed)/(volume of the grinding wheel used) and specific energy = (grinding power)/(material removal rate).
- **grinding**
  - Removing material from a workpiece with a grinding wheel or abrasive belt. See also various grinding techniques: surface , creep-feed , cylindrical , internal , centerless , gear (form) , and thread .
- **grinding stress**
  - Residual stress , generated by grinding, in the surface layer of work. It may be tensile or compressive, or both.
- **grit blasting**
  - Abrasive blasting with small irregular pieces of steel, malleable cast iron, or hard nonmetallic materials.
- **grit size**
  - Nominal size of abrasive particles in a grinding wheel, corresponding to the number of openings per linear inch in a screen through which the particles can pass.
- **groove**
  - In thermal spraying, a method of surface roughening in which grooves are made and the original surface roughened and spread. Also called rotary roughening.
- **ground coat**
  - (1) A porcelain enamel applied directly to the base metal to function as an intermediate layer between the metal and the cover coat. (2) On sheet steel, a porcelain enamel coating containing adherence-promoting agents that may be used either as an intermediate layer between the metal and the cover coat or as a single coat over the base metal.
- **H**
- **hairline craze**
  - Multiple fine surface separation cracks in composites that exceed 6 mm (in.) in length and do not penetrate in depth the equivalent of a full ply of reinforcement. See also crazing .
- **half cell**
  - An electrode immersed in a suitable electrolyte . It may be designed to yield a known constant potential, in which case unknown potentials may be measured against it; for example, the calomel half cell .
- **hanging burr**

  - Loose or flexible portions of a burr that are not firmly attached to the workpiece (i.e., hanging from the workpiece). Sometimes called a flag.
- **hard chromium**
  - Chromium electrodeposited for engineering purposes (such as to increase the wear resistance of sliding metal surfaces) rather than as a decorative coating. It is usually applied directly to base metal and is customarily thicker (>1.2 µm, or 0.05 mils) than a decorative deposit, but not necessarily harder.
- **hard coating**
  - In anodizing aluminum, an anodic oxide coating on aluminum with a higher apparent density and thickness and a greater resistance to wear than conventional coatings.
- **hardenability**
  - The relative ability of a ferrous alloy to form martensite when quenched from a temperature above the upper critical temperature. Hardenability is commonly measured as the distance below a quenched surface at which the metal exhibits a specific hardness (50 HRC, for example) or a specific percentage of martensite in the microstructure.
- **hardening**
  - Increasing hardness of metals by suitable treatment, usually involving heating and cooling. When applicable, the following more specific terms should be used: age hardening , case hardening , flame hardening , induction hardening , precipitation hardening and quench hardening .
- **hardfacing**
  - The application of a hard, wear-resistant material to the surface of a component by welding, spraying, or allied welding processes to reduce wear or loss of material by abrasion, impact, erosion, galling , and cavitation . See also surfacing .
- **hardfacing alloys**
  - Wear-resistant materials available as bare welding rod, flux-coated rod, long-length solid wires, long-length tubular wires, or powders that are deposited by hardfacing . Hardfacing materials include a wide variety of alloys, ceramics, and combinations of these materials. Conventional hardfacing alloys are normally classified as steels or low-alloy ferrous materials, chromium white irons, high-alloy ferrous materials, carbides, nickel-base alloys, or cobalt-base alloys.
- **hardness**
  - A measure of the resistance of a material to surface indentation or abrasion; may be thought of as a function of the stress required to produce some specified type of surface deformation. There is no absolute scale for hardness; therefore, to express hardness quantitatively, each type of test has its own scale of arbitrarily defined hardness. Indentation hardness can be measured by Brinell, Rockwell, Vickers , Knoop, and Scleroscope hardness tests.
- **hardness profile**
  - Hardness as a function of distance from a fixed reference point (usually from the surface).
- **Haring cell**
  - A rectangular box of nonconducting material, with principal and auxiliary electrodes so arranged as to permit estimation of throwing power or electrode polarizations and potentials between them.
- **heat-affected zone**
  - That portion of the base metal that was not melted during brazing, cutting, or welding, but whose microstructure and mechanical properties were altered by the heat.
- **heat checking**
  - A process in which fine cracks are formed on the surface of a body in sliding contact due to the buildup of excessive frictional heat.
- **healed-over scratch**
  - A scratch in a metallic object that occurred in an earlier mill operation and was partially masked in subsequent rolling. It may open up during forming.
- **heat mark**
  - Extremely shallow depression or groove in the surface of a plastic visible because of a sharply defined rim or a roughened surface.
- **hiding power**
  - The ability of a paint to mask the color or pattern of a surface. Usually expressed as ft^2/gal or m^2/L.
- **highlighting**

    - Buffing or polishing selected areas of a complex shape to increase the luster or change the color of those areas.
- **highly deformed layer**
    - In tribology, a layer of severely plastically deformed material that results from the shear stresses imposed on that region during sliding contact. See also Beilby layer and white etching layer .
- **high-solids paint**
    - Paint containing 35 to 80% solids. These products have become popular because of the reduction in solvent emissions associated with their use.
- **high-stress abrasion**
    - A form of abrasion in which relatively large cutting forces are imposed on the particles or protuberances causing the abrasion, and that produces significant cutting and deformation of the wearing surface. In metals, high-stress abrasion can result in significant surface strain hardening. This form of abrasion is common in mining and agricultural equipment, and in highly loaded bearings where hard particles are trapped between mating surfaces. See also low-stress abrasion .
- **high-temperature hydrogen attack**
    - A loss of strength and ductility of steel by high-temperature reaction of absorbed hydrogen with carbides in the steel resulting in decarburization and internal fissuring.
- **hinge area**
    - The juncture of a hanging burr with the more rigidly adhered portion of a burr .
- **Hohman A-6 wear machine**
    - A widely used type of wear and friction testing machine in which a rotating ring specimen is squeezed between two diametrically opposed rub blocks. This design is said to eliminate shaft flexure such as that found in other machines whose load application from the rub block to the ring is from one side only. Block geometry can be changed from flat to conforming or V-block. This type of machine is designed for use with either lubricated or unlubricated specimens.
- **holidays**
    - Discontinuities in a coating (such as porosity, cracks, gaps, and similar flaws) that allow areas of base metal to be exposed to any corrosive environment that contacts the coated surface.
- **homogeneous carburizing**
    - Use of a carburizing process to convert a low-carbon ferrous alloy to one of uniform and higher carbon content throughout the section.
- **honing**
    - A low-speed finishing process used chiefly to produce uniform high dimensional accuracy and fine finish, most often on inside cylindrical surfaces. In honing, very thin layers of stock are removed by simultaneously rotating and reciprocating a bonded abrasive stone or stick that is pressed against the surface being honed with lighter force than is typical of grinding .
- **hot corrosion**
    - An accelerated corrosion of metal surfaces that results from the combined effect of oxidation and reactions with sulfur compounds and other contaminants, such as chlorides, to form a molten salt on a metal surface that fluxes, destroys, or disrupts the normal protective oxide. See also gaseous corrosion .
- **hot dip**
    - Covering a surface by dipping the surface to be coated into a molten bath of the coating material. See also hot dip coating .
- **hot dip coating**
    - A metallic coating obtained by dipping the base metal into a molten metal.
- **hot etching**
    - In metallography, development and stabilization of the microstructure at elevated temperature in etchants or gases.
- **hot shortness**
    - A tendency for some alloys to separate along grain boundaries when stressed or deformed at temperatures near the melting point. Hot shortness is caused by a low-melting constituent, often present only in minute amounts, that is segregated at grain boundaries.
- **Hull cell**
    - A trapezoidal box of nonconducting material with electrodes arranged to permit observation of cathodic or anodic effects over a wide range of current densities.
- **hydrogen damage**

  - A general term for the embrittlement , cracking, blistering , and hydride formation that can occur when hydrogen is present in some metals.
- **hydrogen embrittlement**
  - A process resulting in a decrease of the toughness or ductility of a metal due to the presence of atomic hydrogen. Hydrogen embrittlement has been recognized classically as being of two types. The first, known as internal hydrogen embrittlement, occurs when the hydrogen enters molten metal which becomes supersaturated with hydrogen immediately after solidification. The second type, environmental hydrogen embrittlement, results from hydrogen being absorbed by solid metals. This can occur during elevated-temperature thermal treatments and in service during electroplating, contact with maintenance chemicals, corrosion reactions, cathodic protection , and operating in high-pressure hydrogen. In the absence of residual stress or external loading, environmental hydrogen embrittlement is manifested in various forms, such as blistering , internal cracking, hydride formation, and reduced ductility. With a tensile stress or stress-intensity factor exceeding a specific threshold, the atomic hydrogen interacts with the metal to induce subcritical crack growth leading to fracture. In the absence of a corrosion reaction (polarized cathodically), the usual term used is hydrogen-assisted cracking (HAC) or hydrogen stress cracking (HSC). In the presence of active corrosion, usually as pits or crevices (polarized anodically), the cracking is generally called stress-corrosion cracking (SCC), but should more properly be called hydrogen-assisted stress-corrosion cracking (HSCC). Thus, HSC and electrochemically anodic SCC can operate separately or in combination. In some metals, such as high-strength steels, the mechanism is believed to be all, or nearly all, HSC. The participating mechanism of HSC is not always recognized and may be evaluated under the generic heading of SCC.
- **hydrophilic**
  - (1) Tending to absorb water. (2) Tending to concentrate in the aqueous phase.
- **hydrophobic**
  - (1) Tending to repel water. (2) Lacking an affinity for water.
- **I**
- **identification etching**
  - Etching to expose particular microconstituents; all others remain unaffected.
- **immersion cleaning**
  - Cleaning in which the work is immersed in a liquid solution.
- **immersion coating**
  - A coating produced in a solution by chemical or electrochemical action without the use of external current.
- **immersion etching**
  - Method in which a microsection is dipped face up into etching solution and is moved around during etching. This is the most common etching method.
- **immersion plate**
  - A metallic deposit produced by a displacement reaction in which one metal displaces another from solution, for example: $Fe + Cu^{2+} \rightarrow Cu + Fe^{2+}$.
- **immersion plating**
  - Depositing a metallic coating on a metal immersed in a liquid solution, without the aid of an external electric current. Also called dip plating.
- **impact wear**
  - Wear of a solid surface resulting from repeated collisions between that surface and another solid body. The term erosion (erosive) wear is preferred in the case of multiple impacts and when the impacting body or bodies are very small relative to the surface being impacted.
- **impingement**
  - A process resulting in a continuing succession of impacts between liquid or solid particles and a solid surface. In preferred usage, impingement also connotes that the impacting particles are smaller than the solid surface, and that the impacts are distributed over the surface or a portion of the surface. If all impacts are superimposed on the same point or zone, then the term repeated impact is preferred.
- **impingement attack**
  - Corrosion associated with turbulent flow of liquid. May be accelerated by entrained gas bubbles. See also erosion-corrosion .
- **impregnation**

  - (1) Treatment of porous castings with a sealing medium to stop pressure leaks. (2) The process of filling the pores of a sintered compact, usually with a liquid such as a lubricant. (3) The process of mixing particles of a nonmetallic substance in a cemented carbide matrix, as in diamond-impregnated tools.
- **impression replica**
  - A surface replica made by impression. See also replica .
- **inclusions**
  - (1) A physical and mechanical discontinuity occurring within a material or part, usually consisting of solid, encapsulated foreign material. Inclusions are often capable of transmitting some structural stresses and energy fields, but to a noticeably different degree than from the parent material. (2) Particles of foreign material in a metallic matrix. The particles are usually compounds, such as oxides, sulfides, or silicates, but may be of any substance that is foreign to (and essentially insoluble in) the matrix. See also stringer .
- **induction hardening**
  - A surface-hardening process in which only the surface layer of a suitable ferrous workpiece is heated by electromagnetic induction to above the upper critical temperature and immediately quenched.
- **inhibitor**
  - A substance used to reduce the rate of a chemical or electrochemical reaction, commonly corrosion or pickling .
- **inorganic**
  - Being or composed of matter other than hydrocarbons and their derivatives, or matter that is not of plant or animal origin.
- **interdendritic corrosion**
  - Corrosive attack that progresses preferentially along interdendritic paths. This type of attack results from local differences in composition, such as coring commonly encountered in alloy castings.
- **interface**
  - The boundary between any two phases. Among the three phases (gas, liquid, and solid), there are five types of interfaces: gas-liquid, gas-solid, liquid-liquid, liquid-solid, and solid-solid.
- **intergranular corrosion**
  - Corrosion occurring preferentially at grain boundaries , usually with slight or negligible attack on the adjacent grains. See also interdendritic corrosion .
- **intergranular cracking**
  - Cracking or fracturing that occurs between the grains or crystals in a polycrystalline aggregate. Also called intercrystalline cracking. Contrast with transgranular cracking .
- **intergranular fracture**
  - Brittle fracture of a polycrystalline material in which the fracture is between the grains, or crystals, that form the material. Also called intercrystalline fracture. Contrast with transgranular fracture .
- **intergranular stress-corrosion cracking (IGSCC)**
  - Stress-corrosion cracking in which the cracking occurs along grain boundaries .
- **internal grinding**
  - Grinding an inside of a rotating workpiece by use of a wheel spindle that rotates and reciprocates through the length or depth of the hole being ground.
- **internal oxidation**
  - The formation of isolated particles of corrosion products beneath the metal surface. This occurs as the result of preferential oxidation of certain alloy constituents by inward diffusion of oxygen, nitrogen, sulfur, and so forth. Also called subscale formation.
- **internal shrinkage**
  - A void or network of voids within a casting caused by inadequate feeding of that section during solidification.
- **interrupted-current plating**
  - Plating in which the flow of current is discontinued for periodic short intervals to decrease anode polarization and elevate the critical current density . It is most commonly used in cyanide copper plating.
- **intumescence**

  - The swelling or bubbling of a coating usually because of heating (term currently used in space and fire protection applications).
- **ion**
  - An electrified portion of matter of atomic or molecular dimensions.
- **ion beam assisted deposition**
  - An ion implantation technique in which ion beams are combined with physical vapor deposition .
- **ion beam mixing**
  - An ion implantation technique in which deposited layers (electroplating, sputtering) tens or hundreds of nanometers thick are mixed and bonded to the substrate by an argon or xenon ion beam.
- **ion beam sputtering**
  - An ion implantation technique in which an ion beam of argon or xenon directed at a target sputters material from the target to a substrate ; the sputtered material arrives at the substrate with enough energy to promote good adhesion of the coating to substrate.
- **ion carburizing**
  - A method of surface hardening in which carbon ions are diffused into a workpiece in a vacuum through the use of high-voltage electrical energy. Synonymous with plasma carburizing or glow-discharge carburizing.
- **ion etching**
  - Surface removal by bombarding with accelerated ions in vacuum (1 to 10 kV).
- **ion implantation**
  - The process of modifying the physical or chemical properties of the near surface of a solid (target) by embedding appropriate atoms into it from a beam of ionized particles. The properties to be modified may be electrical, optical, or mechanical, and they may relate to the semiconducting behavior of the material or its corrosion behavior. The solid may be crystalline, polycrystalline, or amorphous and need not be homogeneous. Related techniques are also used in conjunction with ion implantation to increase the ratio of material introduced into the substrate per unit area, to provide appropriate mixtures of materials, or to overcome other difficulties involved in surface modification by ion implantation alone. See also specific techniques: ion beam sputtering , ion beam mixing , plasma ion deposition , and ion beam assisted deposition .
- **ion nitriding**
  - A method of surface hardening in which nitrogen ions are diffused into a workpiece in a vacuum through the use of high-voltage electrical energy. Synonymous with plasma nitriding or glow-discharge nitriding.
- **ion plating**
  - A generic term applied to atomistic film deposition processes in which the substrate surface and/or the depositing film is subjected to a flux of high-energy particles (usually gas ions) sufficient to cause changes in the interfacial region or film properties. Such changes may be in film adhesion to the substrate, film morphology, film density, film stress, or surface coverage by the depositing film material.
- **ion-scattering spectrometry**
  - A technique to elucidate composition and structure of the outermost atomic layers of a solid material, in which principally mono-energetic, singly charged, low-energy (less than 10 keV) probe ions are scattered from the surface and are subsequently detected and recorded as a function of the energy.
- **isocorrosion diagram**
  - A graph or chart that shows constant corrosion behavior with changing solution (environment) composition and temperature.
- **Izod test**
  - A type of impact test in which a V-notched specimen, mounted vertically, is subjected to a sudden blow delivered by the weight at the end of a pendulum arm. The energy required to break off the free end is a measure of the impact strength or toughness of the material. Contrast with Charpy test .
- **J**
- **jet vapor deposition**
  - A vacuum deposition method in which evaporated atoms or molecules are "seeded" into a supersonic jet flow of inert gas into a rapidly pumped vacuum chamber. The jet flow transports the atoms and molecules to the substrate surface, where they are deposited.

- **Jominy test**
    - A laboratory procedure for determining the hardenability of a steel or other ferrous alloy. Hardenability is determined by heating a standard specimen above the upper critical temperature, placing the hot specimen in a fixture so that a stream of cold water impinges on one end, and, after cooling to room temperature is completed, measuring the hardness near the surface of the specimen at regularly spaced intervals along its length. The data are normally plotted as hardness versus distance from the quenched end. Also called the end-quench hardenability test.
- **K**
- **karat**
    - A 24th part by weight; thus 18-karat gold is 18/24 pure.
- **knife coating**
    - A method of coating a substrate (usually paper or fabric) in which the substrate, in the form of a continuous moving web, is coated with a material, the thickness of which is controlled by an adjustable knife or bar set at a suitable angle to the substrate.
- **knife-line attack**
    - Intergranular corrosion of an alloy, usually stabilized stainless steel, along a line adjoining or in contact with a weld after heating into the sensitization temperature range.
- **knurling**
    - Impressing a design into a metallic surface, usually by means of small, hard rollers that carry the corresponding design on their surfaces.
- **L**
- **lacquer**
    - (1) A coating formulation based on thermoplastic film-forming material dissolved in organic solvent. The coating dries primarily by evaporation of the solvent. Typical lacquers include those based on lac, nitrocellulose, other cellulose derivatives, vinyl resins, acrylic resins, and so forth. (2) In lubrication, a deposit resulting from the oxidation and/or polymerization of fuels and lubricants when exposed to high temperatures. Softer deposits are described as varnishes or gums.
- **lamination**
    - In porcelain enamel , a defect resulting from bloating of a sheet steel piece during firing due to a separation in the steel structure.
- **lap**
    - A surface imperfection, with the appearance of a seam , caused by hot metal, fins, or sharp corners being folded over and then being rolled or forged into the surface but without being welded.
- **lapping**
    - Rubbing two surfaces together, with or without abrasives, for the purpose of obtaining extreme dimensional accuracy or superior surface finish .
- **laser surface processing**
    - The use of lasers with continuous outputs of 0.5 to 10 kW to modify the metallurgical structure of a surface and to tailor the surface properties without adversely affecting the bulk properties. The surface modification can take the following three forms. The first is transformation hardening in which a surface is heated so that thermal diffusion and solid-state transformations can take place. The second is surface melting, which results in a refinement of the structure due to the rapid quenching from the melt. The third is surface (laser) alloying, in which alloying elements are added to the melt pool to change the composition of the surface. The novel structures produced by laser surface melting and alloying can exhibit improved electrochemical and tribological behavior.
- **latent solvent**
    - A liquid that cannot itself dissolve a binder but increases the tolerance of the paint for a diluent.
- **lath martensite**
    - Martensite formed partly in steels containing less than approximately 1.0% C and solely in steels containing less than approximately 0.5% C as parallel arrays of packets of lath-shape units 0.1 to 0.3 μm (4 to 12 μin.) thick.
- **lay**
    - Direction of predominant surface pattern remaining after cutting, grinding , lapping , or other processing.
- **ledeburite**

  - The eutectic of the iron-carbon system, the constituents of which are austenite and cementite . The austenite decomposes into ferrite and cementite on cooling below Ar_1, the temperature at which transformation of austenite to ferrite or ferrite plus cementite is completed during cooling.
- **leveler lines**
  - Lines on sheet or strip running transverse to the direction of roller leveling. These lines may be seen upon stoning or light sanding after leveling (but before drawing) and can usually be removed by moderate stretching.
- **leveling action**
  - Ability of a plating solution to produce a plated surface smoother than that of the substrate .
- **linishing**
  - A method of finishing by grinding on a continuous abrasive belt.
- **liquid carburizing**
  - Surface hardening of steel by immersion into a molten bath consisting of cyanides and other salts.
- **liquid honing**
  - Producing a finely polished finish by directing an air-ejected chemical emulsion containing fine abrasives against the surface to be finished.
- **liquid nitriding**
  - A method of surface hardening in which ferrous metal parts are exposed to molten nitrogen-bearing fused-salt baths containing cyanates, cyanides, or both at subcritical temperatures. A typical commercial bath is a mixture of sodium and potassium salts. The anions are 30 to 40% cyanate, 1 to 5% cyanide, and the balance carbonate. The operating temperature for these salt baths is 510 to 595 °C (950 to 1100 °F).
- **liquid nitrocarburizing**
  - A nitrocarburizing process utilizing molten liquid salt baths below the lower critical temperature. Liquid nitrocarburizing processes are used to improve wear resistance and fatigue properties of steels and cast irons. See liquid nitriding .
- **liquid penetrant inspection**
  - A type of nondestructive inspection that locates discontinuities that are open to the surface of a metal by first allowing a penetrating dye or fluorescent liquid to infiltrate the discontinuity, removing the excess penetrant, and then applying a developing agent that causes the penetrant to seep back out of the discontinuity and register as an indication. Liquid penetrant inspection is suitable for both ferrous and nonferrous materials, but is limited to the detection of open surface discontinuities in nonporous solids.
- **localized corrosion**
  - Corrosion at discrete sites, for example, crevice corrosion , pitting , and stress-corrosion cracking .
- **long-term etching**
  - Etching times of a few minutes to hours.
- **lower critical temperature**
  - The temperature below which ferrite is the stable phase. Also called the A_1 temperature.
- **low-stress abrasion**
  - A form of abrasion in which relatively low contact pressures on the abrading particles or protuberances cause only fine scratches and microscopic cutting chips to be produced. See also high-stress abrasion .
- **lubricant**
  - Any substance interposed between two surfaces in relative motion for the purpose of reducing the friction or wear between them. This definition implies intentional addition of a substance to an interface; however, species such as oxides and tarnishes on certain metals can also act as lubricants even though they were not added to the system intentionally.
- **lubricious (lubricous)**
  - Relating to a substance or surface condition that tends to produce relatively low friction.
- **Lüders lines**
  - Elongated surface markings or depressions in sheet metal, often visible with the unaided eye, caused by discontinuous (inhomogeneous) yielding. Also known as Lüders bands, Hartmann lines, Piobert lines, or stretcher strains .
- **lumps**
  - See beads .
- **luster finish**

  - A bright as-rolled finish, produced on ground metal rolls; it is suitable for decorative painting or plating, but usually must undergo additional surface preparation after forming.
- **M**
- **macroetching**
  - Etching a metal surface to accentuate gross structural details, such as grain flow , segregation, porosity, or cracks, for observation by the unaided eye or at magnifications to 25×.
- **machining**
  - Removing material from a part, usually using a cutting tool, and usually using a power-driven machine.
- **mandrel**
  - A form used as a cathode in electroforming ; a mold or matrix.
- **man-made (synthetic) diamond**
  - A manufactured diamond, darker, blockier, and considered to be more friable than most natural diamonds.
- **mask**
  - A device for protecting a surface from the effects of blasting and/or coating. Masks are generally either reusable or disposable.
- **mass finishing**
  - A group of finishing methods that involve loading of components to be finished into a container together with some abrasive media, water, and compound, and then applying some action to the container in order to cause the media and parts to rub against one another, thereby improving the surface of the components. Mass finishing processes include barrel finishing , tumbling , and vibratory finishing .
- **material removal rate**
  - In grinding , the volume of material removed in a unit of time. Material removal rate = work speed × depth of cut × width of cut.
- **matte finish**
  - (1) A metal finish produced by using a sand blast or acid dip, creating a frosted and nonreflective surface that is free of parallel lines. (2) In porcelain enamel , a slightly roughened surface lacking in luster.
- **mechanical activation**
  - The acceleration or initiation of a chemical reaction by mechanical exposure of a nascent solid surface. Metal cutting (machining) is an effective method of exposing large areas of fresh surface.
- **mechanical bond**
  - The adherence of a thermal sprayed deposit to a roughened surface by the mechanism of particle interlocking.
- **mechanical cleaning**
  - Process for removing dirt, scale, or other deposits from surfaces through the use of mechanical means such as abrasive blasting .
- **mechanical plating**
  - A process whereby hard, small spherical objects (such as glass shot) are tumbled against a metallic surface in the presence of finely divided metal powder (such as zinc dust) and appropriate chemicals for the purpose of covering such surfaces with metal.
- **mechanical polishing**
  - A process that yields a specularly reflecting surface entirely by the action of machining tools, which are usually the points of abrasive particles suspended in a liquid among the fibers of a polishing cloth.
- **mechanical wear**
  - Removal of material due to mechanical processes under conditions of sliding, rolling, or repeated impact. The term mechanical wear includes adhesive wear , abrasive wear , and fatigue wear . Compare with corrosive wear and thermal wear .
- **metallic bond**
  - The principal bond between metal atoms, which arises from the increased spatial extension of valence-electron wave functions when an aggregate of metal atoms is brought close together. An example is the bond formed between base metals and filler metals in all welding processes.
- **metallic wear**

  - Typically, wear due to rubbing or sliding contact between metallic materials that exhibits the characteristics of severe wear, for example, significant plastic deformation , material transfer, and indications that cold welding of asperities possibly has taken place as part of the wear process. See also adhesive wear and severe wear .
- **metallizing**
  - (1) Application of an electrically conductive metallic layer to the surface of nonconductors. (2) The application of metallic coatings by nonelectrolytic procedures such as spraying of molten metal and deposition from the vapor phase.
- **metallurgical bond**
  - Adherence of a coating to the base material characterized by diffusion, alloying, or intermolecular or intergranular attraction at the interface between the coating and the base material.
- **metallurgical burn**
  - Modification of the microstructure near the contact surface due to frictional temperature rise.
- **metal penetration**
  - A surface condition in castings in which metal or metal oxides have filled voids between sand grains without displacing them.
- **metal shadowing**
  - The enhancement of contrast in a microscope by vacuum deposition of a dense metal onto the specimen at an angle generally not perpendicular to the surface of the specimen. See also shadowing .
- **metal spraying**
  - Coating metal objects by spraying molten metal against their surfaces. See also thermal spraying and flame spraying .
- **microfinishing grinding**
  - See microgrinding .
- **microgrinding**
  - A precision grinding process that uses extremely fine abrasive (50 μm and finer). Also known as fine grinding and microfinishing grinding.
- **microstructure**
  - The structure of an object, organism, or material as revealed by a microscope at magnifications greater than 25×.
- **microthrowing power**
  - The ability of a plating solution or a specified set of plating conditions to deposit metal in pores or scratches.
- **mil**
  - One thousandth of an inch 0.001 = 25.4 μm.
- **mild wear**
  - A form of wear characterized by the removal of material in very small fragments. Mild wear is an imprecise term, frequently used in research, and contrasted with severe wear . In fact, the phenomena studied usually involve the transition from mild to severe wear and the factors that influence this transition. Mild wear may be appreciably greater than can be tolerated in practice. With metallic sliders, mild wear debris usually consists of oxide particles. See also normal wear and severe wear .
- **mill addition**
  - Any material added to the ball milling charge of a frit .
- **mill finish**
  - A nonstandard (and typically nonuniform) surface finish on mill products that are delivered without being subjected to a special surface treatment (other than a corrosion-preventive treatment) after the final working or heat-treating step.
- **milling**
  - Using a rotary tool with one or more teeth that engage the workpiece and remove material as the workpiece moves past the rotating cutter.
- **mill scale**
  - The heavy oxide layer that forms during the hot fabrication or heat treatment of metals.
- **minimized spangle**
  - A hot dip galvanized coating of very small grain size, which makes the spangle less visible when the part is subsequently painted.
- **mirror-finish grinding**

    - A class of grinding processes in which extremely fine abrasive particles are used to achieve reflective surfaces of precise geometry. These methods are used in finishing such items as molds and dies used for making contact lenses and optical components.
- **mold coating**
    - (1) Coating to prevent surface defects on permanent mold castings and die castings. (2) Coating on sand molds to prevent metal penetration and to improve metal finish. Also called mold facing or mold dressing.
- **molecular beam epitaxy**
    - A vacuum deposition process used to form epitaxial films on semiconductor materials.
- **molten metal flame spraying**
    - A thermal spraying process variation in which the metallic material to be sprayed is in the molten condition. See also flame spraying .
- **molten salt bath**
    - Same as salt bath .
- **morphology**
    - The characteristic shape, form, or surface texture or contours of the crystals, grains , or particles of (or in) a material, generally on a microscopic scale.
- **motor-generator (MG set)**
    - A machine that consists of one or more motors mechanically coupled to one or more generators. In plating , such a machine in which the generator delivers dc of appropriate amperage and voltage.
- **multilayer coating**
    - Same as composite coating .
- **multiple etching**
    - Sequential etching of a microsection, with specific reagents attacking distinct microconstituents.
- **N**
- **negative replica**
    - A method of reproducing a surface obtained by the direct contact of the replicating material with the specimen. Using this technique, the contour of the replica surface is reversed with respect to that of the original. See also replica .
- **neutralization**
    - The balancing of acidity and alkalinity by interaction. In the context of cleaning, the removal of acid soils by alkalines and alkaline soils by acids.
- **nitriding**
    - Introducing nitrogen into the surface layer of a solid ferrous alloy by holding at a suitable temperature (below Ac_1 for ferritic steels) in contact with a nitrogenous material, usually ammonia or molten salt of appropriate composition. Quenching is not required to produce a hard case. See also aerated bath nitriding , bright nitriding , liquid nitriding , and nitrocarburizing .
- **nitrocarburizing**
    - Any of several processes in which both nitrogen and carbon are absorbed into the surface layers of a ferrous material from a molten salt or gaseous atmosphere at temperatures below the lower critical temperature and, by diffusion, create a concentration gradient. Nitrocarburizing is performed primarily to provide an antiscuffing surface layer and to improve fatigue resistance. Compare with carbonitriding .
- **noble metal**
    - A metal that does not readily tend to furnish ions, and therefore does not dissolve readily, nor easily enter into such reactions as oxidation, etc. Contrast with base metal .
- **nodular pearlite**
    - Pearlite that has grown as a colony with an approximately spherical morphology.
- **nonionic detergent**
    - A detergent that produces aggregates of electrically neutral molecules with colloidal properties.
- **normal wear**
    - Loss of material within the design limits expected for the specific intended application. The concept of normal wear depends on economic factors, such as the expendability of a worn part.
- **notch sensitivity**
    - The extent to which the sensitivity of a material to fracture is increased by the presence of a stress concentration, such as a notch, a sudden change in cross section, a crack, or a scratch. Low notch

sensitivity is usually associated with ductile materials, and high notch sensitivity is usually associated with brittle materials.

- **nucleation**
  - In plating of plastics, the preplating step in which a catalytic material, often a palladium or gold compound, is absorbed on a surface of the plastic substrate to act as sites for initial stages of deposition.
- **O**
- **oblique evaporation shadowing**
  - The condensation of evaporated material onto a substrate that is inclined to the direct line of the vapor stream to produce shadows. See also shadowing .
- **oil-based paints**
  - Paints with films that form solids by the air-induced cross-linking of certain unsaturated plant oils known as drying oils. Oxygen is consumed in the process.
- **one-coat ware**
  - (1) Workpieces finished in a single coat of porcelain enamel . Also known as one-coat work. (2) Sometimes a contraction of one-cover-coat ware in which the finish consists of a single cover coat applied over the ground coat.
- **opacifier**
  - A material that imparts or increases the diffuse reflectance of porcelain enamel .
- **opacity**
  - In porcelain enamel , the property of reflecting light diffusely and nonselectively.
- **orange peel**
  - (1) In painting, a pebbled film surface caused by too rapid drying after spraying, by failure of the coating material to exhibit the desired leveling effects, or by uneven flow (application) in roller coating techniques. (2) In porcelain enamel , a surface condition characterized by an irregular waviness that resembles an orange skin in texture; sometimes considered a defect. (3) A surface roughening in the form of a pebble-grained pattern that occurs when a metal of unusually coarse grain size is stressed beyond its elastic limit. Also called pebbles and alligator skin.
- **organic solvent**
  - See chlorinated solvent .
- **organic zinc-rich paint**
  - Coating containing zinc powder pigment and an organic resin.
- **overfiring**
  - In porcelain enamel , a condition sometimes occurring during firing when the temperature of the furnace is too high or the ware is left in the furnace for a greater length of time than necessary.
- **overpickling**
  - Using pickling solutions of greater strength or at higher temperature than recommended, or allowing the workpiece to remain in the pickling tanks for a greater length of time than necessary. Overpickling can lead to blistering of subsequently applied porcelain enamel finishes.
- **oxidation**
  - A reaction in which electrons are removed from a reactant. Sometimes, more specifically the combination of a reactant with oxygen. Contrast with reduction .
- **oxidation reduction**
  - To change the valence state of oxide scale and rust to soluble forms for removal from metal surfaces. Rust is chemically changed in this way to a more soluble form, easily dissolved by acids.
- **oxidative wear**
  - (1) A corrosive wear process in which chemical reaction with oxygen or oxidizing environment predominates. (2) A type of wear resulting from the sliding action between two metallic components that generates oxide films on the metal surfaces. These oxide films prevent the formation of a metallic bond between the sliding surfaces, resulting in fine wear debris and low wear rates.
- **oxide film replica**
  - A thin film of an oxide of the specimen to be examined. The replica is prepared by air, oxygen, chemical, or electrochemical oxidation of the parent metal and is subsequently freed mechanically or chemically for examination. See also replica .
- **oxidized steel surface**

  - Surface having a thin, tightly adhering oxidized skin (from straw to blue in color), which forms when steel is heated in an oxidizing atmosphere.
- **oxidizing agent**
  - A compound that causes oxidation, thereby itself being reduced.
- **oxygen deficiency**
  - A form of crevice corrosion in which galvanic corrosion proceeds because oxygen is prevented from diffusing into the crevice.
- **P**
- **pack carburizing**
  - A method of surface hardening of steel in which parts are packed in a steel box with a carburizing compound and heated to elevated temperatures. Common carburizing compounds contain 10 to 20% alkali or alkaline earth metal carbonates (for example, barium carbonate, $BaCO_3$) bound to hardwood charcoal or to coke by oil, tar, or molasses. This process has been largely supplanted by gas and liquid carburizing processes.
- **pack cementation**
  - A coating process akin to pack carburizing that involves packing the parts to be coated into a retort with a carefully blended mixture of powders and then exposing the pack under hermetically sealed conditions or an inert atmosphere to elevated temperatures. Pack cementation is principally used for the application of aluminum diffusion coatings and ceramic coatings.
- **paint**
  - A material that when applied as a liquid to a surface forms a solid film for the purpose of decoration and/or protection. Generally, a paint contains a binder(s), solvent(s), and a pigment(s). Often other materials are present to give special properties to the paint film. Examples of such additives are rust inhibitors, light stabilizers, and softening agents (plasticizers).
- **passivation**
  - (1) A reduction of the anodic reaction rate of an electrode involved in corrosion . (2) The process in metal corrosion by which metals become passive. (3) The changing of a chemically active surface of a metal to a much less reactive state. Contrast with activation . (4) The formation of an insulating layer directly over a semiconductor surface to protect the surface from contaminants, moisture, and so forth.
- **passivator**
  - A type of corrosion inhibitor that appreciably changes the potential of a metal to a more noble (positive) value.
- **passive**
  - (1) A metal corroding under the control of a surface reaction product. (2) The state of the metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal.
- **passive-active cell**
  - A corrosion cell in which the anode is a metal in the active state and the cathode is the same metal in the passive state.
- **passivity**
  - A condition in which a piece of metal, because of an impervious covering of oxide or other compound, has a corrosion rate much less than that of the metal in the active state.
- **patina**
  - The coating, usually green, that forms on the surface of metals such as copper and copper alloys exposed to the atmosphere. Also used to describe the appearance of a weathered surface of any metal.
- **pearlite**
  - A metastable lamellar aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures above the bainite range.
- **peeling**
  - The detaching of one layer of a coating from another, or from the base metal , because of poor adherence.
- **periodic reverse plating**
  - A method of plating in which the current is reversed periodically. The cycles are usually no longer than a few minutes and may be much less.
- **pH**

  - The negative logarithm of the hydrogen-ion activity or hydrogen-ion concentration in gram equivalents per liter that is used in expressing both acidity and alkalinity on a scale of values running from 0 to 14; 0 to 7 represents acidity; 7 neutrality, and 7 to 14 alkalinity.
- **phosphate coating**
  - Same as phosphating .
- **phosphating**
  - Forming an adherent phosphate coating on a metal by immersion in a suitable aqueous phosphate solution. Also called phosphatizing. See also conversion coating .
- **photoresist**
  - (1) A radiation-sensitive material which, when properly applied to a variety of substrates and then properly exposed and developed, masks portions of the substrate with a high degree of integrity. (2) A photosensitive coating that is applied to a laminate and subsequently exposed through a photo tool (film) and developed to create a pattern that can be either plated or etched.
- **physical vapor deposition (PVD)**
  - A coating process whereby the deposition species are transferred and deposited in the form of individual atoms or molecules. The most common PVD methods are sputtering and evaporation. Sputtering, which is the principal PVD process, involves the transport of a material from a source (target) to a substrate by means of the bombardment of the target by gas ions that have been accelerated by a high voltage. Atoms from the target are ejected by momentum transfer between the incident ions and the target. These ejected particles move across the vacuum chamber to be deposited on the substrate. Evaporation, which was the first PVD process used, involves the transfer of material to form a coating by physical means alone, essentially vaporization. The streaming vapor is generated by melting and evaporating a coating material source bar, by an electron beam in a vacuum chamber. Because both of these methods are line-of-sight processes, it is necessary to use specially shaped targets or multiple evaporation sources and to rotate or move the substrate uniformly to expose all areas. PVD coatings are used to improve the wear, friction, and hardness properties of cutting tools and as corrosion-resistant coatings.
- **pickle**
  - See pickling .
- **pickle stain**
  - Discoloration of metal due to chemical cleaning without adequate washing and drying.
- **pickling**
  - The chemical removal of surface oxides (scale) from iron and steel by immersion in an aqueous acid solution. The most common pickling solutions for carbon steels are sulfuric and hydrochloric acids.
- **pickup**
  - (1) Transfer of metal from tools to part or from part to tools during a forming operation. (2) Small particles of oxidized metal adhering to the surface of a mill product. (3) The amount of slip retained per unit area on dipped porcelain enamel ware.
- **pigment**
  - Small particles added to the paint to influence properties such as color, corrosion resistance , and mechanical strength.
- **pinhole porosity**
  - Porosity consisting of numerous small gas holes distributed throughout a metal; found in weld metal, castings, and electrodeposited metal.
- **pinhole**
  - A porcelain enamel surface defect caused by gas evolution and characterized by a small hole resembling a pin prick that may extend to the base metal .
- **pit**
  - A porcelain enamel surface defect similar to a dimple but slightly smaller.
- **pitting**
  - (1) Forming small sharp cavities in a surface by corrosion , wear, or other mechanically assisted degradation. (2) Localized corrosion of a metal surface, confined to a point or small area, that takes the form of cavities.
- **planishing**
  - Producing a smooth finish on metal by a rapid succession of blows delivered by highly polished dies or by a hammer designed for the purpose, or by rolling in a planishing mill.
- **plasma**

    - A gas of sufficient energy so that a large fraction of the species present is ionized and thus conducts electricity. Plasmas may be generated by the passage of a current between electrodes, by induction, or by a combination of these methods.
- **plasma-assisted chemical vapor deposition**
    - A chemical vapor deposition process that uses low-pressure glow-discharge plasmas to promote the chemical deposition reactions. Also called plasma-enhanced chemical vapor deposition.
- **plasma ion deposition**
    - An ion implantation technique in which ion beams are used to create coatings having special phases, especially ion beam formed carbon coatings in the diamond phase or ion beam formed boron nitride coatings.
- **plasma spraying**
    - A thermal spraying process in which the coating material is melted with heat from a plasma torch that generates a nontransferred arc; molten powder coating material is propelled against the base metal by the hot, ionized gas issuing from the torch.
- **plastic deformation**
    - The permanent (inelastic) distortion of materials under applied stresses that strain the material beyond its elastic limit.
- **plasticizer**
    - A lower molecular weight material added to polymeric materials such as paints, plastics, or adhesives to improve the flexibility.
- **plastic replica**
    - In fractography and metallography, a reproduction in plastic of the surface to be studied. It is prepared by evaporation of the solvent from a solution of plastic, polymerization of a monomer, or solidification of a plastic on the surface.
- **plastisol**
    - A suspension of a finely divided resin in a plasticizer that can be converted to a continuous film by the application of heat. Distinct from baking enamels etc. in that substantially all the original mixture becomes a part of the film; there is no significant evaporation of solvent. The films are usually much thicker than obtainable from coatings that depend on the evaporation of a volatile solvent.
- **plate martensite**
    - Martensite formed partly in steel containing more than approximately 0.5% C and solely in steel containing more than approximately 1.0% C that appears as lenticular-shape plates (crystals).
- **plating**
    - Forming an adherent layer of metal on an object; often used as a shop term for electroplating . See also electrodeposition and electroless plating .
- **plating rack**
    - A fixture used to hold work and conduct current to it during electroplating .
- **plowing**
    - In tribology, the formation of grooves by plastic deformation of softer of two surfaces in relative motion.
- **plunge grinding**
    - Grinding wherein the only relative motion of the wheel is radially toward the work.
- **plymetal**
    - Sheet consisting of bonded layers of dissimilar metals.
- **Poisson burr**
    - A burr formed predominantly by the phenomenon that is responsible for Poisson's ratio. Sometimes called a flow-type burr.
- **polarization**
    - The change in the potential of a electrode during electrolysis , such that the potential of an anode always becomes more noble and that of a cathode less noble than their respective static potentials. Equal to the difference between the static electrode potential and the dynamic electrode potential .
- **polished surface**
    - A surface prepared for metallographic inspection that reflects a large proportion of the incident light in a specular manner.
- **polishing**

  - The smoothing of a metal surface by means of the action of abrasive particles attached by adhesive to the surface of wheels or endless belts usually driven at a high speed.
- **polishing wear**
  - An extremely mild form of wear for which the mechanism has not been clearly identified, but that may involve extremely fine-scale abrasion, plastic smearing of micro-asperities, and/or tribochemical material removal.
- **polymers**
  - A high molecular weight organic compound, natural or synthetic, with a structure that can be represented by a repeated small unit, the mer. Synthetic polymers are formed by addition or condensation polymerization of monomers. When two or more dissimilar monomers are involved, the product is called a copolymer. The lengths of polymer chains, usually measured by molecular weight, have very significant effects on the performance properties of plastics and profound effects on processability.
- **pop-off**
  - Loss of small portions of a porcelain enamel coating. The usual cause is outgassing of hydrogen or other gases from the base metal during firing , but pop-off may also occur because of oxide particles or other debris on the surface of the base metal. Usually, the pits are minute and cone shaped, but when pop-off is the result of severe fishscale the pits may be much larger and irregular.
- **porcelain**
  - A glazed or unglazed vitreous ceramic whiteware used for technical purposes. This term designates such products as electrical, chemical, mechanical, structural, and thermal wares when they are vitreous. This term is frequently used as a synonym for china.
- **porcelain enamel**
  - A substantially vitreous or glassy, inorganic coating (borosilicate glass) bonded to metal by fusion at a temperature above 425 °C (800 °F). Porcelain enamels are applied primarily to components made of sheet iron or steel, cast iron, aluminum, or aluminum-coated steels.
- **pore**
  - (1) A small opening, void, interstice, or channel within a consolidated solid mass or agglomerate, usually larger than atomic or molecular dimensions. (2) A minute cavity in a powder metallurgy compact, sometimes added intentionally. (3) A minute perforation in an electroplated coating.
- **porosity**
  - (1) Fine holes or pores within a solid; the amount of these pores is expressed as a percentage of the total volume of the solid. (2) Cavity-type discontinuities in weldments formed by gas entrapment during solidification. (3) A characteristic of being porous, with voids or pores resulting from trapped air or shrinkage in a casting. See also gas porosity and pinhole porosity .
- **positive replica**
  - A replica whose contours correspond directly to the surface being replicated. Contrast with negative replica .
- **post-nucleation**
  - The step where, if necessary, the catalyst is converted to its final form when plating on plastic substrates. This is the final step prior to electroless plating .
- **poultice corrosion**
  - Same as deposit corrosion .
- **powder adhesion**
  - In dry process enameling , the ability of an electrostatic powder to remain attached by static attraction to a grounded substrate.
- **powder flame spraying**
  - A thermal spraying process variation in which the material to be sprayed is in powder form. See also flame spraying .
- **precipitation**
  - The consolidation of soil particles (the opposite of dispersion) in a cleaning bath, permitting their removal as sludge and prolonging bath life. The hardness of water can be reduced by precipitation with soda ash or trisodium phosphate.
- **precipitation (deposit) etching**
  - Development of microstructure in a metallographic specimen through formation of reaction products at the surface of the microsection. See also staining .
- **precipitation hardening**

  - Hardening in metals caused by the precipitation of a constituent from a supersaturated solid solution. See also age hardening and aging .
- **precision grinding**
  - Machine grinding to specified dimensions and low tolerances.
- **precoated metal products**
  - Mill products that have a metallic, organic, or conversion coating applied to their surfaces before they are fabricated into parts.
- **preshadowed replica**
  - A replica for fractographic or metallographic inspection that is formed by the application of shadowing material to the surface to be replicated. It is formed before the thin replica film is cast or otherwise deposited on the surface. See also shadowing .
- **primary boiling**
  - The evolution of gas during the initial firing of porcelain enamel ; sometimes considered a defect.
- **primer**
  - A coating applied to a surface prior to the application of a paint topcoat or adhesive to improve the performance of the bond.
- **primes**
  - Metal products, principally sheet and plate, of the highest quality and free from blemishes or other visible imperfections.
- **proeutectoid carbide**
  - Primary crystals of cementite formed directly in ferrous alloys from the decomposition of austenite exclusive of that cementite resulting from the eutectoid reaction. See also eutectoid .
- **proeutectoid ferrite**
  - Primary crystals of ferrite formed directly in ferrous alloys from the decomposition of austenite exclusive of that ferrite resulting from the eutectoid reaction. See also eutectoid .
- **proeutectoid phase**
  - Particles of a phase in ferrous alloys that precipitate during cooling after austenitizing but before the eutectoid transformation takes place. See also eutectoid .
- **protective atmosphere**
  - (1) A gas envelope surrounding the part to be brazed, welded, or thermal sprayed, with the gas composition controlled with respect to chemical composition, dew point, pressure, flow rate, and so forth. Examples are inert gases, combusted fuel gases, hydrogen, and vacuum. (2) The atmosphere in a heat treating or sintering furnace designed to protect the parts or compacts from oxidation, nitridation, or other contamination from the environment.
- **pull through**
  - See copperhead .
- **Q**
- **quantitative metallography**
  - Determination of specific characteristics of a microstructure by quantitative measurements on micrographs or metallographic images. Quantities so measured include volume concentration of phases, grain size, particle size, mean free path between like particles or secondary phases, and surface area to volume ratio of microconstituents, particles, or grains.
- **quench-age embrittlement**
  - Embrittlement of low-carbon steels resulting from precipitation of solute carbon at existing dislocations and from precipitation hardening of the steel caused by differences in the solid solubility of carbon in ferrite at different temperatures. Quench-age embrittlement usually is caused by rapid cooling of the steel from temperatures slightly below Ac_1 (the temperature at which austenite begins to form), and can be minimized by quenching from lower temperatures.
- **quench hardening**
  - (1) Hardening suitable alpha-beta alloys (most often certain copper or titanium alloys) by solution treating and quenching to develop a martensitic-like structure. (2) In ferrous alloys, hardening by austenitizing and then cooling at a rate such that a substantial amount of austenite transforms to martensite.
- **R**
- **rack**
  - Same as plating rack .
- **rain erosion**

    - A form of liquid impingement erosion in which the impinging liquid particles are raindrops. This form of erosion is of particular concern to designers and material selectors for external surfaces of rotary-wing and fixed-wing aircraft. See also erosion .
- **rattail**
    - A surface imperfection on a casting, occurring as one or more irregular lines, caused by expansion of sand in the mold. Compare with buckle (2).
- **reactive evaporation**
    - A vacuum deposition process in which trace amounts of an active gas are added to the vacuum chamber; the gas reacts with an evaporating material in the chamber, promoting deposition of the material on a substrate.
- **real area of contact**
    - Same as actual contact area .
- **reamer**
    - A rotary cutting tool with one or more cutting elements (teeth), used for enlarging a hole to desired size and contour. It is supported principally by the metal around the hole it cuts.
- **reaming**
    - An operation in which a previously formed hole is sized and contoured accurately by using a rotary cutting tool (reamer) with one or more cutting elements (teeth). The principal support for the reamer during the cutting action is supplied by the workpiece.
- **reboiling**
    - In porcelain enamel , gas evolution occurring and recurring during repeated firing of the ground coat; sometimes considered a defect.
- **recalescence**
    - (1) The increase in temperature that occurs after undercooling, because the rate of liberation of heat during transformation of a material exceeds the rate of dissipation of heat. (2) A phenomenon, associated with the transformation of gamma iron to alpha iron on cooling (supercooling) of iron or steel, that is revealed by the brightening (reglowing) of the metal surface owing to the sudden increase in temperature caused by the fast liberation of the latent heat of transformation. Contrast with decalescence .
- **reclain**
    - Porcelain enamel overspray that is removed from the spray booth and reconditioned for use.
- **recrystallization**
    - (1) The formation of a new, strain-free grain structure from that existing in cold-worked metal, usually accomplished by heating. (2) The change from one crystal structure to another, as occurs on heating or cooling through a critical temperature. (3) A process, usually physical, by which one crystal species is grown at the expense of another or at the expense of others of the same substance but smaller in size.
- **rectification**
    - The conversion of alternating current into direct current.
- **rectifier**
    - A device that converts alternating current into direct current by virtue of a characteristic permitting appreciable flow of current in only one direction.
- **reduction**
    - A reaction in which electrons are added to a reactant. More specifically, the addition of hydrogen or the abstraction of oxygen. Such a reaction takes place, for example, at the cathode in electrolysis . Contrast with oxidation .
- **reflector sheet**
    - A clad product consisting of a facing layer of high-purity aluminum capable of taking a high polish, for reflecting heat or light, and a base of commercially pure aluminum or an aluminum-manganese alloy, for strength and formability.
- **reflowing**
    - Melting of an electrodeposit followed by solidification. The surface has the appearance and physical characteristics of a hot dipped surface (especially tin or tin alloy plates). Also called flow brightening .
- **Rehbinder effect**
    - Modification of the mechanical properties at or near the surface of a solid, attributable to interaction with a surfactant .
- **relieving**

  - The removal of material from selected portions of a colored metal surface by mechanical means to achieve a multicolored effect.
- **replica**
  - A reproduction of a surface in a material. It is usually accomplished by depositing a thin film of suitable material, such as a plastic, onto the specimen surface. This film is subsequently extracted and examined by optical microscopy, scanning electron microscopy , or transmission electron microscopy , the latter being the most common. Replication techniques can be classified as either surface replication or extraction replication. Surface replicas provide an image of the surface topography of a specimen, while extraction replicas lift particles from the specimen. See also atomic replica , cast replica , collodion replica , Formvar replica , gelatin replica , impression replica , negative replica , oxide film replica , plastic replica , positive replica , preshadowed replica , tape replica method (faxfilm) , and vapor-deposited replica .
- **residual stress**
  - (1) The stress existing in a body at rest, in equilibrium, at uniform temperature, and not subjected to external forces. Often caused by the forming or thermal processing curing process. (2) An internal stress not depending on external forces resulting from such factors as cold working, phase changes, or temperature gradients. (3) Stress present in a body that is free of external forces or thermal gradients. (4) Stress remaining in a structure or member as a result of thermal or mechanical treatment or both. Stress arises in fusion welding primarily because the weld metal contracts on cooling from the solidus to room temperature.
- **resinoid wheel**
  - A grinding wheel bonded with a synthetic resin.
- **resist**
  - (1) Coating material used to mask or protect selected areas of a substrate from the action of an etchant , solder, or plating . (2) A material applied to a part of a cathode or plating rack to render the surface nonconductive.
- **reverse cleaning**
  - Same as anodic cleaning .
- **rinsability**
  - The relative ease with which a substance can be removed from a metal surface with a liquid such as water.
- **ripple (dc)**
  - Regular modulations in the dc output wave of a rectifier unit, or a motor-generator set, originating from the harmonics of the ac input system in the case of a rectifier, or from the harmonics of the induced voltage of a motor-generator set.
- **ripple formation**
  - Formation of periodic ridges and valleys transverse to the direction of motion on a solid surface. Also referred to as rippling.
- **robber**
  - An extra cathode or cathode extension that reduces the current density on what would otherwise be a high-current-density area on work being electroplated.
- **Rochelle copper**
  - (1) A copper electrodeposit obtained from copper cyanide plating solution to which Rochelle salt (sodium potassium tartrate) has been added for grain refinement , better anode corrosion, and cathode efficiency. (2) The solution from which a Rochelle copper electrodeposit is obtained.
- **rolling-contact wear**
  - Wear to a solid surface that results from rolling contact between that surface and another solid surface or surfaces.
- **rollover burr**
  - Burr formed by a cutter when it exits over a surface and allows the chip to be rolled away from the cutter, rather than sheared.
- **root mean square (rms)**
  - A term describing the surface roughness of a machined surface, R_q, calculated as the square root of the average of the squared distance of the surface from the mean line. See also surface roughness .
- **rosette graphite**
  - Arrangement of graphite flakes in which the flakes extend radially from the center of crystallized areas in gray cast iron.

- **rotary roughening**
    - A method of surface roughening prior to thermal spraying wherein a revolving roughening tool is pressed against the surface being prepared, while either the work, or the tool, or both, move.
- **rouge finish**
    - A highly reflective finish produced with rouge (finely divided, hydrated iron oxide) or other very fine abrasive, similar in appearance to the bright polish or mirror finish on sterling silver utensils.
- **rough grinding**
    - Grinding where surface generation occurs at a rapid rate, and tolerances or surface features are less critical compared to the production rate. Usually followed by a subsequent operation.
- **roughness**
    - (1) Relatively finely spaced surface irregularities, the heights, widths, and directions of which establish the predominant surface pattern. (2) The microscopic peak-to-valley distances of surface protuberances and depressions. See also surface roughness .
- **rough-polishing process**
    - A polishing process having the primary objective of removing the layer of significant damage produced during earlier machining and abrasion stages of a metallographic preparation sequence. A secondary objective is to produce a finish of such quality that a final polish can be produced easily. See also final polishing .
- **running-in**
    - The process by which machine parts improve in conformity, surface topography, and frictional compatibility during the initial stage of use. Chemical processes, including formation of an oxide skin, and metallurgical processes, such as strain hardening, may contribute.
- **rust**
    - A visible corrosion product consisting of hydrated oxides of iron. Applicable only to ferrous alloys. See also white rust .
- **S**
- **sacrificial protection**
    - The form of corrosion protection wherein one metal corrodes in preference to another, thereby protecting the latter from corrosion.
- **sagging**
    - (1) A defect characterized by a wavy line or lines appearing on those surfaces of porcelain enamel that have been fired in a vertical position. (2) A defect characterized by irreversible downward bending in a porcelain enamel article insufficiently supported during the firing cycle.
- **salt bath**
    - A molten, usually anhydrous inorganic solution used for heat treating or surface diffusion treatments wherein nitrogen, carbon, or other elements are diffused into the work. Specialized compositions are used for removal of scale , refractory materials, and organic materials from work surfaces.
- **sandblasting**
    - Abrasive blasting with sand. See also blasting or blast cleaning and compare with shotblasting .
- **sanitary ware**
    - Porcelain enamel ware such as sinks, lavatories, and bathtubs.
- **saponification**
    - The conversion of insoluble fats and fatty acids to water-soluble soaps by alkalies. The cleaning of buffing compounds from metallic surfaces can be achieved by saponification.
- **satin finish**
    - A diffusely reflecting surface finish on metals, lustrous but not mirrorlike. One type is a butler finish .
- **scab**
    - A defect on the surface of a casting that appears as a rough, slightly raised surface blemish, crusted over by a thin porous layer of metal, under which is a honeycomb or cavity that usually contains a layer of sand; defect common to thin-wall portions of the casting or around hot areas of the mold.
- **scale**
    - Surface oxidation, consisting of partially adherent layers of corrosion products, left on metals by heating or casting in air or in other oxidizing atmospheres.
- **scaling**

    - (1) Forming a thick layer of oxidation products on metals at high temperature. Scaling should be distinguished from rusting, which involves the formation of hydrated oxides. See also rust . (2) Depositing water-insoluble constituents on a metal surface, as in cooling tubes and water boilers.
- **scanning Auger microscopy (SAM)**
    - An analytical technique that measures the lateral distribution of elements on the surface of a material by recording the intensity of their Auger electrons versus the position of the electron beam.
- **scanning electron microscopy (SEM)**
    - An analytical technique in which an image is formed on a cathode-ray tube whose raster is synchronized with the raster of a point beam of electrons scanned over an area of the sample surface. The brightness of the image at any point is proportional to the scattering by or secondary emissions from the point on the sample being struck by the electron beam.
- **scanning laser acoustic microscopy (SLAM)**
    - A high-resolution, high-frequency (10 to 500 MHz) ultrasonic inspection technique that produces images of features in a sample throughout its entire thickness. In operation, ultrasound is introduced to the bottom surface of the sample by a piezoelectric transducer, and the transmitted wave is detected on the top side by a rapidly scanning laser beam.
- **scanning transmission electron microscopy (STEM)**
    - An analytical technique in which an image is formed on a cathode-ray tube whose raster is synchronized with the raster of a point beam of electrons scanned over an area of the sample. The brightness of the image at any point is proportional to the number of electrons that are transmitted through the sample at the point where it is struck by the beam.
- **scoring**
    - (1) The formation of severe scratches in the direction of sliding. Scoring may be due to local solid-phase welding or to abrasion. In the United States, the term scuffing is sometimes used as a synonym for scoring. Minor damage should be called scratching rather than scoring. (2) In tribology, a severe form of wear characterized by the formation of extensive grooves and scratches in the direction of sliding. (3) The act of producing a scratch or narrow groove in a surface by causing a sharp instrument to move along that surface. (4) The marring or scratching of any formed metal part by metal pickup on the punch or die. (5) The reduction in thickness of a material along a line to weaken it intentionally along that line.
- **scouring**
    - (1) A wet or dry cleaning process involving mechanical scrubbing. (2) A wet or dry mechanical finishing operation, using fine abrasive and low pressure, carried out by hand or with a cloth or wire wheel to produce satin or butler -type finishes.
- **scratch**
    - A groove produced in a solid surface by the cutting and/or plowing action of a sharp particle or protuberance moving along that surface.
- **scratch brush finish**
    - A finish on nonferrous metals produced by buffing that shows a combination of coarse lines with a slight underlying luster.
- **scratch-resistant coatings**
    - Coating applied to glass surfaces to reduce the effects of frictive damage. Examples are SnO_2 or TiO_2 coatings applied to glass containers.
- **screen test**
    - A standard test for fineness of porcelain enamel slip or powder.
- **scuffing**
    - Same as scoring .
- **scumming**
    - A defect characterized by areas of poor gloss on the surface of a porcelain enamel that can be caused by uneven heat distribution in the furnace, overfiring, or underfiring.
- **sealed (anodic) coating**
    - In anodizing aluminum, an anodic oxide coating on aluminum that has been treated in aqueous or steam medium resulting in reduced porosity of the coating.
- **sealing of anodic coating**
    - A process which, by absorption, chemical reaction, or other mechanism, increases the resistance of an anodic coating to staining and corrosion , improves the durability of colors produced in the coating, or imparts other desirable properties.

- **seam**
  - (1) On a metal surface, an unwelded fold or lap that appears as a crack, usually resulting from a discontinuity. (2) A surface defect on a casting related to but of lesser degree than a cold shut . (3) A ridge on the surface of a casting caused by a crack in the mold face.
- **secondary gas**
  - In thermal spraying, the gas constituting the minor constituent of the arc gas fed to the gun to produce the plasma. The primary arc gas, usually argon or nitrogen, is supplemented with secondary gases such as nitrogen, helium, and/or hydrogen, in order to increase the temperature of the plasma.
- **secondary ion mass spectroscopy (SIMS)**
  - An analytical technique that measures the masses of ions emitted from the surface of a material when exposed to a beam of incident ions. The incident ions are usually monoenergetic and are all of the same species, for example, 5-keV Ne^+ ions.
- **sectioning**
  - The removal of a conveniently sized, representative specimen from a larger sample for metallographic inspection. Sectioning methods include shearing, sawing (using hacksaws, band saws, and diamond wire saws), abrasive cutting, and electrical discharge machining.
- **segregation (coring) etching**
  - Development of segregation (coring) mainly in macrostructures and microstructures of castings.
- **seizing**
  - The stopping of a moving part by a mating surface as a result of excessive friction.
- **selective leaching**
  - Corrosion in which one element is preferentially removed from an alloy, leaving a residue (often porous) of the elements that are more resistant to the particular environment. Also called dealloying or parting. See also decarburization , decobaltification , denickelification , dezincification , and graphitic corrosion .
- **selective plating**
  - Same as brush plating .
- **self-fluxing alloys**
  - In thermal spraying, certain materials that "wet" the substrate and coalesce when heated to their melting point, without the addition of a fluxing agent.
- **self-limiting characteristic**
  - Characteristic of electrostatic powders to build only a limited amount of surface film during application due to the buildup of a layer of charged particles that will repel particles of like charge. See also back emission .
- **sensitization**
  - (1) The absorption of a reducing agent, often a stannous compound, on the surface of a plastic substrate . (2) The effect caused by a sensitizing heat treatment .
- **sensitizing heat treatment**
  - A heat treatment, whether accidental, intentional, or incidental (as during welding), that causes precipitation of constituents at grain boundaries , often causing the alloy to become susceptible to intergranular corrosion or intergranular stress-corrosion cracking .
- **sequestration and chelation**
  - To inactivate calcium, magnesium, and iron salts in water so that they will not interfere with cleaning. Chelated alkaline compounds can remove oxides and rust from steel surfaces, eliminating the need for acids that may react with the metal to cause hydrogen embrittlement.
- **serial sectioning**
  - A metallographic technique in which an identified area on a section surface is observed repeatedly after successive layers of known thickness have been removed from the surface. It is used to construct a three-dimensional morphology of structural features. See also sectioning .
- **set**
  - A flow property of porcelain enamel slip affecting the rate of draining, residual thickness, and uniformity of coating.
- **setting-up agent**
  - An electrolyte used to increase the measured pickup of a slip . Also known as set-up agent.
- **severe wear**
  - A form of wear characterized by removal of material in relatively large fragments. Severe wear is an imprecise term, frequently used in research, and contrasted with mild wear. In fact, the

phenomena studied usually involve the transition from mild to severe wear and the factors that influence that transition. With metals, the fragments are usually predominantly metallic rather than oxidic. Severe wear is frequently associated with heavy loads and/or adhesive contact. See also mild wear and normal wear .

- **shadow angle**
  - In shadowing of replicas, the angle between the line of motion of the evaporated atoms and the surface being shadowed. See also replica and shadowing .
- **shadow cast replica**
  - A replica that has been shadowed. See also replica and shadowing .
- **shadowing**
  - Directional deposition of carbon or a metallic film on a plastic replica so as to highlight features to be analyzed by transmission electron microscopy . Most often used to provide maximum detail and resolution of the features of fracture surfaces. See also metal shadowing , oblique evaporation shadowing , and shadow angle .
- **shadow mask**
  - A thermal spraying process variation in which an area is partially shielded during the thermal spraying operation, thus permitting some overspray to produce a feathering at the coating edge.
- **shales**
  - Abrasive particles of platelike shape. The term is applied particularly to diamond abrasives.
- **shaving**
  - (1) As a finishing operation, the accurate removal of a thin layer of a work surface by straightline motion between a cutter and the surface. (2) Trimming parts such as stampings, forgings, and tubes to remove uneven sheared edges or to improve accuracy.
- **sheet**
  - A flat-rolled metal product of some maximum thickness and minimum width arbitrarily dependent on the type of metal. It has a width-to-thickness ratio greater than about 50. Generally, such flat products under 6.5 mm (in.) thick are called sheets, and those 6.5 mm (in.) thick and over are called plates. Occasionally, the limiting thickness for steel to be designated as sheet steel is No. 10 Manufacturer's Standard Gage for sheet steel, which is 3.42 mm (0.1345 in.) thick.
- **shelf roughness**
  - Roughness on upward-facing surfaces where undissolved solids have settled on parts during a plating operation.
- **shelling**
  - (1) A term used in railway engineering to describe an advanced phase of spalling . (2) A mechanism of deterioration of coated abrasive products in which entire abrasive grains are removed from the cement coating that held the abrasive to the backing layer of the product.
- **shielding**
  - (1) A material barrier that prevents radiation or a flowing fluid from impinging on an object or a portion of an object. (2) In an electron-optical instrument, the protection of the electron beam from distortion due to extraneous electric and magnetic fields. Because the metallic column of the microscope is at ground potential, it provides electrostatic shielding. (3) Placing an object in an electrolytic bath so as to alter the current distribution on the cathode . A nonconductor is called a shield; a conductor is called a robber , a thief, or a guard.
- **short-term etching**
  - In metallographic preparation of specimens, etching times of seconds to a few minutes.
- **shot**
  - (1) Small, spherical particles of metal. (2) The injection of molten metal into a die casting die. The metal is injected so quickly that it can be compared to the shooting of a gun.
- **shotblasting**
  - Blasting with metal shot ; usually used to remove deposits or mill scale more rapidly or more effectively than can be done by sandblasting .
- **shot peening**
  - A method of cold working metals in which compressive stresses are induced in the exposed surface layers of parts by the impingement of a stream of shot , directed at the metal surface at high velocity under controlled conditions. It differs from blast cleaning in primary purpose and in the extent to which it is controlled to yield accurate and reproducible results. Although shot

peening cleans the surface being peened, this function is incidental. The major purpose of shot peening is to increase fatigue strength. Shot for peening usually is made of iron, steel, or glass.

- **shrinkage cavity**
    - A void left in cast metal as a result of solidification shrinkage. Shrinkage cavities can appear as either isolated or interconnected irregularly shaped voids.
- **sieve analysis**
    - A method of determining particle size distribution, usually expressed as the weight percentage retained upon each of a series of standard screens of decreasing mesh size.
- **sigma-phase embrittlement**
    - Embrittlement of iron-chromium alloys (most notably austenitic stainless steels) caused by precipitation at grain boundaries of the hard, brittle intermetallic sigma phase during long periods of exposure to temperatures between approximately 560 and 980 °C (1050 and 1800 °F). Sigma-phase embrittlement results in severe loss in toughness and ductility, and can make the embrittled material susceptible to intergranular corrosion .
- **siliconizing**
    - Diffusing silicon into solid metal, usually low-carbon steels, at an elevated temperature in order to improve corrosion or wear resistance.
- **size**
    - In composites manufacturing, a treatment consisting of starch, gelatin, oil, wax, or other suitable ingredients applied to yarn or fibers at the time of formation to protect the surface and aid the process of handling and fabrication or to control the fiber characteristics. The treatment contains ingredients that provide surface lubricity and binding action, but unlike a finish, contains no coupling agent. Before final fabrication into a composite, the size is usually removed by heat cleaning, and a finish is applied.
- **skid-polishing process**
    - A mechanical polishing process in which the surface of the metallographic specimen to be polished is made to skid across a layer of paste, consisting of the abrasive and the polishing fluid, without contacting the fibers of the polishing cloth.
- **skin**
    - A thin outside metal layer, not formed by bonding as in cladding or electroplating, that differs in composition, structure, or other characteristics from the main mass of metal.
- **skin lamination**
    - In flat-rolled metals, a surface rupture resulting from the exposure of a subsurface lamination by rolling.
- **skinning**
    - The formation of a thin, tough film on the surface of a liquid paint film, usually due to reaction with the air or to rapid solvent loss.
- **slab**
    - A flat-shaped semifinished rolled metal ingot with a width not less than 250 mm (10 in.) and a cross-sectional area not less than 105 cm^2 (16 $in.^2$).
- **slip**
    - A suspension of finely divided ceramic material in liquid.
- **sliver**
    - An imperfection consisting of a very thin elongated piece of metal attached by only one end to the parent metal into whose surface it has been worked.
- **sludge**
    - An accumulation of insoluble materials and reaction products that collects in cleaning and processing tanks.
- **slump test**
    - A test used to determine the consistency of slip in which measurement is made of the spreading of a specified volume of slip over a flat plate.
- **slurry**
    - A suspension of solids in water.
- **slurry erosion**
    - Erosion produced by the movement of a slurry past a solid surface.
- **smearing**
    - Mechanical removal of material from a surface, usually involving plastic shear deformation, and redeposition of the material as a thin layer on one or both surfaces. See also transfer .

- **smelt**
  - A batch or lot of frit .
- **smut**
  - A reaction product sometimes left on the surface of a metal after pickling , electroplating, or etching .
- **soak cleaning**
  - Immersion cleaning without the use of current, usually in alkaline solution.
- **soil**
  - Undesirable material on a surface that is not an integral part of the surface. Oil, grease, and dirt can be soils; a decarburized skin and excess hard chromium are not soils. Loose scale is soil; hard scale may be an integral part of the surface and, hence, not soil.
- **solid lubricant**
  - Any solid used as a powder or thin film on a surface to provide protection from damage during relative movement and to reduce friction and wear. Examples include molybdenum disulfide, graphite, polytetra-fluoroethylene (PTFE), and mica.
- **soluble oil**
  - A mineral oil containing additives that enable it to form a stable emulsion with water. Soluble oils are used as cutting or grinding fluids.
- **solvency**
  - The property of removal of soils by dissolving in a cleaning solution. For example, oils and fats are soluble in some solvents.
- **solvent**
  - A usually liquid substance capable of dissolving or dispersing other substances. See chlorinated solvent .
- **solvent cleaning**
  - Cleaning by means of organic solvents.
- **sour gas**
  - A gaseous environment containing hydrogen sulfide and carbon dioxide in hydrocarbon reservoirs. Prolonged exposure to sour gas can lead to hydrogen damage , sulfide-stress cracking , and/or stress-corrosion cracking in ferrous alloys.
- **spalling**
  - (1) Separation of particles from a surface in the form of flakes. The term spalling is commonly associated with rolling-element bearings and with gear teeth. Spalling is usually a result of subsurface fatigue and is more extensive than pitting. (2) In tribology, the separation of macroscopic particles from a surface in the form of flakes or chips, usually associated with rolling-element bearings and gear teeth, but also resulting from impact events. (3) The spontaneous chipping, fragmentation, or separation of a surface or surface coating. (4) A chipping or flaking of a surface due to any kind of improper heat treatment or material dissociation.
- **spangle**
  - The characteristic crystalline form in which a hot dipped zinc coating solidifies on steel strip.
- **specking**
  - Discoloration of an enamel surface due to foreign particles, dirt, or scale embedding themselves in the enamel. May also be caused by base coat migration up through the cover coat in two coat/one fire powder systems. Also known as black specking.
- **spotting out**
  - The delayed appearance of spots and blemishes on plated or finished surfaces that is most prevalent on porous base metals or substrates .
- **spray angle**
  - In thermal spraying, the angle of particle approach, measured from the surface of the substrate to the axis of the spray nozzle.
- **spray cleaning**
  - Cleaning by means of spraying.
- **spray deposit**
  - A coating applied by any of the thermal spray methods. See also thermal spraying .
- **sputter deposition**
  - Same as sputtering .
- **sputtering**

  - The bombardment of a solid surface with a flux of energetic particles (ions) that results in the ejection of atomic species. The ejected material may be used as a source for deposition. See also physical vapor deposition .
- **stabilizing gas**
  - In plasma spraying, the arc gas, which is ionized to form the plasma. Introduced into the arc chamber tangentially, the relatively cold gas chills the outer surface of the arc stream, tending to constrict the arc, raise its temperature, and force it out of the front anode nozzle in a steady, relatively unfluctuating stream.
- **stain**
  - On an enameled surface, an iridescent spot caused by the action of fruit juice or chemicals.
- **staining**
  - Precipitation etching that causes contrast by distinctive staining of microconstituents; different interference colors originate from surface layers of varying thickness. Also known as color etching.
- **standard electrode potential**
  - An equilibrium electrode potential for an electrode in contact with an electrolyte in which all of the components of a specified chemical reaction are in their standard states. The standard for state for an ionic constituent is unit ion activity.
- **stardusting**
  - An extremely fine form of roughness on the surface of a metal deposit.
- **star marks**
  - A defect that sometimes occurs in sheet steel or iron porcelain enamel cover coats where the dried ware is set down too hard on the firing fixture points and the enamel coating is fractured.
- **stars**
  - In porcelain enamel , a defect in the fired surface that appears as a series of small hairlines radiating from a common center. Similar to star marks . Typical of porcelain enamel powder systems.
- **starting sheet**
  - A thin sheet of metal used as the cathode in electrolyte refining.
- **static coefficient of friction**
  - The coefficient of friction corresponding to the maximum friction force that must be overcome to initiate macroscopic motion between two bodies.
- **static electrode potential**
  - The electrode potential measured when no net current is flowing between the electrode and the electrolyte .
- **steadite**
  - A hard structural constituent of cast iron that consists of a binary eutectic of ferrite , containing some phosphorus in solution, and iron phosphide (Fe_3P). The eutectic consists of 10.2% P and 89.8% Fe. The melting temperature is 1050 °C (1920 °F).
- **stereophotogrammetry**
  - A method of generating topographic maps of fracture surfaces by the use of a stereoscopic microscope interfaced to a microcomputer that calculates the three-dimensional coordinates of the fracture surface and produces the corresponding profile map, contour plot, or carpet plot.
- **stippled finish**
  - A pebbly textured porcelain enamel , often multicolored.
- **stopping off**
  - (1) The application of a resist to any part of an electrode: cathode , anode , or plating rack . (2) Depositing a metal (copper, for example) in localized areas to prevent carburization, decarburization , or nitriding in those areas.
- **strain etching**
  - Metallographic etching that provides information on deformed and undeformed areas if present side by side. In strained areas, more compounds are precipitated.
- **stray current**
  - Current through paths other than the intended circuit, such as through heating coils or the tank.
- **stray-current corrosion**
  - Corrosion resulting from direct current flow through paths other than the intended circuit. For example, by an extraneous current in the earth.
- **stress-corrosion cracking (SCC)**

  - A cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. This excludes corrosion-reduced sections that fail by fast fracture. It also excludes intercrystalline or transcrystalline corrosion, which can disintegrate an alloy without applied or residual stress. Stress-corrosion cracking may occur in combination with hydrogen embrittlement .
- **stress relieving**
  - Heating to a suitable temperature, holding long enough to reduce residual stresses, and then cooling slowly enough to minimize the development of new residual stresses.
- **stretcher strains**
  - Elongated markings that appear on the surface of some sheet materials when deformed just past the yield point. These markings lie approximately parallel to the direction of maximum shear stress and are the result of localized yielding. See also Lüders lines .
- **strike**
  - (1) A thin electrodeposited film of metal to be overlaid with other plated coatings. (2) A plating solution of high covering power and low efficiency designed to electroplate a thin, adherent film of metal.
- **striking**
  - Electrodepositing, under special conditions, a very thin film of metal that will facilitate further plating with another metal or with the same metal under different conditions.
- **stringer**
  - In wrought materials, an elongated configuration of microconstituents or foreign material aligned in the direction of working. The term is commonly associated with elongated oxide or sulfide inclusions in steel.
- **strip**
  - (1) A process or solution used for the removal of a coating from a base metal or an undercoat . (2) To remove a coating from the base metal or undercoat.
- **submicron powder**
  - Any powder whose particles are smaller than 1 μm.
- **substrate**
  - (1) The material, workpiece, or substance on which a coating is deposited. (2) A material upon the surface of which an adhesive-containing substance is spread for any purpose, such as bonding or coating. A broader term than adherend . (3) In electronic devices, a body, board, or layer of material on which some other active or useful material(s) or component(s) may be deposited or laid; for example, electronic circuitry laid on an alumina ceramic board. (4) In catalysts , the formed, porous, high-surface area carrier on which the catalytic agent is widely and thinly distributed for reasons of performance and economy.
- **substrate temperature**
  - In thermal spraying, the temperature attained by the base material as the coating is applied. Proper control of the substrate temperature by intermittent spraying or by the application of external cooling will minimize stresses caused by substrate and coating thermal expansion differences.
- **subsurface corrosion**
  - Formation of isolated particles of corrosion products beneath a metal surface. This results from the preferential reactions of certain alloy constituents to inward diffusion of oxygen, nitrogen, or sulfur.
- **sulfidation**
  - The reaction of a metal or alloy with a sulfur-containing species to produce a sulfur compound that forms on or beneath the surface of the metal or alloy.
- **sulfide stress cracking (SSC)**
  - Brittle fracture by cracking under the combined action of tensile stress and corrosion in the presence of water and hydrogen sulfide. See also environmental cracking .
- **sulfochlorinated lubricant**
  - A lubricant containing chlorine and sulfur compounds, which react with a rubbing surface at elevated temperatures to form a protective film. There may be a synergistic effect, producing a faster reaction than with sulfur or chlorine additives alone.
- **sulfurized lubricant**
  - A lubricant containing sulfur or a sulfur compound that reacts with a rubbing surface at elevated temperatures to form a protective film. The shear strength of the sulfide film formed on ferrous

materials is lower than that of the metal but greater than that of the film formed by reaction with a chlorinated lubricant .

- **superabrasives**
    - Exceptionally hard and abrasion-resistant synthetic materials used for a wide variety of abrasive or cutting applications. Synthetic diamond and cubic boron nitride (CBN) are the two superabrasives used for grinding applications. Diamond is the hardest material known, and CBN is the second hardest.
- **superfines**
    - The portion of a metal powder that is composed of particles smaller than a specified size, usually 10 m.
- **superfinishing**
    - An abrasive process utilizing either a curved bonded honing stick (stone) for a cylindrical workpiece or a cup wheel for flat and spherical work. A large contact area, 30% approximately, exists between workpiece and abrasive. The object of superfinishing is to remove surface fragmentation and to correct inequalities in geometry, such as grinding feed marks and chatter marks. Also known as microhoning. See also honing .
- **surface active agent**
    - A substance that affects markedly the interfacial or surface tension of solutions even when present in very low concentrations.
- **surface alterations**
    - Irregularities or changes on the surface of a material due to machining or grinding operations. The types of surface alterations associated with metal removal practices include mechanical (for example, plastic deformation , hardness variations, cracks, etc.), metallurgical (for example, phase transformations, twinning, recrystallization , and untempered or overtempered martensite), chemical (for example, intergranular attack, embrittlement , and pitting), thermal (heat-affected zone, recast, or redeposited metal, and resolidified material), and electrical surface alterations (conductivity change or resistive heating).
- **surface damage**
    - In tribology, damage to a solid surface resulting from mechanical contact with another substance, surface, or surfaces moving relatively to it and involving the displacement or removal of material. In certain contexts, wear is a form of surface damage in which material is progressively removed. In another context, surface damage involves a deterioration of function of a solid surface even though there is no material loss from that surface. Surface damage may therefore precede wear.
- **surface finish**
    - (1) The geometric irregularities in the surface of a solid material. Measurement of surface finish shall not include inherent structural irregularities unless these are the characteristics being measured. (2) Condition of a surface as a result of a final treatment. See also roughness .
- **surface grinding**
    - Producing a flat surface with a rotating grinding wheel as the workpiece passes under.
- **surface hardening**
    - A generic term covering several processes applicable to a suitable ferrous alloy that produces a surface layer that is harder or more wear resistant than the core. The processes commonly used are carbonitriding , carburizing , induction hardening , flame hardening , nitriding , and nitrocarburizing . Use of the applicable specific process name is preferred.
- **surface integrity**
    - A technology that involves the specification and manufacture of unimpaired or enhanced surfaces through the control of the many possible alterations produced in a surface layer during manufacture. Surface integrity is achieved by the proper selection and control of manufacturing processes and the ability to estimate their effects on the significant engineering properties of work materials. See also surface alterations .
- **surface modification**
    - The alteration of surface composition or structure by the use of energy or particle beams. Elements may be added to influence the surface characteristics of the substrate by the formation of alloys, metastable alloys or phases, or amorphous layers. Surface-modified layers are distinguished from conversion or coating layers by their greater similarity to metallurgical alloying versus chemically reacted, adhered, or physically bonded layers. However, surface structures are produced that differ significantly from those obtained by conventional

metallurgical processes. This latter characteristic further distinguishes surface modification from other conventional processes, such as amalgamation or thermal diffusion. Two types of surface modification methods commonly employed are ion implantation and laser surface processing .

- **surface roughness**
  - Fine irregularities in the surface texture of a material, usually including those resulting from the inherent action of the production process. Surface roughness is usually reported as the arithmetic roughness average, R_a, and is given in micrometers or microinches.
- **surface tension**
  - That property, due to molecular forces, that exists in the surface film of all liquids and tends to prevent the liquid from spreading.
- **surface texture**
  - The roughness, waviness , lay , and flaws associated with a surface.
- **surface void**
  - A void which is located at the surface of a material and is a consequence of processing, that is, a surface reaction layer, as distinguished from a volume distributed flaw such as a pore or inclusion .
- **surfacing**
  - The deposition of filler metal (material) on a base metal (substrate) to obtain desired properties or dimensions. See also buttering , cladding , coating , and hardfacing .
- **surfactant**
  - (1) A chemical substance characterized by a strong tendency to form adsorbed interfacial films when in solution, emulsion, or suspension, thus producing effects such as low surface tension, penetration, boundary lubrication, wetting , and dispersing. (2) A compound that affects interfacial tensions between two liquids. It usually reduces surface tension. See also Rehbinder effect .
- **synthetic cold rolled sheet**
  - A hot rolled pickled sheet given a sufficient final temper pass to impart a surface approximating that of cold rolled steel.
- **T**
- **tape replica method (faxfilm)**
  - A method of producing a replica by pressing the softened surface of tape or plastic sheet material onto the surface to be replicated.
- **taper section**
  - A section cut obliquely (acute angle) through a surface and prepared metallographically. The angle is often chosen to increase the vertical magnification of surface features by a factor of 5 or 10. Taper sectioning is usually carried out for microstructural examination of coated metal specimens.
- **tarnish**
  - (1) The dulling, staining , or discoloration of metals due to superficial corrosion . (2) The film so formed.
- **tear burr**
  - Burr formed by the sides of a cutter as the cutter tears a chip from the workpiece. Also a ragged form of the Poisson burr caused by a built-up edge on the cutting tool.
- **tearing**
  - A defect in the surface of porcelain enamel characterized by short breaks or cracks that have been healed.
- **temper**
  - (1) In heat treatment, reheating hardened steel or hardened cast iron to some temperature below the eutectoid temperature for the purpose of decreasing hardness and increasing toughness. The process also is sometimes applied to normalized steel. (2) In tool steels, temper is sometimes used, but inadvisedly, to denote the carbon content. (3) In nonferrous alloys and in some ferrous alloys (steels that cannot be hardened by heat treatment), the hardness and strength produced by mechanical or thermal treatment, or both, and characterized by a certain structure, mechanical properties, or reduction in area during cold working.
- **temper color**
  - A thin, tightly adhering oxide skin (only a few molecules thick) that forms when steel is tempered at a low temperature, or for a short time, in air or a mildly oxidizing atmosphere. The color,

which ranges from straw to blue depending on the thickness of the oxide skin, varies with both tempering time and temperature.

- **tempered layer**
  - A surface or subsurface layer in a steel specimen that has been tempered by heating during some stage of the metallographic preparation sequence (usually grinding) . When observed in a section after etching , the layer appears darker than the base material.
- **tempered martensite**
  - The decomposition products that result from heating martensite below the ferrite-austenite transformation temperature. Under the optical microscope, darkening of the martensite needles is observed in the initial stages of tempering. Prolonged tempering at high temperatures produces spheroidized carbides in a matrix of ferrite . At the higher resolution of the electron microscope, the initial stage of tempering is observed to result in a structure containing a precipitate of fine iron carbide particles. At approximately 260 °C (500 °F), a transition occurs to a structure of larger and elongated cementite particles in a ferrite matrix. With further tempering at higher temperatures, the cementite particles become spheroidal, decrease in number, and increase in size.
- **tempered martensite embrittlement**
  - Embrittlement of high-strength alloy steels caused by tempering in the temperature range of 205 to 370 °C (400 to 700 °F); also called 350 °C or 500 °F embrittlement. Tempered martensite embrittlement is thought to result from the combined effects of cementite precipitation on prior-austenite grain boundaries or interlath boundaries and the segregation of impurities at prior-austenite grain boundaries. It differs from temper embrittlement in the strength of the material and the temperature exposure range. In temper embrittlement, the steel is usually tempered at a relatively high temperature, producing lower strength and hardness, and embrittlement occurs upon slow cooling after tempering and during service at temperatures within the embrittlement range. In tempered martensite embrittlement, the steel is tempered within the embrittlement range, and service exposure is usually at room temperature.
- **temper embrittlement**
  - Embrittlement of low-alloy steels caused by holding within or cooling slowly through a temperature range (generally 300 to 600 °C, or 570 to 1110 °F) just below the transformation range. Embrittlement is the result of the segregation at grain boundaries of impurities such as arsenic, antimony, phosphorus, and tin; it is usually manifested as an upward shift in ductile-to-brittle transition temperature. Temper embrittlement can be reversed by retempering above the critical temperature range, then cooling rapidly. Compare with tempered martensite embrittlement .
- **tempering**
  - In heat treatment, reheating hardened steel to some temperature below the eutectoid temperature to decrease hardness and/or increase toughness.
- **temper rolling**
  - Light cold rolling of sheet steel to improve flatness, to minimize the formation of stretcher strains , and to obtain a specified hardness or temper.
- **tensile burr**
  - The burr produced in blanking or piercing operations in which the slug separates from the stock as a result of tensile stresses.
- **tensile-plus-compressive burr**
  - The burr produced in blanking or piercing operations in which the slug separates from the stock in a stress field that is initially tensile, but changes to compressive at actual separation. This burr is usually associated with small die clearances and short die life.
- **terne**
  - An alloy of lead containing 3 to 15% Sn, used as a hot dip coating for steel sheet or plate. The term long terne is used to describe terne-coated sheet, whereas short terne is used for terne-coated plate. Terne coatings, which are smooth and dull in appearance (terne means dull or tarnished in French), give the steel better corrosion resistance and enhance its ability to be formed, soldered, or painted.
- **thermal embrittlement**
  - Intergranular fracture of maraging steels with decreased toughness resulting from improper processing after hot working. Thermal embrittlement occurs upon heating above 1095 °C (2000 °F) and then slow cooling through the temperature range of 980 to 815 °C (1800 to 1500 °F), and

has been attributed to precipitation of titanium carbides and titanium carbonitrides at austenite grain boundaries during cooling through the critical temperature range.

- **thermal etching**
    - Heating a specimen (usually a ceramic) in air, vacuum, or inert gases in order to delineate the grain structure. Used primarily in high-temperature microscopy.
- **thermal fatigue**
    - Fracture resulting from the presence of temperature gradients that vary with time in such a manner as to produce cyclic stresses in a structure. See also craze cracking .
- **thermal spraying**
    - A group of coating or welding processes in which finely divided metallic or nonmetallic materials are deposited in a molten or semimolten condition to form a coating. The coating material may be in the form of powder, ceramic rod, wire, or molten materials. See also electric arc spraying , flame spraying , plasma spraying , and powder flame spraying .
- **thermal spray powder**
    - A metal, carbide, or ceramic powder mixture designed for use with hardfacing and thermal spraying operations.
- **thermal wear**
    - Removal of material due to softening, melting, or evaporation during sliding or rolling. Thermal shock and high-temperature erosion may be included in the general description of thermal wear. Wear by diffusion of separate atoms from one body to the other, at high temperatures, is also sometimes denoted as thermal wear.
- **thermogalvanic corrosion**
    - Corrosion resulting from an electrochemical cell caused by a thermal gradient.
- **thermomechanical working**
    - A general term covering a variety of metal forming processes combining controlled thermal and deformation treatments to obtain synergistic effects, such as improvement in strength without loss of toughness. Same as thermal-mechanical treatment.
- **thermoplastic**
    - A type of polymer that softens and melts when heated and then resolidifies upon cooling. Thermoplastics generally have linear or branched structures.
- **thermoreactive deposition/diffusion process (TRD)**
    - A method of coating steels with a hard, wear-resistant layer of carbides, nitrides, or carbonitrides. In the TRD process, the carbon and nitrogen in the steel substrate diffuse into a deposited layer with a carbide-forming or nitride-forming element such as vanadium, niobium, tantalum, chromium, molybdenum, or tungsten. The diffused carbon or nitrogen reacts with the carbide- and nitride-forming elements in the deposited coating so as to form a dense and metallurgically bonded carbide or nitride coating at the substrate surface.
- **thermosetting**
    - A type of polymer that does not soften appreciably when heated. Thermosets may char when heated in air. They are generally cross-linked polymers.
- **thick-film circuit**
    - A circuit that is fabricated by the deposition of materials having between 5 and 20 μm (0.2 and 0.8 mil) thickness, such as screen-printed cermet pastes on a ceramic substrate, which are fired in a kiln to create permanent conductive patterns. Compare with thin-film circuit .
- **thick-film lubrication**
    - A condition of lubrication in which the film thickness of the lubricant is appreciably greater than that required to cover the surface asperities when subjected to the operating load, so that the effect of the surface asperities is not noticeable. Also known as full-film lubrication. See also thin-film lubrication .
- **thief**
    - A racking device or nonfunctional pattern area used in the electroplating process to provide a more uniform current density on plated parts. Thieves absorb the unevenly distributed current on irregularly shaped parts, thereby ensuring that the parts will receive an electroplated coating of uniform thickness.
- **thin-film circuit**
    - A circuit fabricated by the deposition of material several thousand angstroms thick (such as a circuit fabricated by vapor deposition). Compare with thick-film circuit .
- **thin-film lubrication**

  - A condition of lubrication in which the film thickness of the lubricant is such that the friction and wear between the surfaces is determined by the properties of the surfaces as well as the viscosity of the lubricant. Under thin-film conditions, the coefficient of friction is often 10 to 100 times greater than under thick-film conditions and wear is no longer negligible. Compare with thick-film lubrication .
- **thread grinding**
  - Thread cutting by use of suitably formed grinding wheel.
- **threading and knurling**
  - A method of surface roughening in which spiral threads are prepared, followed by upsetting with a knurling tool.
- **throwing power**
  - The ability of an electrodeposit to coat recessed areas of an irregularly shaped cathode , usually measured by noting the coating distance up a cylindrical tube that is coated in an electrodeposition bath. Compare with covering power .
- **tiger stripes**
  - Continuous bright lines on sheet or strip in the rolling direction.
- **tint etching**
  - Immersing metallographic specimens in specially formulated chemical etchants in order to produce a stable film on the specimen surface. When viewed under an optical microscope, these surface films produce colors that correspond to the various phases in the alloy. Also known as color etching.
- **titania**
  - A white water-insoluble powder of composition TiO_2 that is produced commercially from the minerals ilmenite and rutile. Used in paints and cosmetics and as an ingredient in porcelain enamels , ceramic whiteware, and ophthalmic glasses. Pure TiO_2 is also used as thin- or thick-film semiconductors.
- **titanium carbide**
  - Very hard, heat-resistant ceramic materials of the composition TiC used in cermets and tungsten carbide cutting tools. Chemical vapor deposited TiC coatings are also used to extend the life of cemented carbide cutting tools.
- **titanium nitride**
  - A hard, high-melting-point ceramic (2950 °C, or 5342 °F) of the composition TiN that is used in cermets and as a coating material for cemented carbide cutting tools. See also carbide tools .
- **tolerance**
  - The specified permissible deviation from a specified nominal dimension, or the permissible variation in size or other quality characteristic of a part.
- **topcoat**
  - Usually the final paint film applied to a surface.
- **topography**
  - The configuration of a surface including its relief and the position of its natural and man-made features.
- **total cyanide**
  - Cyanide content of an electroplating bath (including both simple and complex ions).
- **toughness**
  - Ability of a material to absorb energy and deform plastically before fracturing. Toughness is proportional to the area under the stress-strain curve from the origin to the breaking point. In metals, toughness is usually measured by the energy absorbed in a notch impact test.
- **T-peel strength**
  - The average load per unit width of adhesive bond line required to produce progressive separation of two bonded, flexible adherends, under standard test conditions.
- **transcrystalline cracking**
  - Cracking or fracturing that occurs through or across a crystal. Also termed intracrystalline cracking.
- **transfer**
  - In tribology, the process by which material from one sliding surface becomes attached to another surface, possibly as the result of interfacial adhesion. Transfer is usually associated with adhesion, but the possibility of mechanical interlocking adherence, without adhesive bonding, exists in certain occurrences. Material may also back transfer to the surface from which it came.

- **transfer efficiency**
  - In powder coating, the rate at which a powder is deposited on a target per unit of time divided by the gun output.
- **transferred arc**
  - A plasma arc established between the electrode and the workpiece during plasma arc welding, cutting, and thermal spraying.
- **transgranular cracking**
  - Cracking or fracturing that occurs through or across a crystal or grain. Also called transcrystalline cracking. Contrast with intergranular cracking .
- **transgranular fracture**
  - Fracture through or across the crystals or grains of a material. Also called transcrystalline fracture or intracrystalline fracture. Contrast with intergranular fracture .
- **transition diagram**
  - In tribology, a plot of two or more experimental or operating variables that indicates the boundaries between various regimes of wear or surface damage. The IRG transition diagram is a plot of normal force (ordinate) versus sliding velocity (abscissa), and is used to identify three regions with differing lubrication effectiveness. Various plots have been called transition diagrams, and the context of usage must be established.
- **transmission electron microscopy (TEM)**
  - An analytical technique in which an image is formed by an electron beam directly on a photographic film of phosphor-coated plate. Image contrast is formed by the scattering of electrons out of the beam. TEM is used for very high magnification characterization of metals, ceramics, minerals, polymers, and biological materials.
- **traverse speed**
  - The lineal velocity at which the torch is passed across the substrate during the thermal spraying operation.
- **trees**
  - Branched or irregular projections formed on a cathode during electrodeposition , especially at edges and other areas of high current density .
- **tribology**
  - (1) The science and technology of interacting surfaces in relative motion and of the practices related thereto. (2) The science concerned with the design, friction, lubrication, and wear of contacting surfaces that move relative to each other (as in bearings, cams, or gears, for example).
- **tribosurface**
  - Any solid surface whose intermittent, repeated, or continuous contact with another surface or surfaces, in relative motion, results in friction, wear, and/or surface damage. The surface of a body subjected to a catastrophic collision would not generally be considered a tribosurface because significant damage to the entire body is involved.
- **trimming**
  - The mechanical shearing of flash from molded and forged parts.
- **tripoli compound**
  - A buffing compound containing approximately 75% free or crystalline silica.
- **truing**
  - The removal of the outside layer of abrasive grains on a grinding wheel for the purpose of restoring its face.
- **trunk**
  - The thick base of a burr .
- **tuberculation**
  - The formation of localized corrosion products scattered over the surface in the form of knoblike mounds called tubercles. The formation of tubercles is usually associated with biological corrosion.
- **tumble grinding**
  - Various surfacing operations ranging from deburring and polishing to honing and microfinishing metallic parts before and after plating.
- **tumbling**
  - Rotating workpieces, usually castings or forgings, in a barrel partly filled with metal slugs or abrasives, to remove sand, scale , or fins. It may be done dry, or with an aqueous solution added to the contents of the barrel. See also barrel finishing .

- **turning**
    - Removing material by forcing a single-point cutting tool against the surface of a rotating workpiece. The tool may or may not be moved toward or along the axis of rotation while it cuts away material.
- **U**
- **ultrahard tool materials**
    - Very hard, wear-resistant materials--specifically, polycrystalline diamond and polycrystalline cubic boron nitride--that are fabricated into solid or layered cutting tool blanks for machining applications. See also superabrasives .
- **ultraprecision finishing**
    - Machining processes used to alter surface characteristics such as finish, waviness, roundness, etc., without substantial removal of the work material. Examples include lapping and polishing of optical lenses, computer chips, or magnetic heads, and honing of cylinder liners.
- **ultrasonic cleaning**
    - Immersion cleaning aided by ultrasonic waves that cause microagitation and microcavitation.
- **ultrasonic C-scan inspection**
    - A method for displaying the relative attenuation of ultrasonic waves across the surface (plan view) of a structural component. An ultrasonic transducer is used to scan the surface of a material mechanically in an *x-y* raster scan mode while generating and receiving waves. Either the material is immersed in a water bath or columns of water are provided between the transducer and the material as a medium for ultrasonic energy transmissions. The received wave signals are electronically conditioned and measured to determine relative energy losses of the wave as it progresses through the material at each particular location on the specimen. Ultrasonic C-scan has been used extensively to determine both the initial integrity of a manufactured part and the void content, and to follow the initiation and progression of damage resulting from environmental loading.
- **ultrasonic impact grinding**
    - Material removal by means of an abrasive slurry and the ultrasonic vibration of a nonrotating tool. The abrasive slurry flows through a gap between the workpiece and the vibrating tool. Material removal occurs when the abrasive particles, suspended in the slurry, are struck on the downstroke of the vibrating tool. The velocity imparted to the abrasive particles causes microchipping and erosion as the particles impinge on the workpiece. See also ultrasonic machining .
- **ultrasonic inspection**
    - A nondestructive method in which beams of high-frequency sound waves are introduced into materials for the detection of surface and subsurface flaws in the material. The sound waves travel through the material with some attendant loss of energy (attenuation) and are reflected at interfaces. The reflected beam is displayed and then analyzed to define the presence and location of flaws or discontinuities. Most ultrasonic inspection is done at frequencies between 0.1 and 25 MHz--well above the range of human hearing, which is about 20 Hz to 20 kHz.
- **ultrasonic machining**
    - A process for machining of hard, brittle, nonmetallic materials that involves the ultrasonic vibration of a rotating diamond core drill or milling tool. Rotary ultrasonic machining is similar to the conventional drilling of glass and ceramic with diamond core drills, except that the rotating core drill is vibrated at an ultrasonic frequency of 20 kHz. Rotary ultrasonic machining does not involve the flow of an abrasive slurry through a gap between the workpiece and the tool. Instead, the tool contacts and cuts the workpiece, and a liquid coolant, usually water, is forced through the bore of the tube to cool and flush away the removed material. See also ultrasonic impact grinding .
- **ultraviolet radiation**
    - High-energy short-wavelength radiation used in coatings to cross link primarily acrylic and methacrylic systems by means of free-radical reactions.
- **undercoat**
    - A deposited coat of material that acts as a substrate for a subsequent thermal spray deposit. See also bond coat .
- **underfilm corrosion**
    - Corrosion that occurs under organic films in the form of randomly distributed threadlike filaments or spots. In many cases this is identical to filiform corrosion .

- **underfiring**
  - Firing a porcelain enamel coating at a lower temperature than that recommended, allowing an insufficient length of time in the furnace, or applying too heavy a layer of the enamel. Likely to cause blisters or boiling of the ground coat through the cover coat, or the enamel ground coat may fishscale before the cover coat can be applied and fired.
- **uniform corrosion**
  - (1) A type of corrosion attack (deterioration) uniformly distributed over a metal surface. (2) Corrosion that proceeds at approximately the same rate over a metal surface. Also called general corrosion .
- **unlubricated sliding**
  - Sliding without lubricant but not necessarily under completely dry conditions. Unlubricated sliding is often used to mean "not intentionally lubricated," but surface species such as naturally formed surface oxides and other interfacial contaminants may act in a lubricious manner in nominally lubricated sliding.
- **upper critical temperature**
  - The temperature above which austenite is the stable phase. Also called the A_3 temperature.
- **UV stabilizers**
  - Chemicals added to paint to absorb the ultraviolet radiation present in sunlight. Ultraviolet radiation decomposes the polymer molecules in a paint film, and thus UV stabilizers are used to prolong paint life.
- **V**
- **vacuum carburizing**
  - A high-temperature gas carburizing process using furnace pressures between 13 and 67 kPa (0.1 to 0.5 torr) during the carburizing portion of the cycle. Steels undergoing this treatment are austenitized in a rough vacuum, carburized in a partial pressure of hydrocarbon gas, diffused in a rough vacuum, and then quenched in either oil or gas. Both batch and continuous furnaces are used.
- **vacuum deposition**
  - Deposition of a metal film onto a substrate in a vacuum by metal evaporation techniques.
- **vacuum metallizing**
  - A process in which surfaces are thinly coated by exposing them to a metal vapor under vacuum.
- **vacuum nitrocarburizing**
  - A subatmospheric nitrocarburizing process using a basic atmosphere of 50% ammonia/50% methane, containing controlled oxygen additions of up to 2%.
- **vapor degreasing**
  - See degreasing .
- **vapor-deposited replica**
  - A replica formed of a metal or a salt by the condensation of the vapors of the material onto the surface to be replicated.
- **vapor-phase lubrication**
  - A type of lubrication in which one or more gaseous reactants are supplied to the vicinity of the surface to be lubricated and which subsequently react to form a lubricious deposit on that surface.
- **vapor plating**
  - Deposition of a metal or compound on a heated surface by reduction or decomposition of a volatile compound at a temperature below the melting points of the deposit and the base material. The reduction is usually accomplished by a gaseous reducing agent such as hydrogen. The decomposition process may involve thermal dissociation or reaction with the base material. Occasionally used to designate deposition on cold surfaces by vacuum evaporation. See also vacuum deposition .
- **varnish**
  - (1) In lubrication, a deposit resulting from the oxidation and/or polymerization of fuels, lubricating oils, or organic constituents of bearing materials. Harder deposits are described as lacquers , softer deposits are described as gums. (2) A transparent surface coating which is applied as a liquid and then changes to a hard solid; all varnishes are solutions of resinous materials in a solvent.
- **vehicle**
  - The combination of a paint binder and solvents or diluents, which are used to put the binder in a liquid, usable form.

- **veining**
  - A subboundary structure in a metal that can be delineated because of the presence of a greater than average concentration of precipitate or solute atoms.
- **vibratory cavitation**
  - Cavitation caused by the pressure fluctuations within a liquid, induced by the vibration of a solid surface immersed in the liquid.
- **vibratory finishing**
  - A process for deburring and surface finishing in which the product and an abrasive mixture are placed in a container and vibrated.
- **vibratory polishing**
  - A mechanical polishing process in which a metallographic specimen is made to move around the polishing cloth by imparting a suitable vibratory motion to the polishing system. See also polishing .
- **Vickers hardness test**
  - A microindentation hardness test employing a 136° diamond pyramid indenter (Vickers) and variable loads, enabling the use of one hardness scale for all ranges of hardness--from very soft lead to tungsten carbide. Also known as diamond pyramid hardness test.
- **VI improver**
  - An additive, usually a polymer , that reduces the variation of viscosity with temperature, thereby increasing the viscosity index of an oil.
- **viscosity**
  - The property of a liquid that enables it to resist flow, often measured by the time required for a given volume of liquid to flow through a small hole in the bottom of a cup under controlled conditions. A thick liquid-like molasses has a high viscosity.
- **visual examination**
  - The qualitative observation of physical characteristics, observed by using the unaided eye or perhaps aided by the use of a simple hand-held lens (up to 10×).
- **void**
  - (1) A shrinkage cavity produced in castings or weldments during solidification. (2) A term generally applied to paints to describe holidays , holes, and skips in a film.
- **volatile organic compounds (VOC)**
  - Volatile organic materials, such as solvents, that are present in many coating products.
- **volatiles**
  - Materials, such as water and alcohol, in a sizing or resin formulation, that are capable of being driven off as a vapor at room temperature or at slightly elevated temperature. See also size .
- **W**
- **Wallner lines**
  - A distinct pattern of intersecting sets of parallel lines, sometimes producing a set of V-shaped lines, sometimes observed when viewing brittle fracture surfaces at high magnification in an electron microscope. Wallner lines are attributed to interaction between a shock wave and a brittle crack front propagating at high velocity. Sometimes Wallner lines are misinterpreted as fatigue striations .
- **warpage**
  - (1) Deformation other than contraction that develops in a casting between solidification and room temperature. (2) The distortion that occurs during annealing, stress relieving, and high-temperature service.
- **water break test**
  - A test to determine if a surface is chemically clean by the use of a drop of water, preferably distilled water. If the surface is clean, the water will break and spread; a contaminated surface will cause the water to bead.
- **water marks**
  - Defects in a fired porcelain enamel surface due to water (perspiration) dropping on the dried enamel or not being thoroughly removed from crevices in the workpiece during the drying step after pickling or cleaning. Similar defects may also be caused by too much water in an enamel slip or poor suspension of the enamel slip. Also called water lines or water streaks.
- **waviness**
  - A wavelike variation from a perfect surface, generally much larger and wider than the roughness caused by tool or grinding marks. See also roughness .

- **wear**
  - Damage to a solid surface, generally involving progressive loss of material, due to a relative motion between that surface and a contacting surface or substance. Compare with surface damage .
- **wear debris**
  - Particles that become detached in a wear process.
- **wear scar**
  - The portion of a solid surface that exhibits evidence that material has been removed from it due to the influence of one or more wear processes.
- **weathering steels**
  - Copper-bearing high-strength low-alloy steels that exhibit high resistance to atmospheric corrosion in the unpainted condition.
- **wedge effect**
  - The establishment of a pressure wedge in a lubricant. See also wedge formation (2).
- **wedge formation**
  - (1) In sliding metals, the formation of a wedge or wedges of plastically sheared metal in local regions of interaction between sliding surfaces. This type of wedge is also known as a prow. It is similar to a built-up edge . (2) In hydrodynamic lubrication, the establishment of a pressure gradient in a fluid flowing into a converging channel. This is also known as wedge effect .
- **weld decay**
  - Intergranular corrosion , usually of stainless steels or certain nickel-base alloys, that occurs as the result of sensitization in the heat-affected zone during the welding operation.
- **wet blasting**
  - A process for cleaning or finishing by means of a slurry of abrasive in water directed at high velocity against the workpieces. Many different kinds and sizes of abrasives can be used in wet blasting. Sizes range from 20-mesh (very coarse) to 5000-mesh (which is much finer than face powder). Among the types of abrasives used are: organic or agricultural materials such as walnut shells and peach pits; novaculite, which is a soft type (6 to 6.5 Mohs hardness) of silica (99.46% silica); silica, quartz, garnet, and aluminum oxide; other refractory abrasives; and glass beads.
- **wet etching**
  - In metallography, revealing the microstructure in metals through the use of liquids, such as acids, bases, neutral solutions, or mixtures of solutions.
- **wet milling**
  - The grinding of porcelain enamel materials with sufficient liquid to form a slurry .
- **wet process enameling**
  - A method of porcelain enameling in which slip is applied to a metal article at ambient temperature, dried, and fired.
- **wetting**
  - The penetration of soil by the cleaning solution. Soap and/or wetting agents wetting increase the wetting action of water or solvents on a surface or soil by reducing surface tension. This wetting action helps in dislodging and removing soil.
- **wetting agent**
  - A substance that reduces the surface tension of a liquid, thereby causing it to spread more readily on a solid surface.
- **whiskers**
  - Metallic filamentary growths, often microscopic, sometimes formed during electrodeposition and sometimes spontaneously during storage or service, after finishing. Common on electrical contacts plated with zinc or cadmium.
- **white-etching layer**
  - A surface layer in a steel that, as viewed in a section after etching, appears whiter than the base metal . The presence of the layer may be due to a number of causes, including plastic deformation induced by machining, or surface rubbing, heating during a metallographic preparation stage to such an extent that the layer is austenitized and then hardened during cooling, and diffusion of extraneous elements into the surface.
- **white layer**
  - Surface layer on nitrided steels that is made up of intermetallic compounds, which do not etch and appear white in light microscopy.
- **white rust**

  - Zinc oxide; the powder product of corrosion of zinc or zinc-coated surfaces.
- **wiped coat**
  - A hot dipped galvanized coating from which virtually all free zinc is removed by wiping prior to solidification, leaving only a thin zinc-iron alloy layer.
- **wipe solvent cleaning**
  - A method for removing contaminants from a surface by wetting a clean cloth with a solvent , wiping the surface to be cleaned, and then removing the residual solvent from the surface with a clean, dry cloth.
- **wiping**
  - In tribology, the smearing or removal of material from one point, often followed by the redeposition of the material at another point, on the surface of two bodies in sliding contact. The smeared metal is usually softened or melted.
- **wire flame spraying**
  - A thermal spraying process variation in which the material to be sprayed is in wire or rod form. See also flame spraying .
- **X**
- **x-ray tomography**
  - A method of imaging the internal structure of materials in which an x-ray beam is passed through the sample in multiple directions. The density throughout the sample is reconstructed by a computer from the transmitted x-ray signal.
- **x-ray topography**
  - A technique that comprises topography and x-ray diffraction. The term topography refers to a detailed description and mapping of physical (surface) features in a region. In the context of the x-ray diffraction, topographic methods are used to survey the lattice structure and imperfections in crystalline materials.
- **Z**
- **Zincrometal**
  - A steel coil-coated product consisting of a mixed-oxide underlayer containing zinc particles and a zinc-rich organic (epoxy) topcoat. It is weldable, formable, paintable, and compatible with commonly used adhesives. Zincrometal is used to protect outer body panels in automobiles from corrosion.
- **zinc worms**
  - Surface imperfections, characteristic of high-zinc brass castings, that occur when zinc vapor condenses at the mold/metal interface, where it is oxidized and then becomes entrapped in the solidifying metals.

Abbreviations, Symbols, and Tradenames

- **Abbreviations and Symbols**
- ***a***
  - area
- **A**
  - austenite; ampere
- ***A***
  - cross-sectional area; contact area
- Å
  - angstrom
- **ac**
  - alternating current
- **ABS**
  - acrylonitrile butadiene styrene
- **AC**
  - air cool
- **Ac_1**
  - temperature at which austenite begins to form during heating

- **Ac$_3$**
    - temperature at which transformation of ferrite to austenite is completed during heating
- **AC$_{cm}$**
    - in hypereutectoid steel, temperature at which cementite completes solution in austenite
- **A_e**
    - surface area
- **Ae$_{cm}$, Ae$_1$, Ae$_3$**
    - equilibrium transformation temperatures in steel
- **AEM**
    - analytical electron microscope/microscopy
- **AES**
    - Auger electron spectroscopy; acoustic emission spectroscopy
- **AESF**
    - American Electroplaters and Surface Finishers Society
- **AFM**
    - atomic force microscope
- **AG**
    - aged; alternating grinding
- **AGMA**
    - American Gear Manufacturers Association
- **AISI**
    - American Iron and Steel Institute
- **Ams**
    - Amsler circumferential, rotating disk-on-disk machine
- **AMS**
    - Aerospace Material Specification; acoustic material signature
- **ANSI**
    - American National Standards Institute
- **APCVD**
    - atmospheric-pressure chemical vapor desposition
- **API**
    - American Petroleum Institute
- **Ar$_1$**
    - temperature at which transformation to ferrite or to ferrite plus cementite is completed on cooling
- **Ar$_3$**
    - temperature at which transformation of austenite to ferrite begins on cooling
- **Ar$_{cm}$**
    - temperature at which cementite begins to precipitate from austenite on cooling
- **ARE**
    - activated reactive evaporation
- **ARIP**
    - activated reactive ion plating
- **ARP**
    - Aerospace Recommended Practice
- **ASLE**
    - American Society of Lubrication Engineers (former name of STLE)
- **ASM**
    - American Society for Metals (now ASM International)
