Die sets can be classified as removable or nonremovable. Both types are used in mechanical and hydraulic presses. Nonremovable die sets are used throughout the entire tonnage requirements of available presses. Manually removable die sets are used primarily in presses with pressing capacities up to ~ 2670 kN (300 tons). Above this press size, the die set assembly is moved by a powered system, and removable die set presses with capacities of $\leq 17,800$ kN (2000 tons) are available.

The major advantage offered by nonremovable die sets is flexibility in setup and operation. Presses equipped with nonremovable die sets usually have all adjustments required for setup and operation built into the press and die set, including:

- *Part length adjustment:* Any dimensions of the part in the direction of pressing can be quickly changed during production.
- *Part weight:* Material weight in any level of the part can be changed easily during production.
- *Tooling length adjustment:* Adjustments are provided to accommodate shortening of punch length due to sharpening or refacing.

Another advantage of nonremovable die sets is the greater space available for tooling, compared to the removable type. This space provides more freedom in tooling design. However, presses incorporating nonremovable die sets must be shut down during tooling changes or maintenance. Tooling change and setup time generally is from 1 to 4 hours--but sometimes substantially longer, depending on the complexity of tooling.

Nonremovable die sets are well suited for developing new P/M parts, because press and tooling adjustments can be made quickly to achieve the desired weight, density, and part dimension. Adjustment features of nonremovable die sets make them desirable on long production runs, where changes in powder quality among lots require frequent tooling adjustment to maintain part quality.

Users of removable die sets normally have two or more die sets per press. Tooling can be set up in a spare die outside the press. Removable die sets normally can be changed in less than 30 min, so loss of production time is minimal. On small presses where the die set is also small, the die set is restricted to a given set of tools and is considered semidurable tooling.

One disadvantage of many removable die sets is that pressing is controlled by pairs of pressing blocks made of hardened tool steel, such as D-2. The height of the pressing block controls the height of the part. If the part length dimension is changed due to design, or if the tooling length is changed due to repair, the pressing blocks must be changed accordingly. Removable die sets are ideally suited for shorter production runs. On newer presses with removable die sets, complete powder adjustment is available, even when the die set is outside the machine.

Part Classification

The Metal Powder Industries Federation has classified P/M parts according to complexity. Class I parts are the least complex, and class IV parts are the most complex. To better understand the types of commercially available P/M compacting presses, and their advantages and limitations, an understanding of P/M part classification and tooling systems used to produce parts is necessary. Part thickness and number of distinct levels perpendicular to the direction of powder pressing determine classification--not the contour of the part.

Class I parts are single-level parts that are pressed from one direction, top or bottom, and that have a slight density variation within the part in the direction of pressing (Fig. 4a). The highest part density is at the surface in contact with the moving punch, and the lowest density is at the opposite surface. Parts with a finished thickness of ~ 7.5 mm (0.3 in.) can be produced by this method without significant density variation.

Links

(b) Class IV parts

Fig. 4 Basic geometries of (a) MPIF class I (simple) and (b) MPIF class IV (complex) parts

Class II parts are single-level parts of any thickness pressed from both top and bottom. The lowest density region of these parts is near the center, with higher density at the top and bottom surfaces.

Class III parts have two levels, are of any thickness, and are pressed from both top and bottom. Individual punches are required for each of the levels to control powder fill and density.

Class IV parts are multilevel parts of any thickness, pressed from both top and bottom (Fig. 4b). Individual punches are required for each level to control powder fill and density.

Powder Metallurgy Presses and Tooling

Shape of Rigid Tooling

Rigid tool compaction differs from roll compaction, isostatic compaction, hot isostatic pressing, and injection molding in that a quantity of powder (fill) is confined in a rigid die cavity at ambient temperature. The die cavity is entered by one or more punches, which apply compaction pressure to the fill powder. As a result of the compaction pressure, the fill powder densifies, develops green strength, and assumes the exact shape of the die cavity and punch faces. Following the pressure cycle, the shaped powder fill, now a piece part, is ejected (stripped) from the die cavity.

The physical size of parts made in rigid tool compaction systems is a function of press tonnage capacity, fill depth, and also the length of a green powder fill that can be effectively compacted in terms of a maximum density variance. Parts vary in size from those weighing ~ 1 g (0.035 oz) that are made in presses with capacities as small as 35 kN (4 tons) to those weighing 10 kg (22 lb) that are made in presses with capacities of 8900 kN (100 tons).

Rigid tools must also be constructed oversize, with exact linear dimensions, to compensate for the final volume change. Although theoretical computations are useful, most successful rigid tool sets are based on shrinkage allowances developed from existing tooling and the dimensional histograms developed for particular powders. However, shrinkage allowances can be complex depending on subsequent sintering and binder additives. For example, some metallic powders, such as the carbide and tool steel types, and some gas and centrifugally atomized specialty powders, such as spray-dried tungsten carbide, do not develop significant green strength, because their individual particles are predominantly spherical or they lack plasticity. To compact such powders in rigid tool systems, wax or wax-stearate binders are added, which can occupy up to 20 vol% of the green compacted shape. The development of full metallic properties during sintering also requires a volume shrinkage.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Powder Fill

The important consideration in P/M part production is the fill ratio required to produce parts to a density that is compatible with end use requirements. The fill ratios must remain constant for a given part to maintain dimensional reproducibility. Parts can be of single-level or multilevel design.

Single-level parts, designated as class I by the Metal Powder Industries Federation (MPIF), present the least difficulty to the tool designer, regardless of the size or part configuration. The main consideration is designing a die that is long enough guidance for the lower punch (usually 25 mm, or 1 in.) and providing adequate fill depth for compacting the powder to the required density. This challenge, coupled with the primary mechanical consideration of locating the center of mass in the press center, provides the best potential for producing a uniform quality part. Figure 4(a) shows basic geometries of MPIF class I parts.

Multilevel parts, with industry classifications II through IV, present two additional complications to the tool designer: powder fill and part ejection. Because metal powders tend to compact in vertical columns and generate little hydraulic flow, the tool designer must create fill levels in the tools that compensate for the thickness variations present in the final

part configuration. Uniform density, neutral axis of compaction, and part ejection should be considered to determine the need to vary fill levels and the manner in which these variations are achieved. Excessive density variations contribute to green cracks and sintered distortion.

A common method of varying fill levels is by using multiple lower punches, which are timed to react to one another either through the use of springs or air, or by mounting on separate press platens. Other methods are less effective, because punches are not adjustable and are fixed on one of the tool members, such as the die or core rod.

Fixed levels are commonly referred to as die chokes, core rod steps, or splash pockets (Fig. 5). Fixed fills are sensitive to the apparent density of the material being compacted. In operations that control compacting pressure, such as in hydraulic pressing, fixed fills cause dimensional variations in part thickness. Because mechanical presses are set to operate to a fixed position relative to the die, the variation created by the apparent density of the powder causes overdensification or underdensification, resulting in a corresponding oversize or undersize peripheral area on the part. Green expansion occurs as a part is stripped from the die. Ideally, the part returns to die size through shrinkage during sintering.

Fig. 5 Methods of achieving fixed fill levels. (a) Fixed fill on an upper level using a step die. (b) Fixed fill using a splash pocket to permit a projection feature on an upper punch. (c) Stepped core rod forming an internal shoulder

When a part has more than one level in the compacting direction, the step height should be limited to one-quarter of the overall height for a single punch (Fig. 6a). If a larger step is required, multiple punches should be considered (Fig. 6b).

Fig. 6 Two-level compaction. (a) Single lower punch when $h \leq H/4$. (b) Double lower punches when $h > H/4$.

Fill Height. The fill height is the depth of the loose powder required to give the required part thickness after compaction. The value is determined by the compressibility of the loose powder at the required density. The fill height, h_i , is obtained by multiplying the finished part height by the compression ratio of the powder:

$$h_f = tk_r$$

In this equation, t is the part thickness, k_r is the compression ratio, and $k_r = q/q_a$, where q is the part required compaction density and q_a is the apparent density of the loose powder. If the fill height is greater than the maximum fill height that can be accommodated in the press selected on the basis of the compacting load required, a larger capacity machine should be selected, which has the required fill height capacity.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Tooling Systems

High-production P/M compacting presses are available as standard production machines in a wide range of pressing capacities and production rate capabilities. Presses are designed to produce parts of a specific classification, as discussed previously.

Single-action tooling systems generally are limited to production of class I parts. During the compacting cycle, the die, core rod, and one of the punches (usually the lower punch) remain stationary. Compacting is performed by the moving punch, which is driven by the action of the press. One or more core rods may form any through holes in the part.

During ejection, the upper punch moves away from the formed part, and the part is ejected from the die by the lower punch. The core rod (Fig. 7) is stationary, and the part is ejected from the die and core rod simultaneously. On some presses, the core rod is arranged so that it is free to move upward (float) with the part as it is ejected. The compacted part experiences slight elastic expansion on ejection from the die, which causes the part to free itself from the core rod. The core rod is then free to move downward to the fill position. This floating core rod arrangement reduces ejection forces and core rod wear.

Fig. 7 Compacting sequence utilizing single-action tooling. Dashed line indicates motion of lower punch.

Double-action tooling systems primarily are used to produce class I and II parts. Force is applied to the top and bottom of the part simultaneously, because the punches have the same travel rate. The die and core rod are stationary. Densification takes place from the top and bottom, with the lowest density region near the center of the part. Although the

core rod is fixed in this system, it can be arranged in a floating position. Figure 8 shows the compacting sequence of a double-action tooling system.

Fig. 8 Compacting sequence utilizing double-action tooling. Dashed line indicates motion of component parts.

Floating die tooling systems are similar to double-action arrangements. As shown in Fig. 9, the die is mounted on a yielding mechanism (springs). However, pneumatic or hydraulic cylinders usually are used, because they offer an easily adjustable resisting force. As the upper punch enters the die and starts to compact the powder, friction between the powder and die wall causes the die to move down. This has the same effect as an upward-moving lower punch. After pressing, the die moves upward to the fill position, and the upward-moving lower punch ejects the part. The core rod can be fixed or floating.

Fig. 9 Compacting sequence utilizing floating die tooling. Dashed lines indicate motion of component parts.

Withdrawal tooling systems use the floating die principle, except that the punch forming the bottommost level of the part remains stationary and that the die motion is press activated rather than friction activated. The die and other lower tooling members, including auxiliary lower punches and core rods, move downward from the time pressing begins until ejection is complete.

Figure 10 shows the compacting sequence in a multiple-motion withdrawal tooling system. During compaction, all elements of the tooling system except the stationary punch move downward. The die is mounted on the top press member of the platen and is supported by pneumatic or hydraulic cylinders. Auxiliary punches are mounted on additional platens, which are similarly supported and have positive pressing stops. The stops control the finished length of each of the levels within the compacted part. Before ejection, these stops are released or disengaged so that the platens can be moved further downward. During ejection, the upper punch moves upward, away from the compact, while the die and lower punches move sequentially downward until all tool members are level with the top of the stationary punch. The compact is fully supported by the tooling members during ejection, resting on the stationary punch as the die and lower punches are lowered to release it.

Fig. 10 Compacting sequence utilizing floating die withdrawal double-action tooling. Dashed lines indicate motion of component parts.

The core rod can be provided with pressing position stops to allow a part to be produced with blind or counterbored holes. The core rod is held stationary until the part is free of all other tooling members before moving downward to the ejection position.

At this point in the machine cycle, the feeder moves across the die, pushing the compacted part from the die area and covering the die cavity. The die and auxiliary lower punches move upward to their respective fill positions. The core rod then moves upward, displacing the excess powder into the partially empty feed shoe. The feeder retracts, wipes the top fill level, and readies the press for the next cycle.

Types of Presses

Anvil presses generally are limited to compaction of class I parts in a single direction. Anvil presses do not have an upper punch; a moveable, solid, flat block seals the top of the die. Compacting is done by the lower punch, which, after the anvil is released and moved, moves farther to eject the compact from the die.

Anvil presses are available with pressing capacities ranging from 6.7 to 310 kN (0.75 to 35 tons), with maximum depth of fill ranging from 1 to 75 mm (0.040 to 3 in.). Multiple-cavity pressing frequently is used in anvil presses, with possible production rates of >100,000 pieces per hour. Some anvil presses can be converted to double action, using an upper punch entry system. Anvil presses usually are mechanically driven. Figure 11 shows a schematic of an anvil press operation.

Fig. 11 Compacting sequence utilizing sliding anvil single-action tooling. Dashed line indicates motion of component parts.

Rotary presses generally are limited to compaction of single-level class II parts, although some class III parts, such as flanged bushings, are produced. Rotary machines are available with pressing capacities ranging from 36 to 590 kN (4 to 66 tons), with a depth of fill up to 75 mm (3 in.). Production rates of >60,000 pieces per hour are possible, depending on machine size and the number of tooling stations. Rotary presses are mechanically driven.

Single-Punch Opposing Ram Presses. Like rotary presses, these machines are limited to production of class II and some class III P/M parts. These presses are available in top- and bottom-drive models, with pressing capacities ranging from 36 to 980 kN (4 to 100 tons) and with a maximum depth of fill up to 100 mm (4 in.).

Production rates of up to 3000 parts per hour are possible using mechanical presses with single-cavity tooling, although production rates of 900 to 1800 pieces per hour are more common. Hydraulic presses produce ~900 pieces per hour. Ejection of the part is accomplished by the lower punch moving upward. Mechanical and hydraulic presses are available.

Single-punch withdrawal presses have essentially the same partmaking capabilities as the single-punch opposing ram system in terms of pressing capacity, depth of fill, and production rate. The major difference is that floating dies are used to achieve top and bottom pressing. The die is moved downward to eject the part.

Multiple-motion die set presses can be designed to produce the most complex P/M parts. These presses use floating die and withdrawal tooling methods. Machines are available with either bottom- or top-drive arrangements. Pressing capacities range from 27 to 7830 kN (3 to 880 tons), with a maximum depth fill of 180 mm (7 in.). Production rates vary from more than 6000 pieces per hour on smaller machines to 1800 pieces per hour for 1960 kN (220 ton) presses.

In addition to producing complex parts, the removable die set (tool holder) minimizes press downtime for part changeover if the die set for the next part to be produced is set up outside the press and is ready for installation. Pressing position for each level being produced by a separate tooling member is controlled by fixed-height tooling blocks (stop blocks), which usually are ground to the proper height to produce a given dimension on the part. A small adjustment in the block mounting member allows for minor changes to part dimension. Full range adjustments are available on more recent presses.

Multiple-motion adjustable stop presses have the same partmaking capability as multiple-motion die set presses and use the same tooling methods. Pressing capacities range from 980 to 7340 kN (110 to 825 tons), with a maximum depth of fill of 150 mm (6 in.). These presses do not incorporate removable die sets; however, press stop positions are adjustable, and a change in any dimension of the part in the direction of pressing is easily accomplished.

Powder Metallurgy Presses and Tooling

Advanced Tool Motions

A common limitation of some rigid tooling systems is that part features not perpendicular to the direction of pressing cannot be compacted and stripped. Frequently, it is cost effective to form features such as cross holes and threads by machining. Other nonperpendicular features, notably helix shapes and hidden flanges, can be formed using complex tool motions. Another type of advanced tooling system permits production of complex shapes with magnetic orientation of the microstructure.

Helical shapes, typically helical spur gears, are produced in rigid compaction tool sets with punch rotation capability. In a simple system, a helical form lower punch is engaged in a die with a matching gear form. In such a system, the lower punch remains engaged in the die at all times, as is common practice for all rigid tool systems, so that indexing rotation of the punch to the die is avoided. The die acts as a guide. Rotation is carried out on a thrust bearing, which rests on the punch platen that supports the lower punch. An upper punch is not required, because the top of the die cavity is closed by an upper anvil, which does not enter the die cavity. Central core rods, with or without additional features such as splines and key forms, are commonly operated in this helical tool system.

Helical gears made in this manner are limited to helix angles of $\sim 25^\circ$ and a thickness of 32 mm ($1\frac{1}{4}$ in.) due to fill limitations along the helix tooth form. More complex helical gear tooling systems have been developed for routine production using helical upper punches, driven by follower cams for indexed die entry, with inner and outer lower helical punches for stepped helical gears.

Split Die Systems. Another rigid tooling system that avoids some through-cavity limitations is known as the split die, or "double die," system. It enables the compaction of parts with completely asymmetric upper and lower sections in the pressing direction. Figure 12 shows typical tool motions in split die compaction. This system requires two die-holding platens to carry the upper and lower die. Each platen is controlled and moved independently.

Step 1

Step 2

Step 3

Step 4

Fig. 12 Split die compaction sequence

Wet magnetic compaction (Fig. 13) has enjoyed wide usage in the production of magnetically oriented ferrite shapes. In this production process, a feed shoe is not required. Instead, the die cavity is injected with an aqueous slip (slurry) that has a high concentration of ferrite powder, with the addition of green binders as required. Typically, the die filling pressure is 35 MPa (5000 psi). By using an aqueous slip, many of the gravity die fill problems, such as attainment of uniform powder density and filling the areas that are difficult for the powder to reach, are avoided.

Fig. 13 Wet magnetic compaction. (a) Force-time diagram for magnet presses. (b) Schematic of press tool for chamber-filling method designed for withdrawal operation

Following die fill injection, an orienting magnetic field is applied to the slip, resulting in magnetic polarization of the individual ferrite particles, which remain mobile at this point. The optimal orientation of the ferrite particles directly

determines the quality of the finished permanent magnet. After magnetic orientation, the main pressing load is applied, densifying the ferrite mass and causing the suspending aqueous carrier to be expelled through drainage ports. The compact is imparted with the precision shape and dimensions of both the upper and lower dies, plus any core rods that may be inserted. The cycle is completed by separation of the press platens and ejection of the compacted ferrite shape.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Tooling Design

Traditionally, P/M tooling was designed on the basis of production experience. In simple parts, such as single-level class I and II parts, these determinations proved successful. As state-of-the-art materials and presses advanced to the production of complex, multilevel parts, the "cut-and-try" method of tool design became obsolete. The high cost of complex tooling and adapters, plus downtime to redesign and rebuild tooling, requires the partmaking system, including the press, to be carefully analyzed in terms of load, stress, and deflection.

Tooling layout is required to design a suitable set of tools and to determine the physical dimensions (length and thickness) of tooling members. A preliminary layout helps to determine fill, pressing, and ejection positions and to eliminate interference at these positions.

The die space drawing supplied with every compacting press, which usually starts with the ejection position, is the basis of the tooling assembly layout. Generally, tooling members are never closer than in the ejection position, which constitutes the minimum space available to contain all components and their adapters.

Die Design. Dies are commonly constructed by using inserts that are held in the die case by shrink fitting. The amount of interference between the insert and the die case depends on the inside and outside diameter of each member and on the compacting pressure used. The powder can be considered a fluid in a closed container that transmits the compacting pressure in all directions; therefore, the die must be designed as though it were a pressure vessel with internal pressure.

In actual practice, radial pressure on the die walls due to compacting rarely exceeds 50% of the compacting pressure. The interference fit of the die case and die insert should be such that the stress on the insert always remains in compression for round dies. However, for shaped dies such as gears, cams, and levers, the use of finite element analysis is the best method for accurately determining stress and deflection.

In P/M tooling, the die normally controls the outer peripheral shape and size of the piece part. Typically, it is constructed from materials such as tungsten carbide or high alloy tool steels, such as T15, D2, CPM-10V, or CPM-15V with high hardness and good wear resistance. Dies are usually constructed in one or more sections and compressed into a retaining ring made of a low-alloy steel, such as AISI 4340 or 6150.

Considerations in die design and material selection include initial tool cost, shear strength of the die material, and die shape. A large die may require tungsten carbide, which costs ten times as much as tool steel materials. Tungsten carbide may be the best material for a set of gear tools with a relatively steep helical angle. Sectional die construction may be required for specific shapes such as sharp corners or projections into the die cavity.

Die Wall Thickness. An exact calculation of the stress on die walls is almost impossible from a practical point of view because stress distributions in the compact are extremely complicated and include variables such as part shape, particle size distribution, and other factors that affect transmission of compressive stress in the lateral direction (Ref 2). The vertical axial load can exert a horizontal force after a certain degree of consolidation has been attained. For example, when a simple shape is compacted at 400 MPa, as much as 120 MPa pressure can be exerted radially against the die walls.

If for purposes of simplification, the internal pressure is considered strictly hydrostatic in nature and the confined material is an incompressible liquid, then the die wall thickness for a cylindrical die could be determined by using Lamé's formula:

$$D = d \sqrt{(S + p)/(S - p)}$$

where S is the maximum allowable fiber stress for the material of the die, D is the outer diameter of the die, d is the compact diameter, and p is the radial stress acting on the die wall. This is a simplification because during metal powder compaction the pressure is not hydrostatic and the material is not incompressible. Initially, the powder is compressed with a consequent reduction in the vertical height of the space filled by the powder. The compressed material begins to resemble a solid after a certain degree of compaction has been reached.

Poisson's ratio is 0.3 for fully dense and isotropic steel. While this wrought form value cannot apply to powder metal, it is assumed to be applicable in the fully compacted condition. Thus, the Poisson's ratio is introduced into the previous equation, and the following modified Lamé's formula is used for estimating the die wall thickness for metal powder compaction.

$$D = d \sqrt{(S + \mu p)/(S - \mu p)}$$

where μ = Poisson's ratio = 0.3. This formula, however, does not take into consideration that the internal pressure acting over the length of the compact is balanced by the strength of the die having a larger length. The formula does address the friction at the tooling/powder interfaces resulting in nonuniform pressure distribution in the compact.

Generally speaking, the formula produces more conservative results than are necessary. The interference fit between the shrink ring and the die insert should be such that the stress on the insert always remains compressive for round dies. For shaped dies such as those used for production of gears and cams, the use of finite element analysis is the best method for accurately determining the stress and deflection.

Core Rods. Basically, the core rod is an extension of the die that controls the inner peripheral shape and size of the piece part. Tungsten carbide and M2 or M4 high-speed steels are the most common materials used for core rods. Primary factors in materials selection include wear resistance and hardness, which enable the core rod to resist the high compressive force exerted during compaction and the abrasive action sustained during part ejection. Core rods >25 mm (1 in.) in diameter or area are held to a base by mechanical means, such as a screw, while smaller core rods are held by means of silver solder or braze.

Punches can perform the function of a die or a core rod and carry the full load of the compressive force required to compact the P/M part. Wear resistance and toughness are the most important factors in materials selection. The most commonly used materials are A2, D2, S7, and H13 tool steels. Dimensional control, especially in areas such as concentricity and hole-to-hole location, depends on the amount of clearance that can be maintained between the punches, die, and core rods. Clearance should be calculated for each specific range and size of part. It is important to note that thermal size changes occur during operation, primarily because of the friction created by stripping the compacted part and the speed of the pressing cycle.

Punch Component Stress. Compacting powder causes compressive stress in the punch. This stress must be below the yield strength of the punch material. Calculation of buckling stability should be made for long, thin-walled punches.

Figure 14 shows the effect of axial compressive force on a tubular punch. A tubular punch is subjected to internal pressure during compacting of multilevel parts. In this case, the resulting circumferential tensile stress in the punch wall should be calculated. If the stress and accompanying deflection is excessive, tooling clearances should be designed so that when the outer punch wall expands, it is supported by the die wall before the stress reaches the yield limit (Fig. 15).

Fig. 14 Effect of compressive stress on tubular punch

Fig. 15 Tensile stresses in a tubular punch during compacting. Large arrows indicate action of powder on walls of punch.

During ejection, the punch is subjected to compressive stresses by resisting the stripping action of the die and to tensile stresses from the stripping action of punch. These stresses normally are lower than compacting stresses. Components of the punch subjected to stress include the punch clamp ring and bolts, which should resist the ejection of the punch without permanent deformation. Punch adapters are subjected to bending loads that create a tensile stress around the center hole during compacting. This stress should not exceed the fatigue limit of the adapter material.

Tubular adapters must have sufficient cross-sectional area to withstand the pressing load without permanent deformation. A stepped core rod, or a core rod forming a blind hole, must not buckle during compacting. The base of the core rod must resist, without permanent deformation, whatever ejection loads are imposed on the core rod.

The core rod clamp ring and retaining bolts should be sized to withstand the ejection force on the core rod without permanent deformation. The core rod adapter generally is strong enough to resist both pressing and ejection loads, due to the size of the adapter when space is provided for clamp ring fasteners.

Deflection Analysis. Pressing of P/M parts at pressures >690 MPa (50 tsi) presents unique considerations for size and tolerance in multilevel parts. A variety of tool members should be utilized to establish proper fill ratios, and deflection and springback can occur. Deflection occurs because of the column loading effect on the compacting tools during the briquetting cycle. For column load consideration, the bottom section of the lower punch is considered fixed, while the top section or working end of the lower punch can be considered free to rotate. The amount of deflection on the tool member will be determined by the column slenderness ratio of the punch and the adapter. When the column load is released after the press goes through the bottom dead center compaction point, the deflected punches will return to their original lengths, if their elastic material property limits have not been exceeded. This return movement is generally called springback and can be deleterious to the green part, depending on the fragileness of the green part section geometry involved.

Deflection can be minimized by strengthening the various tool members through changes in physical size or shape and/or by changes in material selection. The most common method of minimizing deflection effects is to equalize deflection using tool members and adapters that are designed to match the deflection characteristics of the most critical member. The ability of the tool designer to find the proper balance is paramount for production of crack-free parts.

When designing tools for production of parts other than single-level class I or II parts, deflection analysis of the tooling, tooling adapters, and press is desirable. These members are essentially stiff springs, each with a different spring rate or modulus. When the compacting load is applied, the parts deflect. When the load is released, they return to their original length. If the press contains two or more separate lower punches, the total deflection of each punch and the supporting members must be the same. Otherwise, the compacted part will move with the punch that has the greatest total deflection, leaving a portion of the part unsupported. This condition is likely to cause cracking during part ejection.

A punch under load normally is in pure compression and therefore will follow Hooke's law. If the punch has varying cross-sectional areas, each length having the same cross-sectional area is calculated individually. The total punch compression is the sum of these calculations. For a long, thin-walled punch, local buckling of the punch wall under load should be investigated. Compression of punches and their supporting members may be calculated using the equation given in Fig. 16.

Fig. 16 Punch compression. P is total punch load, L is length, Y is deflection, A is area of punch, and E is Young's modulus.

Adapter Bending. The adapter, on which the punch is mounted, usually is a flat plate with the punch and the load positioned at the center, around a hole through which either another punch or a core rod passes. This plate, if supported at the outer edge, is subjected to the pressing load around the center hole. Two forms of deflection--bending and shearing--occur in this area. Adapter deflection is linearly proportional to force. Calculated adapter stress should be compared with the allowable adapter material stress to evaluate design suitability.

Press Deflection. Like the tooling and support, the press is subject to deflection. This tendency is considerably less than that of punch compression or adapter bending, but it must be considered in total tool design. Data regarding press deflection should be obtained from the press manufacturer. Deflection is linearly proportional to the amount of force exerted:

$$Y = C \times W$$

where C is the equipment constant, W is pressing force, and Y is deflection.

Tool Materials

Dies. In the most common type of die construction, wear-resistant inserts or liners are held in place by clamping or shrink fitting. The amount of interference between the insert and the die case depends on the inside and outside diameter of each member and on the compacting pressure used. The powder can be considered a fluid in a closed container that transmits the compacting pressure in all directions; therefore, the die must be designed as though it were a pressure vessel with internal pressure.

In actual practice, radial pressure on the die walls due to compacting rarely exceeds 50% of compacting pressure. The interference fit of the die case and die insert should be such that the stress on the insert always remains in compression for round dies. However, for shaped dies, such as gears, cams, and levers, finite element analysis is the best method for accurately determining stress and deflection.

Die inserts for compaction of carbide, ceramic, or ferrite powder most frequently are the medium- or coarse-grain 94WC-6Co grades of cemented carbide. Cemented tungsten carbide containing 12 to 16% Co can be used to make inserts for compacting metal powders in medium-to-long production runs.

The elastic moduli of carbides are considerably higher than those of steels, a fact that should be considered when designing composite steel and carbide die assemblies. Because carbide will deflect only 33 to 40% as much as steel, the steel portion generally should be designed with enough stiffness to support three times the expected loading in order to match the deflection of the carbide. The shrink-fit allowance should be ~ 1.0 mm/m (0.0010 in./in.). Shrink rings and similar supporting parts of the tooling can be made from medium-carbon alloy steel, such as AISI/SAE 4340 or 6150, quenched and tempered to ~ 42 to 46 HRC. It is especially important that supporting parts for carbide tools provide sufficient support; otherwise, the carbide tools are likely to break in service.

Cemented carbides are relatively expensive, and shaping of parts to the required form must be done either by electrical discharge machining or by specialized methods of grinding.

Wear-resistant tool steel inserts are sometimes used instead of carbide inserts. Tool steel inserts are tougher and easier to fabricate than carbide inserts. Powder metallurgy tool steels such as CPM 10V, Vanadis 4, and Vanadis 10 are frequently chosen for medium-to-long production runs because they have wear resistance approaching that of carbides. Other wear-resistant tool steels, usually D2 or D3 or a high-speed steel such as M2 or M4, have been used for short-run applications. Tool steel inserts generally are heat treated to a working hardness of 62 to 64 HRC. For increased wear resistance, a nitrided case may be specified for dies made of CPM 10V, Vanadis V, Vanadis 10, or D2. For certain part designs, a solid die rather than an insert die is a more practical choice; an air-hardening 5% Cr tool steel such as A2 is generally used for such applications.

Punches. The stresses imposed on punches during service are such that toughness is a much more important material requirement than wear resistance, although wear resistance cannot be ignored. Type A2, and sometimes the shock-resisting type S7, are preferred for punches. Wear-resisting grades such as D2 and CPM 10V often lack the required toughness, particularly for solid punches. In type A2, which is deep hardening upon air quenching, an as-quenched hardness of 60 HRC can be developed in the center of a section 125 mm (5 in.) square, even though a solid punch this large would seldom be used. In contrast, for type S7 the maximum section size in which such hardness can be obtained is 65 mm ($2\frac{1}{2}$ in.) square. If sections >125 mm (5 in.) square are required, type A2 should be oil quenched from the austenitizing temperature to ~ 540 °C (1000 °F), then air quenched to 65 °C (150 °F) before tempering. S7 can be carburized or nitrided for added wear resistance.

For applications in which A2 or S7 punch faces become severely abraded, a more wear-resistant grade, such as CPM 10V, D2, D3, or M2, should be considered. Cemented carbide punches and core rods employ a higher cobalt grade ($\sim 11\%$ Co) with a hardness of ~ 90 HRA. They can be made of solid carbide or a composite that uses tungsten carbide in the wear areas. More recently, fine-grain carbides with 10 wt% Co have also been employed in these applications.

Core Rods. Both toughness and wear resistance are important criteria in the selection of core-rod materials, but generally the primary consideration is wear resistance. Tungsten carbide and high-speed steels (M-grades) are the most common materials for core rods. For particularly abrasive conditions, CPM 10V has been used successfully, as have D2, M2, and A2 tool steels that have been nitrided or coated with tungsten carbide. Crucible P/M (CPM) tool steel CPM 15V has recently become popular for these applications.

Tooling support adapters normally are made from medium-carbon alloy steel, such as AISI/SAE 4140 or 6150, heat treated to a hardness sufficient to resist brinelling of the punches into the adapter surface without failing due to fatigue. Adapters should be heat treated to a minimum hardness of 28 to 32 HRC to reduce damage to critical mounting surfaces during handling.

Punch clamp rings normally are not highly stressed members, but they should be made from a heat-treatable steel to prevent damage during handling. Heat treating of the clamp ring is optional.

Operational Factors. Die working surfaces and core rods should be polished or lapped to a mirror-like surface finish, and final polishing should be done in a direction parallel to the axis of the tool. The faces and lands of the punches should also be given a fine finish. An exceptionally smooth surface finish reduces friction, thereby reducing some of the load on the tooling. It also makes it easier to eject the compacts, and it eliminates minute scratches and other stress raisers that could lead to premature fatigue failure.

Hard chromium plating is sometimes recommended to improve the life of tool steel punches and core rods, particularly when abrasive powders are involved. Some users claim that nitrided or chromium-plated die parts have up to ten times the wear resistance of untreated tool steel die parts; others claim that chromium plating is not very effective. Both nitrided and chromium-plated die parts are subject to chipping or flaking, especially at sharp edges. When this is a problem, a diffused surface layer such as that produced by chromizing may prove to be an effective alternative.

Tooling Clearances and Design

As in many other manufacturing operations, process variables (e.g., the type of materials being processed, the density of the part being produced, the amount and type of powder or die lubrication, and production rate) dictate operating conditions. Density and production rate greatly affect tool clearances during a continuous production run in which tooling temperature increases as compacted density and/or production rate increases. Temperature variations and corresponding dimensional changes within the various tooling members must be considered.

Standard tooling clearance is 0.016 mm/25 mm (0.0006 in./1 in.) on the diameter total. Minimum clearance should be used initially, because materials can always be removed from the punch or die to provide additional clearance as needed. In addition, the clearances must be smaller than the size of the powder particles to prevent their entrapment. Smaller clearances will also help reduce possible variations in the dimensions of the parts. The density of the compact produced and the production rate have a great influence on the determination of clearances. Compacting loads will be higher for increased densities. These, as well as higher production rates, increase the tooling temperature. As the temperature increases, dimensional changes occur in the tooling members. For this reason, the clearances must be sufficiently large to prevent seizure of the tools.

A representative value for the clearances between die walls and punches is 0.005 to 0.008 mm for precision parts and an upper limit of 0.013 mm for other parts. Minimum possible clearance should be used initially, because it can be increased as needed by removing material from the punch or the die.

The expansion ("pop out" or "springback") of the compact upon ejection makes it essential that the top edge of the die cavity be properly rounded or flared to allow the compact to make a smooth transition during ejection. Provision of a shallow chamfer is a more practical solution in the case of gears.

Die cavities and punch faces should be lapped and polished to a very high degree of surface finish, preferably $<0.25 \mu\text{m}$.

Shapes and Features. A shape or feature can be die compacted provided that it can be ejected from the tooling and the tools that form the feature have sufficient strength to withstand the repeated compaction loads. Due to the vertical closure of the tooling and the lack of tool motions perpendicular to the pressing direction, part removal from the tools controls many features. Examples of features that cannot be accommodated in die compaction, and therefore require secondary machining operations, include undercuts, reverse taper (larger on bottom than on top), annular grooves, and threads. The following guidelines provide assistance with many possible features in die compaction. Further details are provided in Ref 3.

Wall Thickness. Minimum wall thickness is governed by overall part size and shape. For parts of any appreciable length, walls should be not <1.5 mm (0.060 in.) thick. A maximum length-to-wall thickness ratio of 8 to 1 should be followed to ensure reasonable density uniformity and adequate tool life. Separate tool members (punches) should be used to provide density uniformity and proper ejection.

Steps. Simple steps or level changes not exceeding 15% of the overall part height (H) can be formed by face contours in the punches. A draft of 5° or more is needed to release this contour from the punch face during ejection. Features such as countersinks and counterbores can be similarly formed. This tooling method, as compared to multiple punches, will result in slight density variations from level to level. However, this approach offers the simplest tooling, lower-cost tooling, and closer axial tolerances than multiple punches.

Spherical Shapes. Complete spheres cannot normally be made because the punches would have to feather to zero width (Fig. 17). Spherical parts require a flat area around a major diameter to allow the punch to terminate in a flat section (Fig. 17). Parts that must fit into ball sockets are repressed after sintering to remove the flats.

Fig. 17 Proper design of spherical shapes in P/M parts. Source: Ref 3

Taper and Draft. Draft is not generally required or desired on straight-through parts. While tapered side walls can be produced where required, the tools may demand a short straight surface (A in Fig. 18) at the end of the taper to prevent the punch from running into the taper in the die wall or on the core rod.

Fig. 18 Tapered hole design for P/M parts. Source: Ref 3

Holes. Through holes in the pressing direction are produced with core rods extending through the punches. Round holes require the least expensive tooling, but many other shapes, such as splines, keys, keyways, D-shapes, squares, and so forth can readily be produced. Blind holes, blind steps in holes, and tapered holes, are also readily pressed. For very large parts, lightening holes are added to reduce weight and the area of compacted surface.

Flanges. A small flange, step, or overhang can be produced by a shelf or step in the die. Separate lower punches are used if the amount of overhang becomes too great to permit ejection without breaking the flange.

Alphanumeric Characters. Numbers, lettering, logos, and other characters can be pressed into surfaces oriented perpendicular to the pressing direction. Recessed lettering is preferred because raised letters are fragile, easily damaged in the green compact, and prevent stacking of parts for sintering.

Chamfers, Radii, and Bevels. Chamfers are preferred rather than radii on part edges to prevent burring. It is common practice to add a 0.25 mm (0.010 in.) flat at a 45° chamfer; lower chamfer angles may not require the tooling flat.

Hubs and Bosses. Hubs or bosses that provide for drive or alignment rigidity in gears, sprockets, and cams can be readily produced. However, the design should ensure the maximum permissible material between the outside diameter of the hub and the root diameter gear or sprocket features.

Other Features. Additional information on these and other features (slots, grooves, knurls, studs, fillets, countersinks, etc.) can be found in Ref 3. Because shape complexity is a recognized limitation of die compaction, multipiece assembly is a useful alternative, especially where extensive machining would be required. Pulleys, spools, and sprockets have been produced using sinter bonding, brazing, and welding techniques.

Powder Injection Molding

Randall M. German, The Pennsylvania State University

Introduction

INJECTION MOLDING is widely recognized as a manufacturing approach that can form complicated shapes from plastics. Since the 1920s, there has been a progressive evolution of injection molding from strict use on plastics to use with metal and ceramic powders. This new technology, known as powder injection molding (PIM), combines the productivity of injection molding with the ability to fabricate metals and ceramics. Thus, complicated shapes emerge from materials capable of operating at high temperature, or from materials that have desirable electrical, thermal, optical, or magnetic properties not available with polymers.

Much interest exists in PIM because of five key features: low production costs, shape complexity, tight tolerances, applicability to several materials, and high final properties. Many successful applications rely on particular combinations of these attributes. Examples include orthodontic brackets for straightening teeth, porous filters for treating hot waste water, magnets for controlling computer disk drives, small gears for electric hand tools and toothbrushes, cleats on sporting shoes, surgical tools such as scalpels, electrical connectors, handgun components, eyeglass and wristwatch components, golf clubs, and microwave filters for high-frequency microelectronics.

The technology has undergone widespread commercialization since the 1980s and today is practiced in many variants, reflecting different combinations of powders, binders, molding techniques, debinding routes, and sintering furnaces. An outline of the core production sequence is given in Fig. 1. In this simple form, four steps are required: formation of the feedstock, molding into the tooling, binder removal, and sintering.

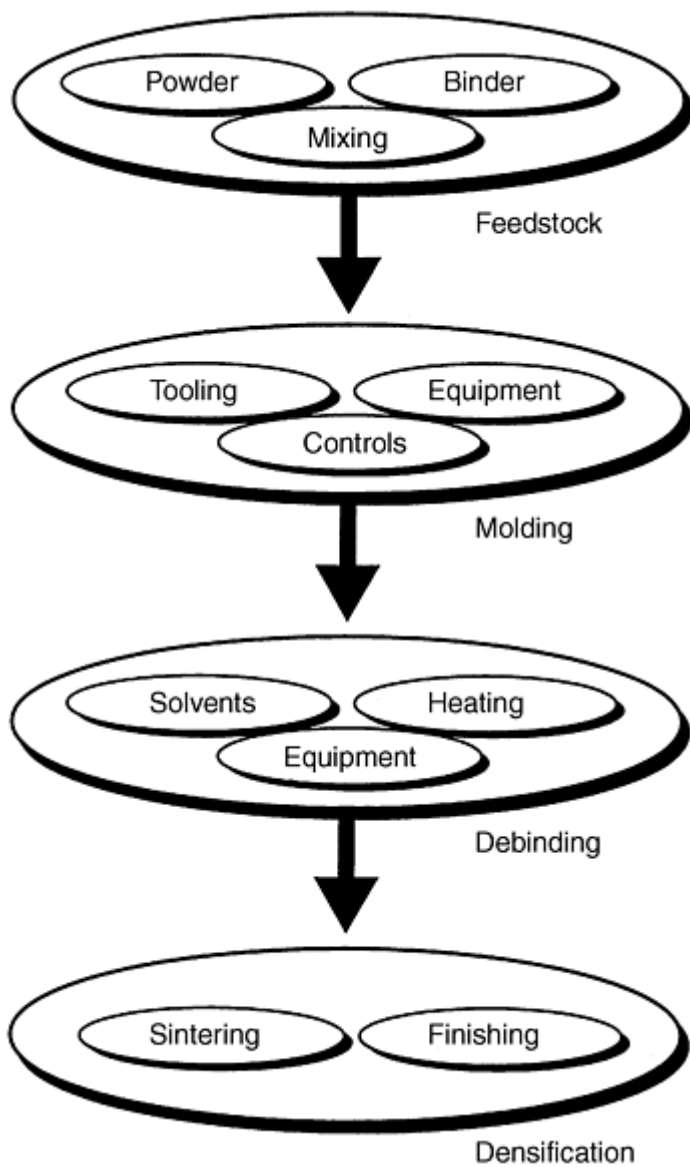

Fig. 1 Flow chart for the major activities making up the powder injection molding process. Processing tends to divide the operations into four major segments.

As schematically illustrated in Fig. 2, the first step in the production sequence is to combine a small quantity of a polymer with the powder to form a feedstock. A thermoplastic polymer is selected to provide flow upon heating in the molding machine. Feedstock for the process is formulated by mixing small powders and thermoplastic binders to form pellets that easily flow in a molding machine. Today there are several suppliers of these precompounded feedstock pellets in a wide variety of compositions. These feedstock pellets are molded into tooling that defines the shape. Once the polymer is heated the mixture can flow by viscous flow. After molding, the binder is removed (debinding) and the remaining powder structure is sintered. These last two steps can be combined into a single thermal cycle because significant shrinkage is associated with sintering. The sintered product may be further densified, heat treated, coined, plated, or machined to complete the fabrication process. Most important, the sintered component has the precision of plastic injection molding in materials that deliver properties unattainable from polymers.

Fig. 2 A flow sketch of the powder injection molding process, showing the fabrication of a component from the original binder and powder, which are combined to form feedstock, then molded, debound, and sinter densified to produce the final component

Powder Injection Molding

Materials and Equipment

Feedstock. PIM begins with the mixing of selected powders and binders. The particles are small to aid sintering, usually between 0.1 and 20 μm with near-spherical shapes. For example, a 5 μm carbonyl iron powder is widely used in the PIM process, as is a -16 μm gas-atomized stainless steel powder. Most common engineering alloys are used,

including various steels, tool steels, and stainless steels. Likewise, ceramics, refractory metals, and cemented carbides are processed in a similar manner. The binder is based on a common thermoplastic such as wax or polyethylene or wax-polypropylene, but food-grade polymers, polyacetal, cellulose, gels, silanes, water, and various inorganic substances are also in use. Usually the binder system consists of two or three components. An example binder, which is molten at 150 °C, consists of 65% paraffin wax, 30% polypropylene, and 5% stearic acid. A typical binder content is near 40 vol% of the mixture; for steel that corresponds to about 6 wt% binder. A few other binder systems are:

- 90% polyacetal, 10% polyethylene
- 69% paraffin wax, 20% polypropylene, 10% carnauba wax, 1% stearic acid
- 75% peanut oil, 25% polyethylene
- 50% carnauba wax, 50% polyethylene
- 55% paraffin wax, 35% polyethylene, 10% stearic acid

Feedstock is a term for the mixture of powder and binder. Many types of powders can be used, but great differences exist in mixing and molding, especially if the particle shape is nonspherical. The formulation of a successful feedstock balances several considerations. Sufficient binder is needed to fill all voids between particles and to lubricate particle sliding during molding. A viscosity similar to that of toothpaste is generally most desirable. Mixing is best achieved using a continuous twin screw compounder. Actually the viscosity depends on several factors. At too high a powder-to-binder ratio there is a high viscosity and insufficient binder to fill all void space between the particles. Consequently, it is hard to mold such a feedstock. Alternatively, too much binder is undesirable because component shape is lost during debinding. Inhomogeneities in the feedstock lead to defects in molding; thus, a high shear is required in mixing to force the binder among all particles. Consequently, special mixing practices are required to compound feedstock for most applications. The final step in feedstock preparation is to form pellets that are easily transported to the molding machine. Figure 3 shows both worms and pellets formed for molding. An important evolution in the technology has been the preparation of feedstock by major chemical companies, removing some of the licensing and technological barriers, allowing rapid growth in the field. Table 1 details the composition of a few common injection molding feedstocks, showing the binder, powder, and formulation details.

Table 1 Examples of powder injection molding feedstock

Powder	Binder, wt%	Solids loading, vol %	Density, g/cm ³	Molding temperature, °C	Viscosity, Pa · s	Strength, MPa
4 μm Fe	60PW-40PE	58	4.90	120	35	5
4 μm Fe	55PW-45PP-5SA	61	5.12	150	19	22
4 μm Fe-2Ni	90PA-10PE	58	4.52	180	190	20
2.5 μm Mo	60PW-35PP-5SA	58	5.97	113	200	7
10 μm stainless	55PW-45PP-5SA	67	5.60	130	100	15
15 μm stainless	90PA-10PE	62	5.33	190	80	20
12 μm tool steel	90PA-10PE	62	5.33	190	180	20

Fig. 3 Feedstock pellets and worms for molding

Pelletized feedstock is injection molded into the desired shape by heating it in the molding machine and hot ramming it under pressure into the tool cavity. By virtue of the binder, the feedstock becomes low enough in viscosity that it can flow into the die cavity under pressure. Cooling channels in the die extract heat and solidify the polymer to preserve the molded shape. The shaping equipment is the same as that used for plastic injection molding. It consists of a die filled through a sprue, runner, and gate from a heated barrel. Most popular is molding in a reciprocating screw machine. Here the screw in the barrel stirs the feedstock while it is melting and acts as a plunger to generate the pressure needed to fill the die. In the actual molding stroke, the molten feedstock is rammed forward to fill the cold die in a split second. Molding pressures depend on several parameters, but might be 60 MPa or more. Pressure is maintained on the feedstock during cooling until the gate freezes to reduce the formation of sink marks and shrinkage voids. After cooling in the die, the component is ejected and the cycle is repeated.

Tooling. The tool materials used in PIM are similar to those encountered in many metal working, plastic injection molding, and powder metallurgy operations. Table 2 identifies some of the common tooling materials. The tool material choice depends on the anticipated number of molding cycles and the required wear resistance. On the one hand, machining difficulty and material costs need to be considered. For molding tools, P-20 is the most common material, because of the combination of strength and cost. Yet wear concerns with PIM make the selection of higher-hardness tool steels most common. Rapid prototype tool materials, including epoxy, have been used in pilot production. Soft alloys of aluminum, zinc, or bismuth are used during tool development because of easy machining. Cemented carbides are useful where wear is a primary concern, but tool fabrication is expensive and tool damage is a problem because of the low toughness. Material cost varies by a factor of ten between these materials. Tool steels are best because of the combined strength, toughness, hardness, and machinability.

Table 2 Construction materials for injection molding tools

Material	Composition	Hardness, HRC	Suggested applications
420 stainless	Fe-14Cr-1Si-1Mn-0.3C	50	Corrosion-resistant cavities, cores, inserts
440C stainless	Fe-18Cr-1Si-1Mn-1C	57	Wear-resistant, small inserts, cavities, cores
H13 tool	Fe-5Cr-1.5Mo-1Si-1V-0.4Mn-0.4C	50	Larger or intricate cavities, high toughness, low wear
M2 tool	Fe-6W-5Mo-4Cr-2V-0.3Mn-0.8C	61	Core and ejector pins
P20 steel	Fe-1.7Cr-0.8Mn-0.5Mo-0.4V-0.35C	30	General purpose, hot runner, large cavities
Cemented carbide	WC-10Co	80	High wear, compressively loaded small inserts

Tool fabrication occurs in a machining center via progressive removal of material from an initially oversized block of material. Most machining is computerized, but there is still the necessity to hand-finish critical components or dimensions in the tool set. A final surface roughness of 0.2 μm (8 $\mu\text{in.}$) is typical, but smoother finishes are used in selected applications. The desired tool hardness is typically more than 30 HRC, which is satisfied by many heat-treated stainless steels or tool steels. Under normal conditions, an injection molding tool set can mold up to one million parts. With soft tool materials like aluminum, the life is less, at 1,000 to 10,000 cycles.

The tool set has the cavity and further consists of the pathway for filling the cavity with ejectors for extracting the component from the cavity. In most instances, the tool set consists of a single cavity. This cavity captures the component shape, and it is oversized to allow for component shrinkage during sintering. Around the cavity are several tool parts needed for opening and closing the cavity, ejecting the component, aligning the die sections, moving inserts, cooling the component, and locating the sprue, runner, and gate. Figure 4 is a sketch of a molding tool set with ejector pins, ejector plate, and keyed slides to ensure proper closure of internal die components. Many operations use a three-plate mold for automated removal of the gate on mold opening.

Fig. 4 A sketch of the tool set for powder injection molding, showing major components

A primary concern in designing injection molding tooling is component shrinkage. On a volume basis, the typical feedstock contains 60% solid and 40% binder. To attain the desired final component properties, the linear shrinkage during sintering may be 15%. The shrinkage in dimensions is known as the shrinkage factor Y , calculated from the solids loading, Φ , and the sintered fractional density, ρ/ρ_T :

$$Y = 1 - \left(\frac{\Phi}{\rho/\rho_T} \right)^{1/3} \quad (\text{Eq 1})$$

where ρ is the final density and ρ_T is the theoretical density for the material. This assumes isotropic shrinkage in sintering. For example, if a 13.8 mm dimension shrinks to 12 mm, then the shrinkage factor is 0.13 or 13%, calculated as the change in a dimension divided by the original dimension. Because the target is the final component size, each dimension of the tool cavity is oversized to accommodate shrinkage. If the desired final dimension is L_f at a fractional density ρ/ρ_T from a feedstock with a fractional solids content of Φ , then the initial dimension of the tooling is given in terms of the tool cavity expansion factor, Z :

$$Z = \frac{1}{1 - Y} \quad (\text{Eq 2})$$

As an example, if the shrinkage factor Y is 0.15 (15% shrinkage), then the tool expansion factor Z is 1.1764. Thus, to obtain a 12 mm final dimension requires a tool dimension of 14.11 mm (12×1.1764). Note that the shrinkage from 14.11 mm to 12 mm is 2.11 mm, so the measured shrinkage factor is $2.1 \div 14.11$ mm, or 0.15 (15%).

At the end of the runner is the gate leading into the die cavity. It is a small opening designed to freeze before the cavity, runner, or sprue freezes. A solidified gate allows removal of the pressure at the machine while the mass in the cavity cools. Gates are usually near 3 mm in diameter. Actual gate size is determined by two factors: the filling shear strain rate and the section thickness. For the gate to freeze before the compact requires a thickness between 10 and 50% of the compact thickness.

In the typical tool set, the feedstock flow path is from the molding machine nozzle into the sprue, along the runner, through the gate, and into the mold cavity, as evident in the test geometry shown in Fig. 5. This five-step geometry has two gates fed by the runner system from the sprue. This flow path is surrounded by various clamping plates, alignment and locating pins, and ejector components. Alignment of the components and their proper sequencing and smooth motions are important to successful PIM. Most of the tool components are available as premachined packages, so only the cavity needs to be custom machined. Also, within this geometry are the cooling or heating networks designed to control mold temperature. One key advantage of injection molding is the ability to fabricate complex shapes that cannot be produced by alternative techniques. Accordingly, complex tool designs are a necessary aspect of injection molding.

Fig. 5 A five-step test geometry with dual gates attached runner and sprue

The number of cavities in the tool set depends on the number of components to be fabricated, the shot capacity of the molding machine, tool fabrication costs, and the available clamping force. Tool sets with up to 40 cavities have been used for high-volume production. Most injection-molded steel components are generated in tool sets with 1 to 16 cavities. A single cavity tool set is satisfactory for low production quantities, below about 200,000 parts. As higher productivity is required, more cavities may be justified, because production increases are gained without the purchase of new molding machines. As the number of cavities increases, the cost of manufacturing the tool set increases, but the net production cost per component decreases. Because tool cost is distributed over the production quantity, there is a minimum total cost that depends on the total production quantity increases.

After molding, the component is cooled in the die cavity. Cooling causes the binder to contract and this results in a progressively lower pressure, eventually allowing ejection of the part. The ejection force depends on the component shape and feedstock. To accomplish ejection, pins in the die body move forward with the ejector plate and push the component from the cavity. If inserts, internal cores, or threads are put into the shape, these must be retracted (possibly by motorized motions) to allow free ejection. Sometimes core pins, inserts, or other features are placed in the cavity before filling and these items become encapsulated in the part, ejecting out on each cycle. Ejector pins blemish the component, because they concentrate ejection force on a soft material. Some of the blemishes associated with molding include ejector pin marks, parting lines, and gate impressions.

For ejection, pins move from flush positions on the tool walls and push against the component to extract it from the cavity. To build in undercuts or holes perpendicular to the molding direction, the tooling must contain side-actuated cores or inserts. Using rotating cores to create threads or rifling patterns without a parting line is also possible. Unlike die compaction, in injection molding it is possible to design into the tooling perpendicular holes, undercuts, and indents using side cores that are mechanically actuated on mold opening and closing. A tool set can contain several such cores, which may be actuated using hydraulic pistons, electric motors, or mechanical motions.

Molding Machines. The three most common molding machines are reciprocating screw, hydraulic plunger, and pneumatic. Table 3 summarizes the attributes of a few such molding machines. Pneumatic machines simply apply gas pressure to move heated feedstock into the mold. They are inexpensive and effective for small components where internal flaws are not objectionable. However, voids form because the feedstock is under low pressure that fails to compensate for shrinkage on cooling. In a hydraulic molding machine, a plunger rams heated feedstock into the mold. Excess pressure is generated to compensate for the volume contraction normally encountered by feedstock cooling. This pressurization is important to forming defect-free compacts, but the control systems usually are not suitable for forming complicated shapes.

Table 3 Sample attributes of powder injection molding machines

Attribute	Low pressure	Moderate tonnage	Intermediate tonnage	High tonnage
Type	Pneumatic	Reciprocating screw	Reciprocating screw	Reciprocating screw
Clamping force, ton	0.7	25	75	200
Clamp type	Pneumatic	Hydraulic	Toggle	Hydraulic
Platen size, mm	480	260	530	900
Drive motor, kW	2	5.5	15	30
Screw diameter, mm	None	18	28	50
Injection volume, cm³	3000	35	70	350
Fill rate, cm³/s	0.5	46	66	100
Injection stroke, cm	...	9	11	14
Plastication capacity, kg/h	...	12	20	40
Screw speed, mm/s	...	110	300	110
Molding pressure, MPa	0.5	190	230	200
Shortest cycle time, s	4.8	2	1.2	3.6
Maximum temperature, °C	150	200	200	200
Control	Open-loop	Adaptive	Closed-loop	Adaptive

High-volume injection molding uses a horizontal reciprocating screw located inside a heated barrel. The screw is designed to compress and transport the feedstock to the die, and it becomes a plunger during mold filling. Figure 6 is a typical layout of a horizontal machine and Fig. 7 is a picture of a contemporary molding machine with vision system, robot, process controller, and data acquisition computer. The tooling is clamped in the center of the machine. The

granulated or pelletized powder-binder feedstock is placed in the hopper for metering into the injection barrel. This is the beginning of the molding operation.

Fig. 6 Overview of a horizontal injection molding machine and key components

Fig. 7 Picture of a research injection molding machine with attached vision system, robot, data acquisition computer, and control computer

The heart of molding lies with the motions of the reciprocating screw. This needs to be wear resistant to withstand abrasion by the particles. It has a helical pitch, the design of which is adjusted for the viscosity of the feedstock, but generally it consists of gradual section changes along its length. Screw rotation is controlled via a hydraulic motor and heat is supplied by external heaters on the barrel.

An important role of the screw rotation is to de-air the feedstock and prepare the next charge for injection. This is termed *metering*, where the screw rotates to pressurize feedstock to the nozzle. During metering the screw acts as a mixer to ensure uniform powder-binder distribution and uniform heating. The screw has a check ring behind the tip that acts as a valve that allows feedstock flow into the front of the barrel. This ring seals on the screw during mold filling and forces molten feedstock to flow into the die cavity through the nozzle at the end of the barrel. Effectively, the screw becomes a plunger during mold filling. Control of the screw rotation, displacement, and pressure is important to the fabrication of precise components by injection molding.

During the molding cycle, the screw initially rotates, compressing the feedstock. Then, during the injection step, the screw moves forward, closing the check ring, and the shot is injected into the mold. A closed-loop control system with a

quick response servohydraulic valve is required for screw position and pressure control. During the fill stroke, the volume of feedstock injected into the mold depends on the cross-sectional area of the screw and on the stroke length. A typical screw diameter is 22 mm, but it might range from 15 to 40 mm (0.6 to 1.6 in.), depending on the machine capacity.

Feedstock flow in molding depends on the applied pressure and viscosity. For a cylindrical runner, the volumetric feedstock flow rate, Q , varies with the runner diameter, D , to the fourth power according to Poiseuille's equation:

$$Q = \frac{P \pi D^4}{128 \eta L} \quad (\text{Eq 3})$$

where P is the applied pressure on the feedstock, L is the runner length, and η is the feedstock viscosity. The rate of mold filling is very sensitive to the injection pressure and runner diameter. Usually a high feedstock flow rate is needed in order to fill the die before the feedstock cools.

The barrel holds the rotating screw and is surrounded by heaters that control the mixture temperature. There are often multiple heater zones to ensure temperature control during mold filling. Because cold feedstock is abrasive, the first heater zone is geared to rapidly heat the feedstock, and subsequent zones might be at lower temperatures. The materials used in constructing the screw and barrel are critical to long service without contamination. Hard materials and close tolerances are required to reduce abrasive wear. Tool steels containing vanadium carbide and boride-clad tool steels prove most durable. Similarly, other machine components in the flow path can exhibit considerable wear, resulting in a loss of machine control.

All of the molding steps are controlled by a computer that might even correct errors during molding. Besides the molding machine, coordination is required with the peripheral operations needed in automation schemes. For example, robots are used to stage the compacts for debinding. Other automation features include conveyor systems, parts and tooling storage with automated retrieval, and continuous feedstock preparation and component debinding steps.

Powder Injection Molding

Randall M. German, The Pennsylvania State University

Process Description

Molding Cycles. A typical sequence for the injection pressure and screw position are shown in Fig. 8. Prior to filling, the screw rotates in the barrel and the external heaters bring the feedstock to temperature. The dwell time for the feedstock in the barrel must be sufficient to ensure thorough and uniform heating. Then, during molding, the screw plunges forward in a split second. This is traced by the screw displacement curve in Fig. 8. Three pressure curves are included to show that pressure is high at the source (hydraulic pressure) and lags at the cavity. The rapid rise in hydraulic pressure induces feedstock flow into the mold. Once the cavity is filled, the gate freezes and there is little effect of hydraulic pressure on the cavity pressure. The nozzle pressure is intermediate between these two.

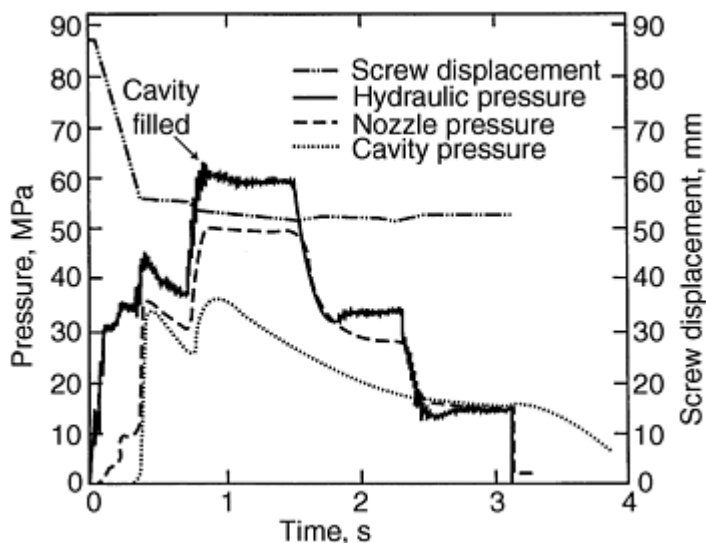

Fig. 8 Plots of the screw position and pressures involved in molding

Moldability is a measure of the ease by which a feedstock can be shaped to a given specification. A high moldability is desired from a feedstock. In practice, several combinations of temperature, fill rate, and pressure exist that produce defect-free components. This pressure is generated by the forward motion of the screw in the barrel as a plunger. A low pressure gives incomplete packing with cavities or sink marks on the compact surface. Excessive packing pressure causes the compact to stick in the die, resulting in severe ejection problems.

To compensate for the flow resistance and pressure gradients in the molding system, the screw position and hydraulic system pressure vary during molding in a coordinated manner. Friction along the flow path decreases pressure. After mold filling, pressure is held during the packing stage. The objective is to compensate for the thermal contraction of the feedstock during cooling. Finally, when the binder has sufficiently cooled to hold the component shape and withstand the ejection forces, the die is opened and the component is ejected. The ejector motion can be from the hydraulic system or a separate mechanical motion.

The time for molding relates to the cavity size, filling time, and cooling time. It can be as short as 5 s or as long as 1 min. Initial feedstock flow requires that the molding temperature be higher than the softening point of the binder. This is usually between 50 and 200 °C (122 to 392 °F). A low temperature results in short shots (incomplete mold filling), while a high temperature degrades the binder or causes flashing or powder-binder separation, and requires prolonged cooling. Molding pressure affects the mold filling rate and is usually limited by the machine design. Once the component has cooled, the final step is component ejection. Short shots occur if either the molding temperature or pressure is too low. At the higher pressures and temperatures the components stick to the die walls or open the die along the parting line, giving flash. Voids are captured in a part if the feedstock shoots across the cavity without pushing out all of the air. This is termed *jetting* and is very undesirable. Jetting occurs with too high a fill rate, so most molding machines are programmed for a fill rate that prevents jetting.

Table 4 gives the range of molding conditions and one example of a specific component and its molding conditions. That component is a steel trigger guard for a rifle formed from carbonyl iron powder and a binder based on paraffin wax, polypropylene, and stearic acid. Once the component is molded, the polymer binder phase is extracted and the compact is sintered to near-full density. These steps are covered in the sintering articles in this Volume.

Table 4 Typical powder injection molding parameters

Parameter	Typical range	Trigger
Barrel temperature, °C	100-200	160
Nozzle temperature, °C	80-200	180
Mold temperature, °C	20-100	40
Screw rotation speed, rpm	35-70	35
Peak injection pressure, MPa	0.1-130	20
Packing pressure, MPa	0-10	8
Fill time, s	0.2-3	0.6
Packing time, s	2-60	3
Cooling time, s	18-45	20
Cycle time, s	8-360	37

Densification. Usually the binder is removed from the component prior to sinter densification. A wide array of options exist for binder extraction. Thermal debinding is the easiest to envision. The component is slowly heated to decompose the binder. As illustrated by Table 5, many variants exist. There are some differences in component precision and debinding rates. For this tabulation, the measured rates are compared on an equivalent basis of 5 μm steel powder and 10 mm section thickness. The most popular approach is to immerse the component in a solvent that dissolves some binder, leaving some polymer behind to hold the particles in place for subsequent handling. The remaining binder is thermally extracted as part of the sintering cycle. Newer binders are water soluble, so the debinding solvent is water. Major growth is occurring in the use of catalytic phase erosion for debinding. Most of the binder is attacked by a catalytic vapor, and the residual binder is removed during heating to the sintering temperature. This can now be performed as a continuous process at the beginning of sintering. Debinding is highly variable as to binder system, technique, and section thickness. Solvent and catalytic debinding ensure the best dimensional control, because the binder is kept rigid during extraction. For these techniques penetration rates of 1 to 2 mm/h are common.

Table 5 Comparison of debinding techniques and times

Binder system	Debinding technique	Conditions	Time
Wax-polypropylene	Oxidation	Slow heat 150 °C, hold, heat to 600 °C in air	60 h
Wax-polyethylene	Wicking	Slow heat to 250 °C, hold, heat to 750 °C in hydrogen	4 h
Wax-polymer	Supercritical	Heat in freon vapor at 10 °C/min to 600 °C under 10 MPa pressure	6 h
Wax-polyethylene	Vacuum extraction	Slow heat while passing low-pressure gas over compacts, heat to sintering temperature	36 h
Water-gel	Vacuum sublime or freeze dry	Hold in vacuum to extract water vapor from ice	8 h
Oil-polymer	Solvent immersion	Hold in ethylene dichloride at 50 °C	6 h
Water-gel	Air drying	Hold at 60 °C	10 h
Polyacetal-polyethylene	Catalytic debind	Heat in nitric acid vapor at 135 °C	4 h

Note: Section thickness, 10 mm; particle size, 5 μm ; solids loading, 60 vol%

The next step is sintering, which can be incorporated directly into a thermal debinding cycle. Sintering bonds the particles together, leading to densification. Often sintering serves the dual role of densification and chemical homogenization. In the latter process, mixed powders are molded and sintering causes them to form homogeneous alloys by long-range atomic motion. Usually sintering shrinkage is uniform and isotropic, so the molded component is oversized to deliver the desired final dimensions. For metals, sintering is performed in a protective atmosphere or vacuum at a peak temperature that causes rapid elimination of the pores that were previously filled with binder. Steels and stainless steels are sintered at 1120 to 1350 °C range for 30 to 120 min, with shrinkages of 12 to 18%. Table 6 details some common sintering cycles, giving the initial green density, heating rate, maximum temperature, hold time, sintering atmosphere, support material, and final density. If the powder structure is formed homogeneously, then sintering is uniform and final dimensions can be held to close tolerances.

Table 6 Sample sintering cycles for powder injection molding materials

Material	$D, \mu\text{m}$	$\rho_G, \%$	$dT/dt, ^\circ\text{C}/\text{min}$	$T, ^\circ\text{C}$	t, min	Atmosphere	Support	$\rho_s, \%$

D , particle size; ρ_G , green density; dT/dt , heating rate; T , sintering temperature; t , time; ρ_s , sintered density

After sintering, the component has excellent strength, with properties near or even superior to those available from other processing routes. Final densification can be assisted by both hot and cold deformation, including hot isostatic pressing. Other post-sintering steps include coining, drilling, reaming, machining, plating, passivation, and heat treatment. Options in heat treatment include tempering, precipitation hardening, nitriding, and carburization.

A typical PIM component is a trigger guard for a sporting shotgun, the curved piece that surrounds the trigger below the barrel. It is fabricated from a low-alloy iron-nickel steel, usually with a final weight of 40 g. A mixture of 5 μm Fe and 8 μm Ni powders are used. These are combined with wax and polyethylene to form feedstock that can be molded at 58 vol% solids. During molding, the nozzle temperature in the molding machine is 175 $^\circ\text{C}$ with a die temperature of 40 $^\circ\text{C}$. The maximum pressure applied during mold filling is 20 MPa and a pressure of 8 MPa is held on the feedstock during cooling. The mold filling time is rapid (about 0.5 s), but the mold cooling time is 18 s, with a total cycle time of 37 s between parts.

Powder Injection Molding

Randall M. German, The Pennsylvania State University

Advantages and Limitations

Process Attributes. As emphasized already, PIM can produce a range of components from powders. A main attraction is the economical production of complex parts from high-performance materials. Because of the high final density, the PIM products are often superior to those produced by other powder fabrication routes. Most materials are available, including all common ceramics and alloys: steel, stainless steel, tool steel, silicon nitride, cemented carbide, silicon carbide, copper, tungsten heavy alloys, nickel-base alloys, alumina, cobalt-base alloys, and composites that include tungsten-copper and molybdenum-copper.

Besides the primary advantages of shape complexity, low cost, and high performance, several other attributes are worthy of notice. Producing both internal and external threads in the molded component is possible, thereby avoiding post-sintering machining. Also, waffle patterns and insignias can be molded directly into the component. Furthermore, the surface finish is typically good.

PIM vs. Die Compaction. Some confusion exists about the difference between PIM and traditional die compaction. The latter process is widely employed in forming powders into squat (low-height) shapes that can be ejected from compression tooling. Die compaction usually employs high forming pressures but gives less shape complexity. Most

important, uniaxial die compaction results in density gradients in the compact, unlike PIM, which is hydrostatic. Density gradients result in distortion during sintering. Consequently, components fabricated from pressed powder are either sintered at lower temperatures, where sintering shrinkage is avoided, or machined after sintering. Otherwise, dimensional scatter becomes unacceptably large. Because of forming pressure gradients, sintering temperature differences, and differing performance levels, PIM and traditional powder compaction are usually not applied to the same structures. The PIM approach is suited for complex shapes sintered to near-full density, while die compaction is suited to simple shapes, sintered at lower temperatures to lower performance levels. The low porosity in PIM materials gives a high strength, toughness, ductility, conductivity, magnetic response, and so on.

Advantages. Besides the traditional materials, PIM can also produce specialty materials such as nickel superalloys, intermetallics, precious metals, refractory metals, and ceramic-fiber reinforced ceramic composites. Co-molding is another possibility, where two materials are combined to make a laminated structure. Such components can be joined in the green condition. This option has merit for creating corrosion barriers, wear surfaces, electrical interconnections, or high-toughness structures.

For the producer, injection molding is a desirable option because of manufacturing ease, including process control, flexibility, and automation. Inherently, injection molding is associated with large production volumes. Various components are produced at rates approaching 100,000 per day. On the other hand, small production runs are possible, with as few as 5000 parts per year being economical. This flexibility fits well with the current desires for quick response in manufacturing.

As with all technologies, the essence centers on economics. Powder injection molding is cost advantageous for the more complex shapes. The largest advantage comes from the elimination of the secondary operations, such as grinding, machining, drilling, or boring, that typically are required for precision components. Also, since the feedstock material (runners, sprues, and damaged moldings) can be recycled, material use is nearly 100%. This is especially important for costly raw materials such as refractory metals, specialty ceramics, and precious metals.

Process Limitations. Generally, PIM is viable for all shapes that can be formed by plastic injection molding. Still, for shapes with simple or axial-symmetric geometries, it is not competitive with traditional screw machining or die compaction and sintering.

In some cases another limitation is the component size. Large components require more powder (a large expense in some compositions), and large molding and sintering devices, which are more expensive and difficult to control. Small components with simple geometries can be more economically produced by standard machining, die compaction, or casting techniques.

Debinding is a key problem with PIM because the time for binder removal depends on the section thickness. Consequently, various manufacturers have set upper limits on section thicknesses, ranging from 10 to 50 mm. On the other hand, PIM has been used to form section thicknesses less than 0.5 mm. In practice, dimensional tolerances are typically within 0.3% of a target, although holding tighter tolerances on critical dimensions is possible. For better dimensional control, machining or coining is required after sintering. Density gradients can result from uneven filling, thickness variations, or direction changes during molding, and they often cause component warpage in sintering. Thus, manufacturers minimize changes in section thickness and if possible hold the variation in thickness within a factor of two. However, 10- to 100-fold section thickness changes are possible. Maximum sizes depend on several factors, including tool costs, powder costs, and equipment capacities. Typically, the largest dimension is below 100 mm, with the total component volume being below 100 cm³. However, much larger components are in production.

The small particles used in PIM are more expensive than larger powders or wrought materials. This becomes a barrier to large component fabrication, because powder cost becomes a larger fraction of the production cost. On the other hand, as consumption increases, the powder cost continues to decline.

Substantial problems facing the technology are the lack of knowledge on the part of end users, missing property data, and the shortage of personnel trained in the basic process. These problems are acute with the ceramic materials because of the high sensitivity of ceramics to microstructural flaws induced during molding. Further, a lack of design guidelines has inhibited PIM from being adapted as a replacement for other production routes. These problems are being addressed via seminars and educational literature. However, the many process variants create initial confusion.

Design Guide

Certain component characteristics are best suited to PIM. Early identification of a match with these characteristics ensures technical and economic success. The considerations involve the materials, properties, component size and shape, tolerances, production costs, production quantity, and delivery schedule. Powder injection molding is best applied to the fabrication of complex, small components, especially those that would otherwise require multiple assembly or forming operations in alternative production routes. Further advantages occur when the material is expensive or difficult to process by alternative techniques. However, the shape complexity that can be produced is limited. Various shapes require secondary machining operations or complicated tooling that increase the manufacturing expense.

Tolerances are another concern. Precise tolerances prove difficult to achieve; production variations on a dimension are $\pm 0.1\%$ for special cases, and $\pm 0.3\%$ is more typical. Besides dimensional variability, successful component design must allow for noncritical placement of the parting line, ejector pin marks, and gate. It is also desirable to include a slight draft or taper of 0.5 to 2° to assist in ejection from the mold. Because precision tooling is expensive, the production quantity must justify the initial tooling cost. These factors need to be evaluated early to ensure feasibility. Greatest success is attained by early discussions of the manufacturing approach so that features can be incorporated that will aid PIM processing.

To emphasize the contemporary fabrication range, Table 7 summarizes the minimum, maximum, and typical features. Some explanation is in order. Components are characterized by the geometric aspects, including the largest dimension and the wall thickness. For PIM, the wall thickness is usually small, and it might be less than 10% of the largest dimension. Further, the variation in thickness over the part is usually small. The blades of scissors are an example where the length is much greater than the thickness, and the thickness is not highly variable. It is thickness that determines debinding time and is the main limitation of PIM.

Table 7 General criteria for powder injection molding

Attribute	Minimum	Maximum	Typical
Thickness, mm	0.2	25	10
Thickness variation	None	100×	2×
Longest dimension, mm	2	1,000	100
Tolerances, % (standard deviation)	0.03	2	0.3
Number of dimensional specifications	20	1,000	100
Mass, g	0.02	20,000	40
Material	Simple element	Composites	Alloys
Properties	Unimportant	Highest attainable	Handbook
Cost per part, \$	0.20	400	2
Production quantity per year	200	20,000,000	150,000

Another gage of PIM candidates is through the information content, which is akin to the number of dimensions on the engineering drawing. A simple shape, like a flat washer for a bolt, has only a few features, while a microcomputer circuit has many millions of features; both would be poor applications for PIM. Common PIM successes involve several dimensions in the 20 to 40 g range--a wristwatch case is one example that matches well with the technology. The typical mass is low, and similar attributes are evident in components for electronic packaging, computer disk drives, surgical tools, and firearms. On the other hand, metal, ceramic, and carbide bodies have been fabricated that are several kilograms in mass and up to 1 m in maximum length. These are somewhat lower-precision structures used in electric power turbines, steel mills, and furnace construction. The general production limit for precise components is 250 g, although several special processes have evolved to produce precise components as large as 1 kg.

Only in a few instances are mechanical or physical properties unimportant, such as in jewelry and wristwatch cases. More typically the goal is to attain near-handbook properties for the selected material. Likewise, only rarely are properties

pushed to the limits for any material. In these cases secondary hot isostatic pressing or other treatments might be employed to ensure maximum properties. From a cost consideration, typical prices are moderate, but that assumes a high production volume to justify the cost of tool construction, and dimensional tolerances that are compatible with the inherent process variability. Thus, a general processing window exists that proves most feasible. The typical parts are small enough to be held in a hand, but can be as small as the tip of a pencil. This implies that very large objects are difficult or expensive to produce by PIM, as contrasted with other forming technologies.

Geometric Considerations. In a simple sense, if a shape can be formed from plastic, then PIM is viable. Tables 7 and 8 provide general quantitative and qualitative component design guidelines.

Table 8 Nominal powder injection molding component design guidelines

<p>Restrictions</p> <ul style="list-style-type: none"> • No inside closed cavities • Corner radius greater than 0.075 mm • Smallest hole diameter 0.1 mm • Weight range 0.02 g to 20 kg • No undercuts on internal bores • 2° draft on long parts • Minimum thickness 0.2 mm
<p>Desirable features</p> <ul style="list-style-type: none"> • Gradual section thickness changes • Weight less than 100 g • Assemblies in one piece • Small aspect ratio geometries • Largest dimension below 100 mm • Wall thickness less than 10 mm • Flat surfaces for support
<p>Allowed design features</p> <ul style="list-style-type: none"> • Holes at angles to one another • Stiffening ribs • Protrusions and studs • D-shaped and keyed holes • Hexagonal, square, blind, and flat bottom holes • Knurled and waffle surfaces • External or internal threads • Part number or identification in die

The particle size is a dictate for the minimum section thickness. The powder size needs to be less than one-tenth of the smallest thickness. Particle size limits the sharpness of all corners, because the minimum particle radius is the edge radius, but more typically several particles are needed to fill out the dimension. A conceptual limit on an edge radius is 0.05 mm and a corner radius is 0.1 mm.

Table 8 also lists options in the design or production of PIM compacts. These options include square holes, flat-bottomed holes, knurled surfaces, faces, twists, curls, helical geometries, and external or internal threads. Although these features are not needed to make a PIM compact viable, they are possible and add to the design flexibility. Certain attributes, such as component size and mass, will increase as experience and manufacturing optimization occur. Already components up

to 10 kg and 1,000 mm maximum length have been fabricated by PIM. These require special efforts and are not routine products. With respect to changes in the section thickness, a ratio of 2 is typical; however, compacts have been successfully fabricated with thickness changes of 100:1.

Component design has a great influence on the success of PIM. Identification of injection molding as a production process in the design stage allows changes that increase the ease and lower the manufacturing cost. Possible design shifts that give essentially the same functional features are sketched in Fig. 9. Two alternatives are shown in each case. Both alternatives achieve the same design objectives, but one is better aligned with the specifics of the PIM approach.

Fig. 9 Recommended designs for powder injection molding components and suggestions for improved processing

Table 9 summarizes the minimum and typical tolerances possible in PIM processing without secondary operations. Generally, the ability to hold tolerances increases with production experience. With little effort, dimensional tolerances can be held within 0.5% (one standard deviation). A controlled process with solvent, wicking, or catalytic debinding allows dimensions to be held with a deviation of 0.3% or less, and critical dimensions can be held within 0.1%. With newer binder systems and integrated process controls these values can be improved to 0.05%. In the production of jet engine ceramic casting cores, the mass ranges from 10 to 1200 g and part lengths range from 2 to 50 cm. These cores are produced with final dimensional scatter of $\pm 0.05\%$ on length (one standard deviation) in production quantities over

50,000 per week. Larger dimensions exhibit more scatter. Fortunately, the component density can be held within $\pm 1\%$ and weight variation to $\pm 0.1\%$.

Table 9 Typical standard deviation of powder injection molding production components

Feature	Best possible	Typical
Angle	0.1°	2°
Density	0.2%	1%
Weight	0.1%	0.4%
Dimension	0.05%	0.3%
Absolute dimension	0.04 mm	0.1 mm
Hole diameter	0.04%	0.1%
Hole location	0.1%	0.3%
Flatness	0.1%	0.2%
Parallelism	0.2%	0.3%
Roundness	0.3%	0.3%
Perpendicularity	0.1% or 0.1°	0.2% or 0.3°
Average roughness	0.4 μm	10 μm

Powder Injection Molding

Randall M. German, The Pennsylvania State University

Materials and Applications

The availabilities of small powders that match the needed characteristics for molding determine the production materials used in PIM. Most of the classic engineering materials are available except aluminum, glass, lead, and tin. Typically ferrous alloys and alumina-base ceramics are used most often. For the stainless steels, the 316L composition is used frequently, because of its combined strength and corrosion resistance. Another favorite is 17-4 PH stainless steel, which is precipitation hardenable. Other compositions with more chromium are available, and for easier sintering, two-phase compositions that have high levels of molybdenum (up to 6%), chromium (up to 22%), or silicon (up to 3%) are preferred. These are sometimes called duplex stainless steels, because of the two-phase final microstructure. Stainless steels, iron-nickel compositions, and alumina are the materials most often used. Figures 10, 11, 12, 13, and 14 show a few examples of PIM components.

Properties. The properties attainable with PIM are generally equivalent to those possible via other production techniques. Although many PIM components are selected for thermal, optical, or wear applications, the bulk of the property evaluation has focused on mechanical properties. A few sample mechanical properties of PIM materials are given in Table 10. However, there is considerable variability. For example, there have been several reports on 316L stainless steel formed by PIM. Sintered densities ranged from 93 to 100% of theoretical, with a reported mean yield strength of 220 MPa, but a range from 170 to 345 MPa. The lowest strength occurred with the lowest density. Likewise, a range from 18 to 81% elongation has been reported, with a mean of 45% and a standard deviation of 17%. The scatter reflects variations between vendors, especially in controlling impurities such as carbon, oxygen, and nitrogen during debinding and sintering. These same impurities degrade corrosion resistance.

Table 10 Selected mechanical properties of powder injection molding metals and alloys

Material	Composition, wt%	Density, %	Yield strength, MPa	Ultimate tensile strength, MPa	Elongation, %	Hardness
4140 (HT)	Fe-1Cr-0.4C	93	1240	1380	2	40 HRC
4640 steel (HT)	Fe-2Ni-1Mo-0.4C	97	1400	2000	3	30 HRC

Tungsten heavy alloy	W-4Ni-1Fe	99	650	1000	20	50 HRA

HT, heat treated

In the Fe-2Ni steels, when the carbon level is almost zero the sintered yield strength is about 190 MPa and the fracture elongation is 30%. When the carbon level is increased to 0.5%, the heat-treated material has a yield strength of 1230 MPa with 1% fracture elongation. These dramatic shifts in strength and ductility are due to the retained carbon. For ductile

systems, the strength will typically have a standard deviation of 20 MPa and the elongation will have a standard deviation of approximately 1%.

The dynamic properties, such as fatigue and impact toughness, depend on the pore structure. In the case where the final pores are small and spherical, there is competitive resistance to crack propagation. Unfortunately, dynamic properties are not commonly tested. Early reports gave fatigue endurance strengths of 219 MPa for Fe-7Ni, 237 MPa for Fe-7Ni-0.5C, 575 MPa for 4640 steel, and 517 MPa for 17-4 PH stainless steel. Improved fatigue strength comes with case hardening. Hot tensile tests on PIM 316L stainless steel have shown a steady decline in strength as temperature increases, with yield strengths of 258, 177, 121, 71, and 62 MPa at temperatures of 180, 300, 500, 700, and 900 °C. The ductility remained fairly high, over 25% up to 900 °C.

Impact toughness tends to be low when measured with pre-notched samples, largely because of residual porosity effects on cracking. Fracture toughness has been evaluated for only a few PIM materials, but these are similar to more conventional processing routes.

Corrosion resistance of the PIM stainless steels is a concern. When properly processed without contamination, the PIM products are corrosion resistant, and they are often superior to wrought materials for thin sections. Corrosion is highly dependent on impurities, density, and final thermal cycles. However, as a simple generalization, often the sintered corrosion properties match or exceed the typical properties observed with alternative processing routes.

The soft magnetic characteristics are of interest for the ferrous systems such as iron, Fe-2Ni, Fe-3Si, Fe-0.45P, Fe-0.6P, and Fe-50Ni. Of these, the Fe-50Ni alloy has the most attractive combination of high magnetization and low coercive force. Experience shows considerable variability in the coercive force. Part of this variation is directly due to differences in sintered density, but impurity control is also a major factor. Like corrosion and strength, the magnetic characteristics are sensitive to contaminants in the compacts.

Economics. Cost is the critical parameter in determining the feasibility of PIM production. It depends on many factors, not the least being the initial tooling cost. Other factors include the number of cavities in the tool set, production quantity, powder cost, details of the fabrication steps, surface roughness, packaging requirements, labor rates, and required tolerances. The best applications for PIM involve high production quantities of complex parts formed from materials that are difficult to fabricate. A desirable production quantity is more than 50,000 per year, although at quantities over approximately 100,000 per year the tooling cost per compact is not significantly less, because of needed tooling refinishing. For production of 250,000 per year or more, the use of multiple cavity tooling is typical, and up to 16 cavities are typical. New products are planned to reach production rates of 300,000 to 500,000 per day. Current industry growth rates are near 22% per year, after reaching sustained rates of 32% per year through the 1990s.

Binder-Assisted Extrusion

David E. Alman and Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Introduction

BINDER-ASSISTED EXTRUSION is a plastic forming process in which a highly viscous feedstock, that is, a powder mixed with a binder and other rheology modifiers (also termed the paste), is forced through a die to form a shaped product. The binder-assisted extrusion process is used commercially to produce ceramic parts, such as furnace tubes, bricks, insulators, pipes, tiles, tubular capacitors, catalyst supports, magnets, heat exchangers, wires, and springs (Ref 1, 2, 3, 4, 5, 6, 7, 8). However, binder-assisted extrusion has also been used to fabricate metals and high-temperature superconductors (Ref 9, 10), as well as being a technique for aligning reinforcement in the processing of advanced composites (Ref 11, 12, 13). Depending on the powders being shaped, the extrusion process can be performed at room temperature with the utilization of a solvent-based binder, or at elevated temperatures with a plastic binder system.

The basic principles of binder-assisted extrusion are similar to powder injection molding (PIM) in that both processes consist of four very similar steps: (1) feedstock or paste preparation; (2) product shape forming (powder extrusion in one case, powder injection in the other); (3) binder removal; and (4) the consolidation step, that is, sintering. During the feedstock/paste preparation stage, the powders are mixed with the constituents of the binder to obtain the proper flow characteristics. Feedstock preparation may consist of several steps (e.g., dry mixing, wet mixing, and high-shear mixing) to remove agglomerations, to produce a uniform mixture, and to coat the powder particles with the binder. During the forming step, the feedstock/paste is extruded through the appropriately shaped die. At this point in the process, the part must possess enough structural integrity to be manipulated while maintaining its shape. In the finishing step the part is cut to size, dried, and thermally processed. Table 1 summarizes the steps generally followed in making a part using the binder-assisted extrusion process. Knowledge and control of each step in the process are crucial to the production of a sound part.

Table 1 Stages of binder-assisted extrusion

Processing stage	Purpose	Potential difficulties
Dry mixing	Uniformly mix all solid components	Regions of poorly mixed solids
Wet mixing (for solvent-based binders systems)	Uniformly distribute particles in liquid	Air entrapment; liquid rheology may prevent mixing; adherence to surfaces
High-shear mixing	Break down agglomerates; ensure binder surrounds individual powder particle	Binder--powder separation; incomplete deagglomeration
Degassing	Remove entrapped gas	Hard to achieve in some equipment
Extrusion	Shape feedstock	Binder--powder separation; excessive pressure drop; lamination flow defects between confluent streams; surface defects
Extrudate handling and cutting	Remove product from extruder and cut to desired length	Damage to weak product; surface damage; closure of internal holes during cutting
Binder removal	Remove binder; aid shape retention	Dry cracks from solvent-based binder system; incomplete binder burnout resulting in residual contaminants in product
Sintering	Generate strength in product; remove porosity	Temporary weakness in extrudate

Adapted from Ref 6

Binder-assisted extrusion differs from PIM in that the extrusion usually consists of a constant cross section. Although parts with complicated cross sections can be produced, a selection of which is shown in Fig. 1.

Fig. 1 Schematic of typical cross sections produced by binder-assisted extrusion. Source: Ref 2

Binder-assisted extrusion and its derivatives have many advantages and some important disadvantages when compared to other powder processing techniques, for example, powder compaction in dies, isostatic pressing, slip and tape casting, and so forth. According to Benbow and Bridgwater (Ref 6), the primary advantages of using the binder-assisted extrusion processes include:

- The formation of complicated cross sections
- The small amount of binder/liquid added to the solids
- The ability to shape very hard powders
- A uniform density distribution
- The construction of long, thin sections
- Competitive capital and operating costs relative to other processes

The disadvantages include:

- The final structure is dependent on the powder properties.
- The strength is not imparted during the extrusion process itself.
- Structural defects may be introduced.
- Structure or strength are not generally adjustable by changing the extrusion conditions.
- Binder and rheology modifiers can adversely affect product properties, and the rate at which the binder and rheology modifiers can be removed from the extrudate is slow.

Binder-Assisted Extrusion

David E. Alman and Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Feedstock/Paste

The feedstock, or paste, is the moldable material that is subsequently used to make the part. It is important that during preparation the feedstock is able to retain its shape long enough to allow handling and further processing. Correct feedstock formulation and preparation is thus crucial for a defect-free, successful extrusion. The required characteristics of the feedstock include the following (Ref 2):

- The feedstock must be sufficiently plastic to flow under pressure into the desired cross section, while retaining enough rigidity to resist deformation due to its own weight, that is, slumping.
- The feedstock must have enough fluidity so that it does not stick to the die or other tooling, and that upon exit from the die it possesses a smooth surface.
- Phase separation within the feedstock (i.e., separation of the binder and powder) must not occur during extrusion.

Fundamentals of Flow

Fluids can be broadly classified according to the relation between applied shear stress and the rate of deformation of the fluid. Fluids in which the shear stress is directly proportional to the rate of deformation are Newtonian, that is:

$$\tau = \eta \left(\frac{d\gamma}{dt} \right) \quad (\text{Eq 1})$$

For fluids where this proportionality does not hold, that is, where they possess nonlinear behavior, they are broadly classified as non-Newtonian. Some well-known categories of non-Newtonian fluid flow are dilatant, viscoelastic, and Bingham.

When discussing the flow characteristics of the feedstock, only viscous, plastic, and elastic effects are considered (Ref 6). In the extrusion process, to facilitate flow of the feedstock in the extruder and die assemblies, it should be viscoelastic,

that is, the feedstock should possess an initially high strain rate that decreases over time as elastic stresses are developed. This type of behavior is more commonly referred to as "strain-thinning" behavior, or pseudoplasticity. Paints possess a strain-thinning characteristic; that is, they have a low viscosity at high shear rates (smooth paint flow during brushing) and a high viscosity at low shear rates (particles remain in suspension during storage) (Ref 2). Thus, the characteristic of major import in the extrusion process is the decrease in viscosity of the feedstock with increasing shear strain rate. Consequently, the flow stress (τ) for a pseudoplastic material, having a yield stress (τ_o), is given by:

$$\tau = \tau_o + \eta(\dot{\gamma})^n \quad (\text{Eq 2})$$

where $\dot{\gamma}$ is the shear rate equal to $d\gamma/dt$, η is the shear rate factor, or the viscosity, and n is the exponent of shear rate. In the case of pseudoplastic materials, the value of the exponent is less than 1.

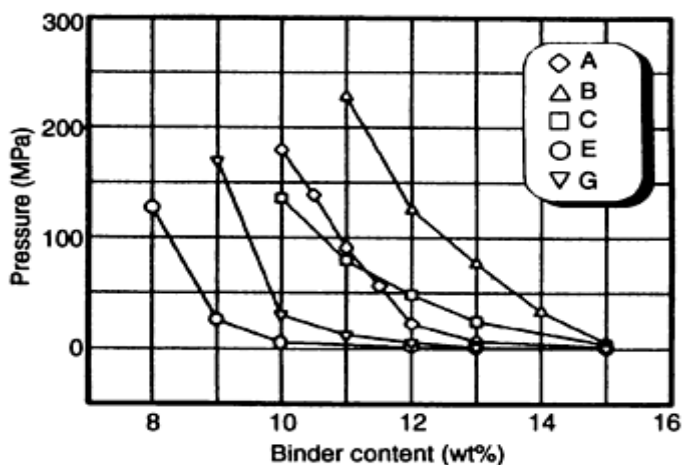

During compression, when the feedstock flows through the barrel, shear strain rates are low and high viscosity prevents phase separation and promotes consolidation. By contrast, during shaping, when the feedstock deforms as it flows through the die, shear strain rates are high and a low-viscosity feedstock minimizes the required extrusion pressure. A feedstock possessing pseudoplastic behavior, therefore, possesses both a high viscosity at low shear strain rates and a low viscosity at high shear strain rates, which is why it is the desirable feedstock flow behavior for binder-assisted extrusion.

Feedstock Formulation

The characteristics of both the binder and powders need to be considered in feedstock formulation. Binder content is one of the most important parameters in the formulation process. The binder is used to provide the proper rheological behavior for the shaping of the powders. The binder physically separates the individual powder particles and acts as lubrication between the powder/binder mixture and the die walls during the extrusion process. There is a narrow range of binder volume fractions that produce a feedstock with rheological characteristics suitable for producing good extrusions (Ref 1, 2, 5, 6, 14, 15, 16). If insufficient binder is present in the feedstock, it will not flow easily and high pressures will be needed to extrude the feedstock (Ref 6, 14, 15, 16). This situation is shown in Fig. 2(b), which shows the pressure needed to extrude stainless steel powders with different weight fractions of binder (Ref 16). Notice that as the binder weight fraction decreases, the extrusion pressure increases for all powder configurations. Conversely, if too much binder is added to the powder, the feedstock will be too soft and pliable, and the extruded part will most likely slump. To prevent slumping, the strength of the extruded part must exceed ρgh , where h is the height of the extruded part, ρ is the density of the feedstock, and g is the acceleration due to gravity. Slumping can be prevented by adding coagulants to the binder formulation, or by utilizing binders that will gel as a result of heat input during subsequent processing steps (Ref 1, 2, 3, 4, 5, 6). Generally, the minimum amount of binder required to prevent slumping of the part is what should be used. Typically, a feedstock for hot extrusion will contain between 30 and 40 vol% plastic binder. A solvent-based feedstock for room-temperature extrusion can contain upwards of 50 vol% of a liquid phase.

(a)

(b)

(c)

(a) Stainless steel powder particle size distributions. (b) Extrusion pressure versus binder content for stainless steel powders of different particle size distributions (reduction ratio = 10; extrusion velocity = 10 mm/min). (c) Extrusion pressure versus utilization of powders with a bimodal particle size distribution (mixtures of powders A and C). Source: Ref 16

The powder particle characteristics, such as size, shape, and size distribution, can influence the extrusion process in several important ways. For instance, the largest powder particle that can be processed must be less than the smallest dimension found in the extruded part. This criteria may be significant during production of parts that contain thin sections, like honeycombs where the wall thicknesses can be as thin as 100 μm . In practice, a good rule of thumb is that the absolute maximum powder particle dimension should be less than one-tenth that of the smallest die dimension (Ref 6). Powder particle size distributions (e.g., whether it is bimodal or widely distributed) that allow efficient packing will result in feedstock formulations with minimal binder content (Ref 6, 14, 15, 16). Proper extrusion also depends on having some excess binder, over and above that which is necessary to fill the interparticle voids, to lift and separate the powder particle surfaces, and to facilitate flow. For a given weight fraction of binder, extrusion pressures will be lower for powders packed efficiently, as shown in Fig. 2. The reduced pressure arises because a larger percentage of the binder is being used for filling the space between the powder particles, rather than for facilitating flow as in the case where the powders are not efficiently packed. Also, an extruded part, with the minimum amount of binder needed to hold its shape, will be easier to handle, and it will ultimately lead to a part with a higher density (i.e., minimum porosity).

Binders

The selection of an appropriate binder system is dependent on the physical and mechanical properties of the powders being extruded. It is important to select a fugitive binder that can be completely removed, as residual contaminants can degrade the mechanical properties of the finished product. To facilitate proper rheological behavior, binder formulations may contain several components, including solvents, surfactants, deflocculants, coagulants, lubricants, plasticizers, and preservatives.

Solvent-Based Binders for Room-Temperature Extrusions

Solvent-based binder systems are used for room-temperature extrusion. Typically, a water soluble clay and/or an organic polymer binder is dissolved in water (Ref 1, 3, 5, 17). The water uniformly disperses the binder throughout the powder and provides the rheological characteristics necessary for proper extrusion. The organic binder is used to increase the viscosity of the feedstock and to change the flow characteristics of the powder/water feedstock from Newtonian to the desired pseudoplastic flow required for good extrusions. Nonaqueous binder systems are also used. Table 2 lists some of the more common aqueous and nonaqueous binders used in the extrusion process (Ref 5, 17). Organic binders are available in a wide range of viscosities and are typically sold as a function of the molecular weight or the strength of their molecular bonds. Typically, the viscosity of the feedstock for extrusion should be about 10 Pa · s (Ref 17).

Table 2 Typical binder systems for room temperature extrusions

Aqueous binders	
Binder type	Viscosity grade ^(a)
Gum arabic	VL
Lignosulfonates	VL
Dextrins	VL to L
Polyvinyl alcohol	VL to M
Acrylates	VL to M
Polyethylene-imine	L to H
Methylcellulose	L to H
Sodium carboxymethylcellulose	M to VH
Polyethylene oxide	M to VH
Natural gums	H to VH
Alginates	M to VH
Nonaqueous binders	
Binder	Solubilities
Acrylics (PMMA, PMA, PBMA, PEMA)^(b)	Ketones, alcohols, glycol ethers, hydrocarbons
Polystyrene	Ketone, hydrocarbons
Cellulosics (ethyl, methyl, acetate, butyrate)	Wide
Polyethylene oxide	Polar organics

Adapted from Ref 5

- (a) Viscosity grade is defined as concentration of binder in aqueous solution required to give a solution viscosity of 2 Pa · s. Very low (VL) > 10 wt%;

Low (L) 3-10 wt%; Medium (M) 1-3 wt%; High (H) 0.3-1 wt%; Very high (VH) < 0.3 wt%.

- (b) PMMA, polymethyl methacrylate; PMA, polyethyl methacrylate; PBMA, polybutyl methacrylate; PEMA, polymethacrylic acid.

Plastic Binders for Hot Extrusion

Plastic binders, utilized for hot extrusion, are blends of organic and metall-organic polymers, with a small percent of modifying agents (Ref 7). Typically, the feedstock contains 65 vol% powder, 35 vol% binder, and has a viscosity between 200 and 500 Pa · s, within the temperature range of 80 to 220 °C, and at a shear rate of between 100 and 1000 s⁻¹. Many of the exact binder/feedstock formulations utilized for hot extrusion are proprietary. However, many binder/feedstock combinations are based on waxes (Ref 7, 9, 13, 16, 18, 19, 20, 21), and those suited for PIM should work just as well for binder-assisted extrusion. A list of several binder/feedstock systems utilized in PIM can be found in Ref 22.

Feedstock Preparation--Mixing

The purpose of mixing the powder and the binder is to produce a uniform feedstock suitable for extrusion where all of the powder particles have been coated with the binder. Areas of inhomogeneity (e.g., pockets of uncoated powder and/or pure binder) can result in strength-limiting defects in the final product. Obtaining uniformity of the feedstock can be problematic because of the stiffness of the final extrudable mixture. Mixing of the powder and binder consists of several steps. For a solvent-based binder system for extrusions made at room temperature, the solid components (i.e., the powders, clays, organic polymers) are first mixed in the dry state. The liquid solvent is then added to the thoroughly mixed powders. To maximize homogeneity of the feedstock, wet mixing occurs first by slurry mixing and then through high-shear mixing. During this stage, it is common practice to add extra solvent to lower the viscosity of the feedstock in order to facilitate homogeneity during mixing. The excess solvent is then removed by the partial drying of the feedstock mixture prior to extrusion. In an alternative approach, the liquid solvent and powders are mixed to form a low-viscosity slurry, to which the solid component of the binder is incrementally added until the mixture possesses the desired viscosity.

High-shear mixing can be performed in a pug-type mill, in which two rows of shafts rotate in opposite directions. The purpose of this type of mixing is to break down the agglomerates inherent in the starting powders and any formed during subsequent mixing. It is important to avoid separation of the liquid and solid phases during high-shear mixing.

In the hot-extrusion process, the specific components that make up the plastic binder are compounded. The powder and binder are then dry mixed. The material is then run through a high-shear, screw-type pug mill, where the powder/binder is mixed, then melted and remixed under high-shear conditions. It is finally pumped through a die to form a strand. The strands are pelletized and fed into the extruder. Similar procedures employed during feedstock preparation for PIM can be applied in the feedstock preparation for hot extrusion.

Binder-Assisted Extrusion

David E. Alman and Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Extrusion

Extrusion is the pressing of the feedstock into and through a die of size and cross-sectional shape appropriate to that of the product. The specific steps (Ref 1) used in binder-assisted extrusion are: (1) feedstock/paste delivery into extruder, (2) consolidation and flow of feedstock/paste through the barrel, (3) deformation and shaping of feedstock/paste as it flows through the die, (4) flow of feedstock/paste through the die land, and (5) part ejection. For the feedstock to flow through the die, the pressure generated by the extruder must be greater than the resistive forces associated with the deformation of the feedstock at the die entrance due to the reduction in diameter and the drag forces along the die wall. The pressure drop along the axis of the extruder reflects the amount of work required to overcome the resistive forces. The pressure is highest in the barrel and lowest at the exit of the die landing, as shown in Fig. 3. There is a pressure drop at the exit of the die, which tends to be small in magnitude compared to the drop associated with the deformation and motion of the feedstock. However, if pressure drop upon exiting is too high, there can be significant "springback," or elastic rebound, of the extruded part. Springback can result in axial cracking and warpage of the part after it has left the die. Slower extrusion rates, longer extrusion dies, and the incorporation of short relief sections at the end of the die (i.e., a negative taper) all contribute to minimize the effect of springback (Ref 5).

Fig. 3 Pressure profile in the extrusion die. Source: Ref 5

Equipment

Two common extruders are used in the binder-assisted extrusion process: the screw, or auger-type, extruder and the piston, or ram, extruder. In piston extrusion (Fig. 4), the feedstock, commonly a degassed billet, is inserted in the barrel, and the piston compresses it, forcing the feedstock down the barrel and through a die of the desired shape. As the ram contacts and compresses the feedstock, the pressure increases (Fig. 5). As the feedstock is pushed along barrel by the piston, the pressure falls as a result of drag forces along the barrel wall. As the feedstock enters the die, the pressure once again rises. Constant pressure in the barrel can only be maintained if inverted extrusion is employed (Ref 5). (In inverted extrusion the die moves instead of the feedstock.)

Fig. 4 Ram extruder. Source: Ref 6

Fig. 5 Pressure profile in the barrel of a ram extruder. Source: Ref 5

Two advantages of the piston extrusion process are (Ref 1, 2, 3, 4, 5, 6): (1) very high pressures can be generated independent of the feedstock properties and (2) there is precise control over output flow. As a consequence, piston extruders are commonly used for the production of intricately shaped components. However, a drawback to the use of piston extruders is the intermittent nature of the process and the low capacity inherent with batch-type processes. However, with the aid of a screw extruder to load the piston barrel with the feedstock, as depicted in Fig. 4, piston extrusion can be made to perform semicontinuously.

Screw extruders are used to produce parts in large batches in a continuous process. Potential capacities of screw extruders can be as high as 100 tonnes/h (Ref 1, 2, 3, 4, 5, 6). The screw extruder typically consists of several sections (shown schematically in Fig. 6). The feedstock is fed into a pug mill, which supplies high-shear mixing. The feedstock is then forced through a perforated plate where it is shredded. This shredded material falls into the main extruder chamber. Degassing can occur at this stage, making use of a vacuum system attached between the two chambers. In the extruder chamber, the feedstock is consolidated and forced through the forming die. Screw extruders may use single- or twin-screw configurations. When using a twin-screw system, the two screws are able to rotate in either the same or the opposite direction. Twin-screw extruders force the feedstock through the barrel using positive displacement, whereas in the single screw extruder, the movement of the feedstock is entirely dependent on the frictional forces that develop among the screw, the feedstock, and the barrel (Ref 1, 2, 3, 4, 5, 6). For conveying, feedstock properties are less significant with a twin-screw extruder than for a single-screw extruder. A comparison of the operating parameters for the single- and twin-screw extruders is given in Table 3.

Table 3 Comparison of single and twin-screw extruders

Factor	Single screw	Twin screw
Energy loss	Viscous flow	Heat transfer
Feedstock transport	Wall friction dependent	Positive displacement
Throughput	Pressure dependent	Independent
Shear forces	Larger	Smaller
Power/kg of material	Higher	Lower
Temperature gradients	Higher	Lower
Air evacuation	Simple	Difficult
Capital cost	Lower	Higher

Fig. 6 Screw extruder. Source: Ref 6

In a single-screw extruder pressure builds up as the segmented feedstock is conveyed and compressed, as shown in Fig. 7 (Ref 23). The segmented feedstock becomes continuous in the metered zone, and the pressure continues to rise. Finally, the feedstock is conveyed into the die, where it is deformed. It is at this point that the highest pressures are generated. The pressure in the die is dependent on the screw geometry and the feedstock rheology (Ref 1). Larger and/or tapered screws may be used to generate higher pressures. The number of flights of the screw controls the number of feed columns that are displaced. Larger helical angles increase the potential delivery rate, but reduce the compressive thrust on the feedstock. The required ratio of screw diameter to part diameter increases as the yield strength of the feedstock increases or when the die land area increases. The length of the feed section is commonly five times that of the screw diameter, and the length of the metering section is ten times that of the screw diameter. Typical screw geometries include (Ref 1, 2, 3, 7) a helical angle between 5 and 20°, radial clearance between the screw and barrel of 0.1 % of screw diameter, and a channel depth ratio of about 3 to 1. Generally, these dimensions are selected based on standard screw geometries developed for commercial extrusions of other products, such as thermoplastics and food articles. However, recent experiment results indicate that for optimal binder-assisted powder extrusion, larger helical angles should be used (Ref 24).

Fig. 7 Pressure profile in the barrel of a screw extruder. Source: Ref 23

Flow through the Extrusion Die

The flow through the die is composed of two parts: (1) flow from the barrel into the die land (i.e., flow through the die entry) and (2) flow through the die land (Ref 1, 5, 6, 14, 15, 16, 24, 25, 26, 27, 28). The feedstock deforms--that is, it extends in the axial direction and decreases in cross-sectional area--as it flows through the entrance to the die. For a square entry die, the work required to deform and extend the feedstock in the axial direction results in a pressure drop (ΔP_1) at the entrance to the die. This pressure drop is given by the following equation (Ref 6, 25):

$$\Delta P_1 = \sigma_b \ln \left(\frac{A_0}{A} \right) \quad (\text{Eq 3})$$

where σ_b is the internal yield stress of the feedstock, and A_0 and A are the barrel and die cross-sectional areas, respectively. For a circular square entry die (Fig. 8), the pressure drop at the entrance is represented by the following equation (Ref 6, 25):

$$\Delta P_1 = 2 \sigma_b \ln \left(\frac{D_0}{D} \right) \quad (\text{Eq 4})$$

where D_0 and D are the initial and final diameters, respectively.

Fig. 8 Circular square entry die. Source: Ref 6

The flow through the die land is resisted by drag forces along the die wall, that is, friction force between the feedstock and the die wall. The drag force acts over the perimeter of the die land. The pressure drop (ΔP_2) required to cause flow through the die land can be derived from a simple force balance (Ref 6):

$$\Delta P_2 A = \tau_f M L \quad (\text{Eq 5})$$

where τ_f is the extruded part-wall shear stress (assumed to be independent of the position on the perimeter), and A , M , and L are the cross-sectional area, perimeter, and length of the die land, respectively. For flow through a die with a circular cross section, a geometry used for wire and bar production, the pressure drop is given as:

$$\Delta P_2 = 4\tau_f \left(\frac{L}{D} \right) \quad (\text{Eq 5a})$$

where D is the diameter of the die land. For flow through a die land with a square cross section, a geometry used to make brick and tile, the following equation represents the pressure drop:

$$\Delta P_2 = \tau_f \left(\frac{b+c}{bc} \right) L \quad (\text{Eq 5b})$$

where b and c are the depth and width of the rectangular cross section. Finally, for flow in the space between two annular cylinders, a geometry used to make tubular products, the equation for the pressure drop is given by:

$$\Delta P_2 = 4\tau_f \left(\frac{L}{D_1 - D_2} \right) \quad (\text{Eq 5c})$$

where $D_1 - D_2$ are the outer and inner diameters of the tube, respectively.

The total pressure drop (ΔP) required for feedstock flow through a circular, square entry die is (Ref 6, 25):

$$\Delta P = \Delta P_1 + \Delta P_2 = 2\tau_b \ln \frac{D_0}{D} + 4\tau_f \left(\frac{L}{D} \right) \quad (\text{Eq 6})$$

where σ_b and τ_f are related to the flow characteristics of the feedstock. Experimentally (Ref 25), it has been found that $\sigma_b = (\sigma_o + \alpha v^n)$ and $\tau_f = (\tau_o + \beta v^m)$, which is very similar in form to Eq 1. Here, σ_o is the yield stress, extrapolated to zero velocity; α characterizes the effect of velocity on the yield stress; τ_f is the initial wall shear stress; β is a factor accounting for the velocity dependence of wall shear stress; n and m are shear-thinning exponents; and v is the feedstock velocity. The values of feedstock parameters (σ_o , τ_o , α , β , m , and n) are determined from ram extrusion experiments in which extrusion pressures are measured through two dies of differing die-land lengths and at a range of extrusion velocities. For a circular square entry die the extrusion pressure can be calculated as:

$$\Delta P = 2(\sigma_o + \alpha v^n) \ln \frac{D_0}{D} + 4(\tau_o + \beta v^m) \ln \frac{L}{D} \quad (\text{Eq 7})$$

The pressure calculated using Eq 7 is compared to the measured pressure for an alumina extrusion in Table 4. Differences in calculated and measured pressures may be attributed to the die-entry velocity being a function of the shear rate factor and shear-thinning exponent (Ref 27).

Table 4 Comparison of calculated and measured extrusion pressures for extrusion of alumina powder

Extrusion velocity, mm/s	Extrusion pressure, kPa	
	Measured	Calculated using Eq 7
Square entry--circular die land ($D_0=25.4$ mm; $D=9.5$ mm; $L=50.8$ mm)		
1.3	5.05	5.0
2.7	6.26	5.6
5.3	7.74	6.5
13.3	11.00	9.6
Square entry--square die land ($A_0=506$ mm ² ; $A=9.0$ mm ² ; $b=3.0$ mm; $c=3.0$ mm; $L=3$ mm)		
4.7	1.89	1.23
18.7	3.58	2.27
46.7	5.21	4.53

Note: Feedstock: 83 wt% Al₂O₃, 3.5 wt% clay, 6 wt% water, 7.5 wt% glucose. $\sigma_o = 24$ kPa, $\alpha = 18$ kPa · s/mm; $\tau_o = 19$ kPa; $\beta = 18$

Conical or tapered dies are frequently used in extrusion processes. For flow through a conical die entry, the feedstock is subjected to both compressive and shear stresses, with the generation of significant drag forces along the die wall. The pressure drop (ΔP_1) for flow through a die with a conical entry can be written as (Ref 6):

$$\Delta P_1 = (\sigma_o + \alpha_1 v^n + \tau_o \cot \theta) \ln \left(\frac{D}{D_0} \right) + \left(\frac{\beta_1 v^m \cot \theta}{m} \right) \quad (\text{Eq 8})$$

where θ is the die entrance angle (note that for a square entry die $\theta = 90^\circ$ and the $\cot \theta = 0$; thus Eq 8 reverts to Eq 4). The flow velocity in the tapered die is a function of both radial and axial location. The material nearest the central axis experiences more acceleration, and experiments utilizing striated feeds of different colors (Ref 30), and monitoring extrusion with nuclear magnetic resonance (Ref 29), indicate that the differential flow velocity between the center and wall of the die increases with increasing die entrance angle (as shown in Fig. 9).

Fig. 9 Influence of die taper on the extrudate velocity profile. Source: Ref 30

Analysis of the preceding equations reveal that the extrusion pressure will be high when the extrusion velocity is high and when the ratio of the die land length to die diameter (L/D) is large, which is consistent with practice (Fig. 10). The extrusion pressure will also be high when the reduction ratio (D/D_0) is large and when the die entry angle (θ) is small (Fig. 11). Finally, the extrusion pressure will be high when the friction in the die land is high (Fig. 12). From Fig. 12, the addition of lubricants decreases the frictional force along the die land, and thus reduces the work required for feedstock flow.

Fig. 10 Influence of extrudate velocity and die land aspect ratio (L/D) on extrusion pressure. Extrusion of Al_2O_3 powder; binder is clay, starch, and water; $D_o = 25.4$ mm, $D = 3.2$ mm. Source: Ref 6

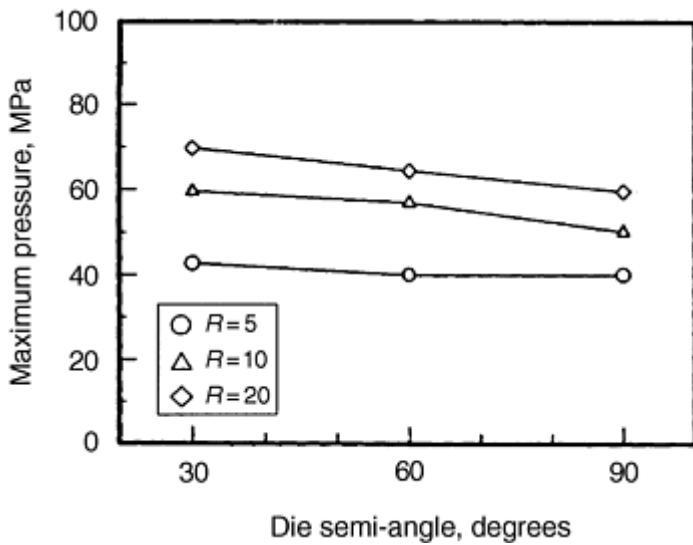

Fig. 11 Influence of die semiangle and reduction ratio on extrusion pressure (extrusion of ZrO_2 powder; binder is hydroxypropyl methylcellulose and water). Source: Ref 28

Fig. 12 Influence of lubrication on extrusion pressure. Source: Ref 1

A more generalized form of Eq 7 and 8 is given by Eq 9 (Ref 6, 26):

$$\Delta P = f(v) \ln \frac{A_0}{A} + g(v) \frac{M}{A} \quad (\text{Eq 9})$$

where $f(v)$ and $g(v)$ are used to characterize the feedstock flow behavior. In this case, $f(v)$ is a function of the change in cross-sectional area of the feedstock due to extension into the die entry, and $g(v)$ is a function of the shear flow, or drag of the feedstock along the die land. In Eq 9, A_0 and A are the cross-sectional areas of the barrel and die, respectively, while M is the perimeter distance of the die land.

Practical Concerns for Extrusion Die Design

A large die entrance angle may result in a zone of static material (analogous to the dead-metal zone in metal extrusion) at the periphery of the die. Static material may be a source of defects and should be avoided (Ref 1, 2, 3, 4, 5, 6). For industrial extrusions, die entrance angles are usually less than 25° and the (L/D) ratios range from 2-to-1 to 4-to-1 (Ref 1, 2, 3, 4, 5, 6). The tooling must have a smooth finish and should be inspected for wear, as extrusion pressure will increase with increasing surface roughness of the die (Fig. 13). Finally, uniform cross sections are an important aspect of tool and part design. Nonuniform cross sections can cause flow-rate differentials that will affect the flow characteristics of the part during extrusion, as well as causing variations in the final product (e.g., flaws, density gradients, etc.). Therefore, parts with sharp edges should be avoided, and for tube production the spider should be designed with a "bullet point" at the die entrance (Ref 1, 2, 3, 4, 5, 6).

Fig. 13 Influence of die land surface roughness on extrusion pressure. Top, extrusion pressure versus extrudate velocity for a variety of die land surface roughness. Bottom, roughness profiles (all dimensions in millimeters; s, smooth die had an internal diameter of 6.38 mm). Extrusion of Al_2O_3 powder; binder is clay, starch, and water; $D_o = 25.4$ mm, $D = 6.35$ mm, $L = 25.4$ mm. Source: Ref 6

Extrusion Flow Defect

There are three principal types of flow defects that can occur during extrusion (Ref 1, 5, 6, 30): lamination, surface fracture, and phase separation. Lamination-type flow defects occur when two adjacent flow streams do not properly join together. This will be the source of a structural flaw in the final product. These defects occur during the forming of tubes or multihole extrusions and are caused by flow of the feedstock around the supports of the spiders. Typically, the spider is supported in the center of the die by three prongs at 120° to each other. The feedstock must squeeze around these prongs and reunite on the other side to form, for example, a continuous hollow cylinder prior to exiting the die. Lamination defects can also form in the barrel of a screw extruder. At the point where the feedstock leaves the screw, the trailing face of one twist comes into contact with the leading face of the preceding twist. It is here where lamination defects can occur, mitigated by the reduction in the cross section of the die after streams are brought together.

Surface fractures (or "feathering") are imperfections or tears that form at the surface of the extruded part (shown in Fig. 14). They arise from drag forces that build up parallel to the surface of the extruded part. Surface fractures tend to occur when the die land has sharp corners (i.e., for dies with square or triangular cross sections) and at high extrusion velocities. The advent of surface fractures can be mitigated by (Ref 6):

- Employing a die that consists of a large die land length to diameter (L/D) ratio, resulting in a high pressure drop in the die land, suppressing the effects that occur at the junction of the die entry and land
- Utilizing a tapered die

- Using lubricants in the feedstock or by designing the die so that lubricants can be injected into the die land during extrusion (this may also be accomplished by warming the die-wall surface)
- Formulating the feedstock in such a manner that the strength of the feedstock is significantly greater than the initial wall shear stress

Fig. 14 Examples of surface flaws in extruded alumina (feedstock in wt%): 75% Al_2O_3 powder, 3% bentonite clay, 17% glucose solution; 5% water; $D_o = 25.4$ mm, $D = 3.2$ mm, $L = 9.5$ mm. (a) No flaws ($v = 0.23$ mm/s). Surface flaws: (b) $v = 1.2$ mm/s, (c) $v = 2.3$ mm/s, and (d) $v = 6.0$ mm/s. Source: Ref 6

Phase separation or seepage is another common problem that occurs during extrusion. This situation occurs when the phases move at significantly different velocities as a result of the pressure gradient. This condition arises when the permeability through the packed powder particles is high and the binder viscosity is low. As a result, the feedstock becomes dry and the pressure needed for the extrusion of the feedstock rises (Fig. 15). Evidence of phase separation in the feedstock include:

- Accumulation of liquid or binder at the die exit, or wet and dry patches on the extruded part surface
- High extrusion pressure at low extrusion rates rather than at high extrusion rates (i.e., the slower the extrusion speed, the more time available for phase separation)
- Extrusion pressure increases rather than decreases as the feedstock flows through the die.

Phase migration is affected by both the powder properties and binder rheology. The migration of the binder is a function of the interparticle void space. Therefore, employing fine powders (to a first approximation the interparticle void space is equivalent to the powder diameter, assuming that the powders do not agglomerate), or powder mixtures that pack efficiently, will reduce the interparticle void space and decrease the propensity for phase separation during extrusion (Ref 6, 14, 15). Selection of a binder system with the appropriate rheological characteristics will also help mitigate phase separation. Thus, a feedstock with a high initial yield stress (τ_o , in Eq 2) will lessen phase separation.

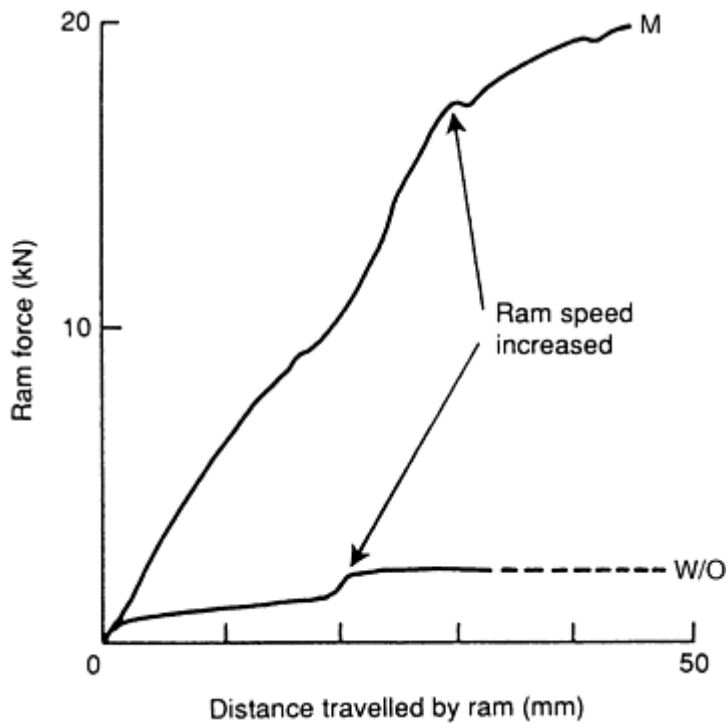

Fig. 15 Effect of binder powder phase separation on extrusion pressure. M, phase migration or separation; W/O, no phase migration. Source: Ref 14

Binder-Assisted Extrusion

David E. Alman and Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Postextrusion Processing

Cutting of the extruded part to the desired length can be accomplished by fixing the cutting device at the die exit. For continuous and large throughput extrusions, the ratio of the cutting speed to the extruded part speed will be a significant factor. As the ratio of speeds increase, the angle between the cutter and extruded part will approach 90° (Ref 6). It is important that the cutting operation not cause any surface tears or close any small internal holes found in complex parts, such as the holes in catalysts supports.

Binder Removal

The binder needs to be removed from the part prior to final consolidation. For solvent-based binders, removal occurs in two steps: (1) drying to remove the solvent and (2) thermal treatment to remove the organic component of the binder. Drying occurs by solvent evaporation at the surface. Solvent dispersed in the interior of the part must be able to diffuse to the surface to be removed. Solvent evaporation at the surface and subsequent diffusion through the part are accelerated by temperature. Shrinkage will occur during the drying process; hence, care must be taken to ensure that the solvent has enough time to diffuse through and then evaporate, as differential drying rates will result in differential shrinkage rates. Differential shrinkage rates can generate tensile stresses in the part, which may be relieved by the generation of a crack in the extruded part.

Most solid-phase organic binders used in binder-assisted extrusion can be burned off in an appropriate environment (e.g., inert, oxidizing, or reducing atmosphere, depending on the chemistry of the binder) at a temperature between 300 and 1000 °C. The burnoff must be slow to allow the carbonaceous gases generated by the decomposition of the organic species to escape through the interconnected pores. Too rapid of a burnoff rate can crack or fracture the part. If the organic binders used for solvent-based extrusion are not burnt off properly, they will decompose, leaving residual carbon and other contaminants trapped within the part, which will subsequently degrade the performance over time. The exact thermal treatment (i.e., its temperature/time profile and environment) will depend on the actual binder used in the feedstock. Plastic binders for hot extrusion are removed via thermal treatments. The techniques used in PIM can also be utilized for plastic binder removal in the hot-extrusion process.

Consolidation

Consolidation of the powders, of course, occurs through sintering. The time/temperature profile and sintering environment depend on the materials being consolidated. For some materials, sintering may be an extension of the binder-removal operations, provided the environment for organic-binder removal does not interfere with the sintering process for the material in question.

Binder-Assisted Extrusion

David E. Alman and Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Examples of Binder-Assisted Extrusion

Ceramics

Binder-assisted extrusion is most commonly used to form ceramic parts (Ref 1, 2, 3, 4, 5). Room-temperature extrusion, utilizing water-based solvent binder systems, has been used to produce a variety of ceramic parts, a selection of which are listed in Table 5. Hot extrusion is commonly used to produce advanced structural ceramics (e.g., Si_3N_4), or where the powders tend to be water sensitive or are extremely small ($<1 \mu\text{m}$) in size (Ref 7).

Table 5 Examples of extruded ceramics

Product	Ceramic
Furnace tubes	Alumina, mullite, silicon carbide, zirconia
Insulators	Alumina, beryllia, steatite
Tubular capacitors	Barium titanate
Catalyst supports	Cordierite, alumina, silica, aluminosilicates
Resistance heaters	Barium titanate
Electronic substrates	Alumina, cordierite
Magnets	Ferrites
Heat-exchanger tubes	Silicon carbide, mullite

After Ref 5

A typical solvent-based binder formulation for extruding alumina (in vol%) is 46% Al_2O_3 powder, 4% ball clay, 2% methyl cellulose, and 48% water (Ref 1). However, clays can cause contamination problems for nonoxide ceramics, such as silicon carbide (Ref 1). For these materials, a high-molecular-weight organic polymer, such as cellulose ether, can be substituted for the clay. The polymer is dissolved in a liquid phase and yields a solution with a high viscosity at low stresses and a low viscosity at high stresses. A typical feedstock formulation for room-temperature extrusion of silicon carbide (in vol%) is 50% SiC powder, 6% hydroxyethyl cellulose, 42% water, and 2% polyethylene glycol (Ref 1).

High-Temperature Superconducting Wires

Ceramic superconductor (e.g., $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$) wires have been fabricated via binder-assisted extrusion (Ref 8, 9, 18, 19, 31, 32). Both solvent-based and polymer binders have been used, and extrusions have been made at room and elevated temperatures. For solvent-based binder systems, care must be taken to select a solvent that does not contaminate the ceramic superconducting powders. A binder system that has been used in the extrusion of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ powders at room temperatures is (Ref 19): ethyl cellulose as the organic binder, glycerol as the solvent, and stearic acid as a lubricant. Other solvents that are compatible with $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ powders include methylethylketone, methanol, and xylene (Ref 32). Polymers, such as polyethylene, polystyrene, and waxes, have been used as binders for hot extrusion of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ powders (Ref 9, 18, 19). Wires with diameters of between 0.2 and 20 mm, with lengths well over 15 m, have been produced by binder-assisted extrusion. Because the extruded wire is flexible prior to binder removal, coils can be made by wrapping the wire around a mandrel.

With $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ powders that possess a platelike morphology, the apparent viscosity of the feedstock can significantly influence the critical current density for superconductivity (Ref 19). This is shown in Fig. 16, where the platelike particles align unidirectionally during the extrusion process as a result of the high apparent viscosity of the mixture.

Fig. 16 Influence of feedstock viscosity on the critical current density (J_c) for and bulk density for binder-assisted extruded superconducting wires. Source: Ref 19

Metals

Metals, for example, stainless steels (Ref 16, 28), high-speed tool steels (Ref 33, 34), and tungsten alloys (Ref 10), have been produced using binder-assisted extrusion. Again, both room-temperature and hot extrusions have been made. Acrawax C has been used as a plastic binder for the hot extrusion of a high-speed tool steel. A water-soluble hydroxypropyl methylcellulose has been employed as the binder system for the room-temperature extrusion of stainless steel powders. A solvent-based binder has been employed in the extrusion of the tungsten powders. The hot-extrusion technique has also been employed to fabricate 1.5 mm diam wires of a two phase Ni_3Al and NiAl (Ni-36.8 at.% Al) intermetallic alloy (Ref 21).

Composites

As mentioned previously, when particles possess a platelike morphology, they will tend to align under certain extrusion conditions. The same is true for chopped fibers mixed with the powder (Ref 11, 12, 13, 20, 35, 36, 37, 38). Fibers tend to align parallel to the flow direction when extruded from a converging (i.e., constricting) nozzle, as shown in Fig. 17. When the flow occurs in a diverging nozzle, the fibers tend to align perpendicular to the flow direction. However, for alignment like this to occur, the maximum powder particle size cannot be greater than the edge-to-edge separation between the fibers. The relationship between fiber diameter, fiber volume fraction, and powders size can be derived from a simple geometric model. The maximum allowable powder particle size (λ) for fiber alignment is given as (Ref 13):

$$\lambda = \left(\frac{\pi D^2}{2\sqrt{3} V_f} \right)^{1/2} - D \quad (\text{Eq 10})$$

where D is the fiber diameter and V_f is the fiber volume fraction. Analysis of this equation reveals that smaller powders are required for alignment as the volume fraction of fibers increase. This behavior is illustrated in Fig. 18.

Binder-Assisted Extrusion

David E. Alman and Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Conclusions

Binder-assisted extrusion is a commercially used powder forming technique. In this technique, powders are mixed with a binder to produce a feedstock with rheological characteristics that facilitate extrusion. The process consists of four basic operations, each step is critical for producing a defect free product. The steps include (1) feedstock formulation and preparation, (2) extrusion for shaping, (3) binder removal, and (4) sintering. Feedstock preparation involves mixing the powders with the binder and is a critical step in producing homogeneous mixtures. Both the characteristics of the powders and the binder influence the rheology of the feedstock. The feedstock is then extruded through a die to form a part with a particular cross section. Care must be taken to avoid flow defects during extrusion. Postextrusion processing includes binder removal and consolidation. At this stage, it is important to completely remove the binder so residual contaminants are not left behind that can degrade the physical and mechanical properties of the final product. Finally, binder-removal cycles should be designed to prevent cracking.

Binder-assisted extrusion is used to produce a variety of industrial parts. These parts may be ceramic or metallic in nature. This technique is amenable to producing long objects such as tubes, bricks, and honeycombed structures, as long as the parts have regularly shaped cross sections. Table 6 compares and contrasts the various powder forming approaches.

Table 6 Comparison of powder forming techniques

Forming method	Shape of product	Advantages of method	Potential difficulties and disadvantages
Die pressing	Two-dimensional; flat objects	Economics; readily automated; products can be directly sintered	Limited sizes and shapes; potential density gradients
Doctor blade	Thin sheets	High productivity; secondary operations can be used to produce laminates and multilayered substrates	Binder removal may be difficult
Slip casting	Thin-walled products; irregular shapes	Utilizes simple equipment; can create relatively complex shapes	Distortions occur during castings; drying of slurry and slurry control can be difficult
Binder-assisted extrusion	Long objects with regular cross sections	Continuous production possible; no limitation on length of product	Objects with large cross sections require large equipment; binder removal can be difficult
Injection molding	Complex shapes	Mass produce, complex parts; readily automated; dimensional control; good surface finish	Economics (mold costs are high); binder removal can be difficult

Warm Compaction

Francis G. Hanejko, Hoeganaes Corporation

Introduction

THE FERROUS P/M INDUSTRY continues to grow because of developments in raw materials and part production processes enabling the manufacture of components with greater complexity and higher levels of performance. Advances in raw materials include higher compressibility iron powders, molybdenum prealloyed steels, diffusion-alloyed powders, and the use of binder-treated iron powders. These new powders and premix technologies offer P/M users greater flexibility in mechanical properties at traditional part densities, typically less than 7.1 g/cm^3 . However, end users of P/M parts are demanding still higher levels of mechanical properties available solely through higher part densities. Traditional methods used to achieve higher densities include the use of copper infiltration, double-pressing/double-sintering (DP/DS), and powder forging. Because these techniques involve the use of secondary processing, significant cost penalties are encountered, often negating the potential cost savings realized by powder metallurgy. Warm-compaction process is a technique to achieve DP/DS densities and mechanical properties utilizing a single compaction process. The process incorporates the use of heated powder and heated tooling in standard compacting presses to achieve higher green and sintered densities.

Temperatures above room temperature and below the hot-forging range are used extensively in wrought steels to lower forging loads and minimize distortion. Work at MeriSinter AG in the mid-1980s found certain advantages to be present when ferrous, bulk lubricated powders were heated in the vicinity of $100 \text{ }^\circ\text{C}$. It was of particular interest that compressibility improved with heating as compared to the some powders in an unheated condition (Ref 1). The practical application of warm compaction of powders was realized in 1994 with the introduction of Hoeganaes Inc. Ancordense

and Densemix powders (Ref 2). Figure 1 schematically illustrates the warm-compaction process. The powder and die temperatures used vary from 75 to 150 °C, with every 100 °C rise in compaction temperature resulting in a 0.08 g/cm³ increase in green density (Ref 3). Experimental work at Höganäs AB showed a 30% decrease in the compressive yield strength of iron powder when the powder was heated to 150 °C (Fig. 2) (Ref 4).

Fig. 1 Warm-compaction process

Fig. 2 Effect of temperature on the yield strength of pure iron powder. Source: Ref 4

The maximum green density achieved via P/M techniques depends on the amount and type of premix additives used with iron powder. To calculate the maximum green and sintered densities attainable, it is useful to review the concept of pore-free density (PFD). Pore-free density is defined as the density of a green compact in which all the interparticle porosity is eliminated (Ref 2). This PFD can be calculated from the specific density and percentage of each additive in the premix. The calculation for PFD is given as:

$$\text{PFD} = \frac{1}{\sum (\% \text{ element in premix} / \text{specific gravity of additive})} \quad (\text{Eq 1})$$

in which the percentage of each element is the weight percentage used and is expressed as a decimal.

Once the PFD is calculated, a practical upper limit of green density is 98% of the calculated value. The specific density of several common ferrous powders and typical premix additives are listed in Table 1. Additions of materials with specific densities higher than the base iron increase the PFD, while additions of materials with lower specific densities (lubricants and graphite) will lower the PFD.

Table 1 Specific density as measured by pycnometry

Material	Specific density, g/cm ³
Ancorsteel 1000B	7.841
Ancorsteel 4600V	7.844
Distaloy 4800A	7.896
Atomized copper	8.047
Inco nickel powder 123	8.846
Graphite	2.295
Lubricants	0.90-1.15

Because of the reduced compressive yield strength at 150 °C, attaining 98% of the PFD is achieved with lower compaction pressures. In addition, compaction at 150 °C reduces the amount of lubricant between the particles while simultaneously increasing the amount of added lubricant reaching the die-part interface (Ref 5). This redistribution of the lubricant not only increases the green density, but reduces the ejection forces by 25 to 33% (Ref 2, 5). This enhanced lubricity implies that lower amounts of lubricant are necessary (typically 0.60% lubricant for warm compaction compared to 0.75% in conventional compaction), which again contributes to the attainment of higher green and sintered densities.

Advantages of the warm-compaction process include higher green densities, enhanced green strength, improved mechanical and soft magnetic properties, and greater uniformity of density throughout the as-sintered part. The balance of this article details the process and the improved properties resulting from warm compaction.

Warm Compaction

Francis G. Hanejko, Hoeganaes Corporation

Effects on Green and Sintered Properties

Warm compaction results in a 0.10 to 0.25 g/cm³ increase in the green and sintered densities of P/M parts (Ref 2). Figure 3 shows the improved green and sintered densities achieved with a diffusion-alloyed powder premixed with 0.6% graphite. At lower compacting pressures, the beneficial effect of warm compaction is greater than the improvement observed at higher compaction pressures. Figure 4 summarizes the transverse rupture strength results of the diffusion-

bonded material compacted by both conventional and warm-compaction techniques under compaction conditions of 410 to 690 MPa.

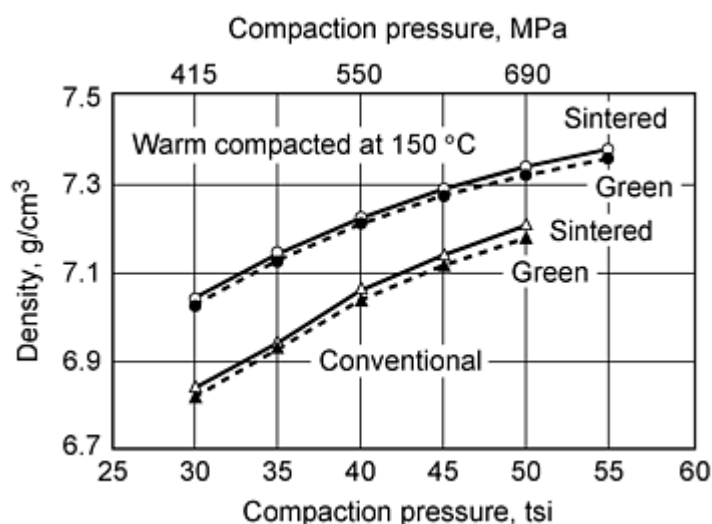

Fig. 3 Compressibility of diffusion-bonded 4% Ni, 1.5% Cu, and 0.5% Mo with 0.6% graphite and 0.6% lubricant

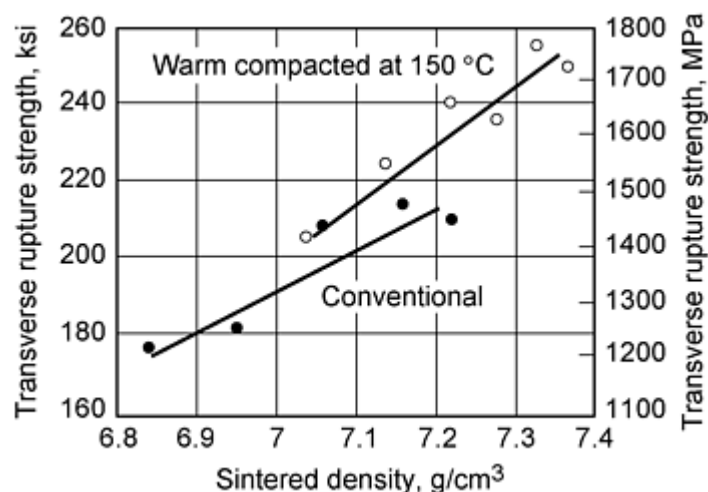

Fig. 4 Sintered transverse rupture strength of diffusion-bonded 4% Ni, 1.5% Cu, and 0.5% Mo with 0.6% premixed graphite

Table 2 summarizes the as-sintered mechanical properties of various warm-compacted premix compositions (Ref 6). This processing is applicable to all iron and low-alloy powder compositions. The magnitude of the increase in sintered density depends on the material system and subsequent part processing. Premixes containing copper additions exhibit growth during the sintering process; this growth negates the beneficial effects of the warm-compaction processing. Consequently, copper-containing premixes are not considered ideal candidates for warm compaction (Ref 7).

Rotating bending fatigue testing was performed on a variety of warm-compacted materials in both the as-sintered and heat-treated conditions; Table 3 summarizes the available data (Ref 8, 9). As expected, increasing the density increased the fatigue endurance limit; however, higher-temperature sintering did not consistently improve the fatigue endurance limit. Reviewing Table 3, it is observed that no generalized correlation exists between the fatigue endurance limit and the tensile strength of P/M materials. It is recommended that designers use available data when specifying the fatigue endurance limit of P/M components.

Double pressing of conventionally compacted parts results in improved part densities and mechanical properties. In experimental work performed by Donaldson and others, warm-compacted P/M parts were presintered at 870 °C (1600 °F)

and subsequently re-pressed at up to 690 MPa (50 tsi) at room temperature (Ref 10, 11, 12). Following re-pressing, the part was then sintered at either 1120 °C or 1260 °C, resulting in sintered densities ranging from 7.5 to 7.6 g/cm³. Figures 5 and 6 present data on transverse rupture strength and impact energy from this study. These higher densities of the double-pressed/double-sintered (DP/DS) warm compacted materials produced an approximately 15% improvement in the transverse rupture strengths (Fig. 5), but more importantly resulted in a 50 to 80% improvement in the impact energy (Fig. 6) when compared to the 7.4 g/cm³ density level (Ref 10). This study demonstrated the potential for significantly improved mechanical properties of P/M materials via DP/DS of a warm-compacted component. The resultant mechanical properties of such parts are equivalent to the properties of ductile cast irons and machined carbon steel forgings.

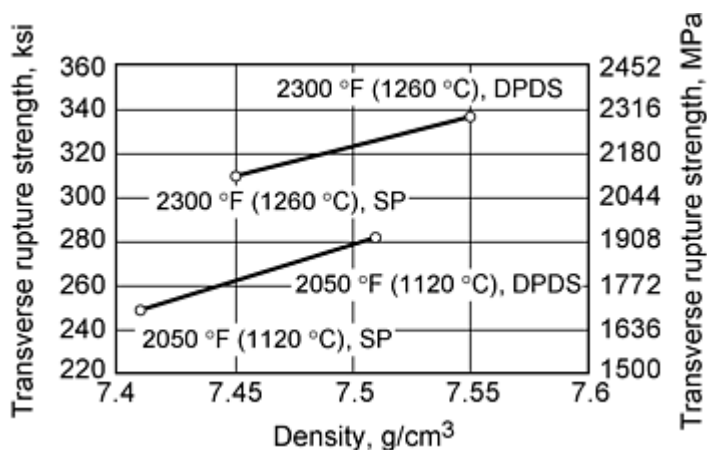

Fig. 5 Transverse rupture strength of diffusion-bonded 4% Ni, 1.5% Cu, and 0.5% Mo premixed with 0.3% graphite subsequently carburized and tempered

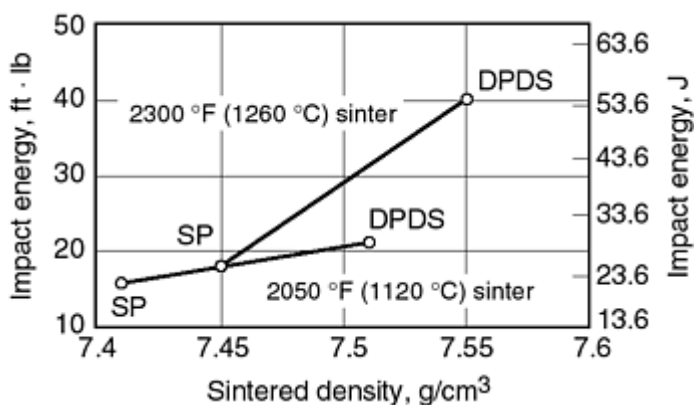

Fig. 6 Impact energy for diffusion-bonded 4% Ni, 1.5% Cu, and 0.5% Mo premixed with 0.3% graphite subsequently carburized and tempered

Green Strength Enhancement. Warm-compaction processing provides improved green strength of the as-compacted component. This increase in the green strength results from the synergy of greater powder particle deformation with enhanced particle welding during compaction, plus the presence of the unique binder and lubricant utilized in the ANCORDERSE material (Ref 2, 5). The improved green strengths are realized at densities significantly below the pore-free density (Fig. 7). These data imply the potential of warm compaction being used in lower-density applications where the enhanced green strength reduces part breakage or part chipping of fragile features.

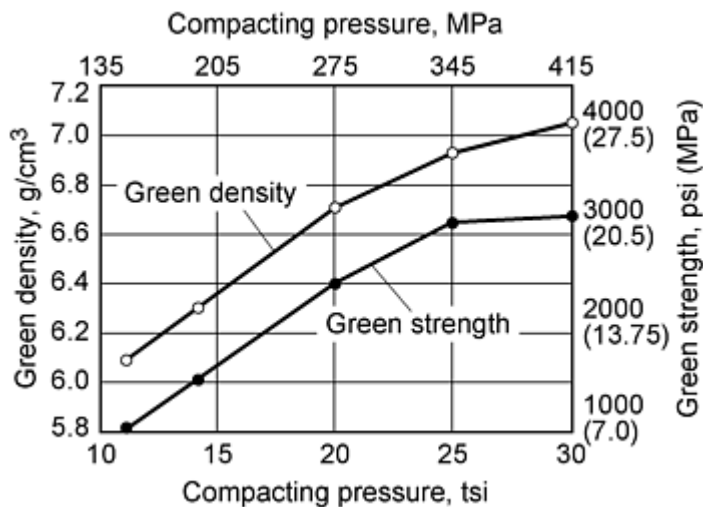

Fig. 7 Green density and green strength of warm-compacted FN0205 at low compacting pressures

A consequence of the enhanced green strength via warm compaction is the ability to green machine the as-compacted part. This concept has been used in a commercial application of a P/M safety locker part (Ref 13). After compaction, the component was milled in the green condition, thus reducing the overall part cost. A machinability study utilizing a drilling test was conducted on a molybdenum prealloyed material premixed with 2% Ni, 0.5% graphite, and 0.6% lubricant (Ref 14). This study concluded that satisfactory surface finishes are achieved with machining conditions using high speeds and high feed rates. Additionally, modifications of the standard drill bit geometry from a standard 90° chisel bit to a 135 split-point drill bit enhanced the as-machined surface finish. Prior to establishing green-machining parameters, it is recommended that testing be conducted to examine the effects of tool-bit geometry, machining feed rate, and machining speed. Green machining of P/M parts in combination with sinter hardening offer the part designer greater flexibility in part design and material selection.

Warm Compaction

Francis G. Hanejko, Hoeganaes Corporation

Magnetic Applications

The use of warm compaction of P/M magnetic alloys effects higher sintered densities with corresponding higher saturation induction levels and higher permeabilities with no change in the coercive force (Ref 15). Sintered densities in excess of 7.4 g/cm^3 are possible using warm compaction of iron-phosphorus alloys. At this density level, the magnetic and mechanical performances of this family of materials are equal to the properties of a low-carbon steel forging. Table 4 summarizes the mechanical and magnetic property data for a 0.45% P/M phosphorus steel processed to 7.4 g/cm^3 and an AISI 1008 steel forging. From these data, the P/M material is a suitable replacement for the wrought steel.

Table 4 Magnetic and mechanical properties of a warm-compacted iron-phosphorus steel versus AISI 1008

Property	Fe-0.45 wt% P	AISI 1008
Density, g/cm^3	7.35	N/A
Sintering temperature, °C (°F)	1120 (2050)	N/A
0.2% yield strength, MPa (ksi)	285 (42)	285 (42)
Tensile strength, MPa (ksi)	405 (59)	383 (56)
Elongation, %	12	37
Maximum permeability	2700	1900
Coercive force, Oe	1.9	3.0
Saturation at 15 Oe, G	15,000	14,400

N/A, not applicable

Warm-compaction processing enables the introduction of a new class of P/M materials for use in alternating current (ac) magnetic applications (Ref 15, 16, 17). These materials utilize a high-strength polymer and warm-compaction processing to produce components that do not require sintering. The polymer acts to both electrically insulate the powder particles and provide strength without the need for sintering. As-compacted green densities in excess of 7.2 g/cm^3 are possible. Manufacturing flexibility can produce a variety of material options with unique magnetic performance. Applications for these materials include automotive ignition coils and stators for high-speed electric motors.

Table 5 summarizes these ac magnetic materials and their magnetic performance. These materials are ideally suited for applications with operating frequencies above 400 Hz. Optimizing the amount and type of insulation produces components that can operate at frequencies up to 50,000 Hz. The unique three-dimensional structure of these materials can be used to carry magnetic flux in any direction. The strength of these materials in the as-compacted condition is approximately 103 MPa (15 ksi) transverse rupture strength. Employing a 315 °C (600 °F) thermal treatment to the as-compacted part raises the transverse rupture strength to approximately 240 MPa (35 ksi).

Table 5 Magnetic performance of insulated iron powders

Material	Initial permeability	Maximum permeability	Coercive force, Oe	Induction at 40 Oe, G
Iron powder with 0.6% plastic	120	425	4.7	11,200
Iron powder with 0.75% plastic	100	400	4.7	10,900
Iron powder with oxide coating and 0.75% plastic	80	210	4.7	7,700

Warm Compaction

Francis G. Hanejko, Hoeganaes Corporation

Commercial Powder Heating and Delivery Systems

Successful utilization of the warm-compaction process necessitates that the powder, powder shuttle, and compaction tooling be heated to the proper temperature. Recommended temperature control of the heated powder and tooling is ± 2.5 °C. It is imperative that the temperature of the powder not exceed 170 °C (320 °F); above this temperature the lubricant and binder degrade, resulting in diminished powder flow. Heating of the tooling is accomplished using cartridge heaters embedded in the stress ring of the die. Typically, eight to twelve 500 W cartridge heaters are required to heat the tooling to 150 °C (300 °F) in approximately 30 min. Heating of the powder shuttle is necessary to maintain the powder temperature during the transfer of the powder into the die cavity. Top-punch heating is recommended to eliminate the possibility of a tool binding between the top punch and core rod(s). Heating the core rod and lower punches is not necessary; where practical, incorporating a cartridge heater in the core rod will provide greater temperature uniformity.

Currently, three commercial powder heating and delivery systems are available. Each system is capable of delivering heated powder at the proper temperature. Additionally, each has the capability of heating and controlling temperatures in the die, the punches, and the powder shuttle system. The three systems are:

- Cincinnati Inc. El Temp System
- Abbott Furnace Company Thermal Powder Processor
- Slotheater

The Cincinnati Incorporated El Temp system utilizes an auger to both heat and transport the powder from the powder feed hopper to the heated shuttle (Ref 18). The auger operates within a resistively heated shell; additionally, the auger is hollowed, allowing preheated air to provide for additional heating capability. The amount of powder heated is determined by the part weight and press speed. Production systems are available that heat up to a maximum of 9 kg/min (20 lb/min). A unique feature of the El Temp system is its direct interface with the Cincinnati computer operating system of the press, allowing for control of all press and heating functions from a single touch screen.

The Abbott Furnace Company Thermal Powder Processor, TPP 300 (patent pending) uses a low-pressure fluidizing air 35 kPa (5 psi) to heat the powder within a sealed reactor. Heating of the powder is accomplished in a stream of air that passes across resistively heated elements. As powder is withdrawn from the bed into the delivery system, additional powder is drawn into the reactor. This system uses a stand-alone programmable logic controller (PLC) controller to heat the powder, die, and powder shuttle. Units are available that can deliver powder up to 3.5 kg/min (8 lb/min) and 3.5 to 9 kg/min (8 to 20 lb/min). The TPP 300 is portable and can be adapted to any press. These units have no moving parts, thus minimizing maintenance.

The Slotheater uses the principle of direct contact of the powder with the heated surfaces of an oil-filled slotted heat exchanger (Ref 4). The powder flows via gravity from the press feeder hopper into the slot heater where it is heated and then flows into the powder delivery system. The temperature of the heated oil is controlled to a temperature approximately 4 °C (7 °F) hotter than the desired temperature of the powder. To achieve uniform temperature of the powder, the residence time of the powder in the heater must be at least 5 min. Commercial units are available that can deliver 3.5 kg/min (8 lb/min) of hot powder. However, the design is scalable to achieve up to 9 kg/min (20 lb/min).

Considerable attention has been given to the actual mechanism of heating the powder; however, attention must also be given to the powder shuttle system. Although no commercial systems exist, it is a relatively easy task to design and build a hot powder feed shoe. Heating of the feed shoe is accomplished by embedding cartridge heaters and a thermocouple in the aluminum feed shoe. Temperature control of the feed shoe is necessary to prevent any heat loss during the residence time of the powder in the shoe. Both a closed shoe and an open shoe have been successfully used. Unlike conventional powder shoes, the amount of powder in the feed shoe is critical. Excessive amounts of powder in the feed result in a long residence time within the feed shoe, possibly resulting in a temperature drop causing excessive part-to-part weight variations.

Warm Compaction

Francis G. Hanejko, Hoeganaes Corporation

Tooling Design for Warm Compaction

The tooling design for warm compaction is essentially the same as for regular compaction with typical radial tooling clearance of 0.01 to 0.02 mm (0.0004 to 0.0008 in.). The choice of carbide inserts or tool steel inserts is not critical. Carbide inserts have proven to be successful; however, the designer is cautioned that additional interference fits are required to compensate for the differential thermal expansion of the carbide insert compared to the steel stress ring.

One word of caution in the design of tooling is the stress involved during the compaction to near-pore-free densities. As the density increases, the tooling loads increase rapidly. This increase in tooling pressure necessitates that thicker stress rings be used and the allowances made for the greater tool deflections. Shown in Fig. 8 is the green expansion as a function of the green density of powder compacts compacted using both conventional room-temperature compaction in addition to warm-compaction conditions. Note that the green expansion at equivalent density is lower for the warm-compacted material. The rationale for the lower green expansion for the warm compacted material is explained by the fact that lower compacting pressure was required to achieve this same density; thus the tooling load was decreased. However, as the green density increases to near-pore-free density, the green expansion increases dramatically. With this increased density, the tooling loads increase, resulting in greater expansion of the part.

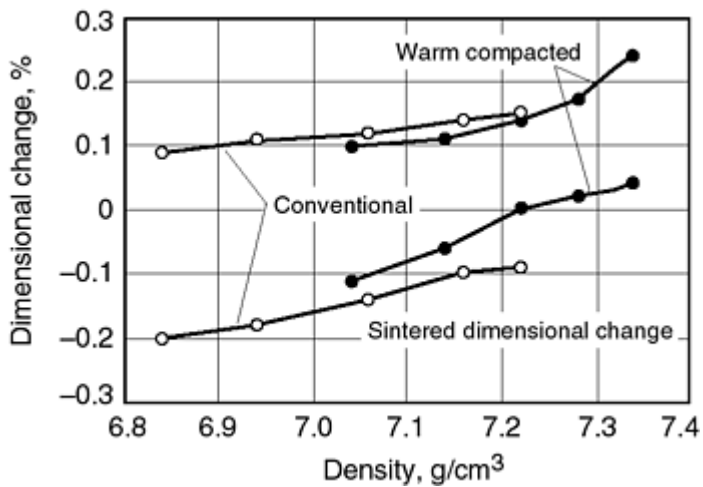

Fig. 8 Green expansion and sintered dimensional change of warm-compacted material relative to conventional compaction techniques

This increased green expansion can cause microlaminations in the compacted part. These microlaminations are serious problems because they reduce the structural integrity of the sintered component. In multilevel parts, these microlaminations usually occur at the transition from one level to another. Incorporating top-punch hold-down during the ejection cycle often prevents these cracks from occurring. However, even top-punch hold-down is not sufficient to prevent microcracking if the density of the part exceeds 98% of the theoretical density.

Warm Compaction

Francis G. Hanejko, Hoeganaes Corporation

Part Processing Considerations

Studies conducted by Hoeganaes, Presmet, QMP, and others demonstrated that the part-to-part variability of the warm-compaction process is equivalent to conventional compaction (Ref 10, 19, 20). Equal press speeds were achieved with the warm-compaction process compared to conventional compaction. The limiting feature in part production is the rated capacity of the powder heating system and the part weight. Although conventional compacting presses are used, attention must be given to prevent the heat generated in the tooling from reaching critical bearing components. Cincinnati Inc. recommends that stainless steel adapter plates be used to minimize the flow of heat to the critical components (Ref 18). Additionally, incorporating an air gap between the die body and die pot within the press minimizes the transfer of heat.

Effects of Prolonged Time at Temperature and Regrinding of Green Parts. Laboratory testing performed by Hoeganaes demonstrated that binder-treated powder can be reheated to warm-compaction temperatures a maximum of 4 cycles with minimal loss of powder flow and compressibility (Ref 4). Additionally, the powder can be held at temperature up to 4 h with no degradation of the apparent density, flow, green density, and green strength.

Although powder metallurgy is considered a low-scrap manufacturing process, nonusable parts are generated during the setup stage. To address this issue of potential green scrap, laboratory work was initiated at Hoeganaes Corporation to study the effects of adding reground warm-compacted powder into new premixes. This work demonstrated that additions up to 5% regrind can be successfully compacted without any degradation in the strength or flow characteristics of the premix. Although it is not recommended that regrind additions be made to critical components, this work demonstrated that additions can be made without any loss in powder or sintered properties.

Warm Compaction

Francis G. Hanejko, Hoeganaes Corporation

Potential Applications of Warm Compaction

Because warm compaction is a single-press and single-sinter process, the process is ideal for complex multilevel P/M parts that require high mechanical properties that cannot be obtained at conventional compaction densities. Higher density (or equivalent density at lower compaction pressures) can be achieved with warm compaction as compared with cold compaction (Table 6).

Table 6 Density and process comparison between warm and cold compaction

Base powder	Graphite	Lubricant	Compaction	Sintering	Sintered density, g/cm ³
Distaloy AE^(a)	0.5 %	0.7% Kenolube	600 MPa cold compaction	1120 °C, 30 min, Endogas	7.07
		0.6% Densmix	600 MPa warm compaction	1120 °C, 30 min, Endogas	7.31
		0.6% Kenolube	650 MPa cold compaction	1120 °C, 30 min, 90% N ₂ /10% H ₂	7.1
		0.6% Densmix	500 MPa warm compaction	1120 °C, 30 min, N ₂ /10% H ₂	7.1
Distaloy DC^(b)	0.5 %	0.6% Kenolube	650 MPa cold compaction	1120 °C, 30 min, 90% N ₂ /10% H ₂	7.1
		0.6% Densmix	500 MPa warm compaction	1120 °C, 30 min, 90% N ₂ /10% H ₂	7.1
Distaloy AE	0.8 %	0.6% Kenolube	600 + 500 MPa cold compaction (DPDS) ^(c)	750 + 1120 °C, 20 + 30 min, 90% N ₂ /10% H ₂	7.3
		0.6% Densmix	700 MPa warm compaction	1120 °C, 30 min, 90% N ₂ /10% H ₂	7.3

- (b) Distaloy DC is a diffusion bonded powder utilizing a prealloy 1.50% Mo powder with 2.0% Ni.
- (c) DPDS, double-press double sinter.

Recent articles have demonstrated the usefulness of the warm-compaction process in the fabrication of an automotive turbine hub for high-performance engines (part weight 1100 g), the manufacture of helical gears with gear densities in excess of 7.3 g/cm^3 , lock components (part weight 27 g), and gearing with complex gear forms or spiral gears requiring high gear densities (Ref 22, 23, 24). The current production parts made by warm compaction are parts with a complex shape that are not adaptable for double pressing and double sintering. Warm compaction offers a simplified manufacturing process with resulting mechanical properties that met or surpassed the part specification.

Mechanical properties of warm-compacted steel powders were compared to selected wrought and forged alloys (see Table 7). Note that the yield and tensile strengths of the warm-compacted alloys were equivalent to those of wrought alloys. Thus it would seem that components made from these alloys are suitable candidates for the warm-compaction process. It must be noted that the elongation of the P/M materials is significantly lower than the wrought alloys chosen (except for the heat-treated ductile iron). Thus, proper application of the warm-compaction process must consider the reduced elongation and impact energy of the P/M part.

Table 7 Comparison of warm-compacted materials to selected wrought and cast alloys

Material	Yield strength		Tensile strength		Elongation, %	Hardness
	MPa	ksi	MPa	ksi		
AISI 1020	345	50	440	64	35	77 HRB
AISI 1050	427	62	745	108	20	96 HRB
AISI 8620	358	52	635	92	26	90 HRB
AISI 8620 Heat treat	1390	202	1482	215	10	45 HRC
Ductile iron 120-90-02	860	125	965	140	2	36 HRC
Powder forged F-0005	765	111	827	120	10	27 HRC
Powder forged FL-4605	1172	170	1455	211	9.5	47 HRC
FLN-4205 at 7.39 g/cm^3	1220	177	1503	218	1.9	42 HRC
FD-0405 at 7.33 g/cm^3	938	136	1248	181	1.7	41 HRC

One significant advantage of the warm-compaction process is the increased density uniformity achieved in the compacted part (Ref 22, 23). Quantitative metallographic techniques demonstrated this feature in both a helical gear and an automotive turbine hub. Figure 9 demonstrates the greater uniformity of sintered density achieved with a turbine hub compared to a conventionally compacted part. This enhanced density uniformity results in increased load-carrying capacity with reduced dimensional variations because of the uniform density.

Fig. 9 Variation in sintered density and dimensional change of turbine hub processed by conventional P/M and warm compaction

Future applications of the warm-compaction process will exploit the ability to achieve higher green densities at lower compaction pressures, thus minimizing the tooling stresses. Additionally, with the increased interest in the sinter-hardening process, warm compaction offers the potential to green machine these components prior to sintering and subsequent hardening.

Cold Isostatic Pressing

Peter E. Price, Consultant

Introduction

COLD ISOSTATIC PRESSING (CIP) is a materials processing technique in which high pressure is applied to metal powder in a sealed elastomer container shaped for the application. The powder is converted from a loose aggregate into a partially dense compact that has sufficient green strength to permit careful handling and transfer to the following process operation. Water treated with corrosion inhibitor is the usual pressurization medium. Compacting pressures range from 207 to 414 MPa (30 to 60 ksi), although pressures as high as 758 MPa (110 ksi) have been used. Compaction is performed at ambient temperature. The density of the loose powder poured into the elastomer mold is increased from 55 to 65% of theoretical, a nominal range for uncompacted powder, to 75 to 85% of the 100% theoretical density value of the metal being processed.

There are two variations of the CIP process depending on the way the elastomer mold is utilized. In the "dry-bag" process, the elastomer mold is fixed to the pressure vessel and the equipment is designed for high production rate of small parts more typically in ceramics than in metals. In the "wet-bag" process, the mold is filled outside the vessel, transferred in, pressure compacted, and removed. In this process, multiple molds can be processed simultaneously according to the size of the pressure vessel. The wet-bag method is illustrated schematically in Fig. 1. Dry-bag methodology has much greater application in ceramics processing than in powder metallurgy, however, and is not further discussed here.

Fig. 1 Schematic of wet bag CIP process

Molded parts are designated as being in the "green" or unsintered state following common terminology used for die-compacted metal powder parts. The usual next step is sintering to increase density to a maximum value close to theoretical or to a designed lower value for intentionally porous structures. Cold isostatic pressing also can be used as a preliminary densification step in containerized hot isostatic pressing (HIP) where the objective is to increase the "fill factor" of the HIP capsule and permit increased dimensional control in that process. Post-sintering operations can include forging, extrusion, rolling, coining, and HIP. Certain powder metals such as titanium, which can be sintered to a closed-pore condition, are most suited to the widest selection of post-sintering process operations.

Cold isostatic pressing of metal powders was invented by H.D. Madden of the Westinghouse Lamp Company in 1913 (U.S. Patent 1,081,618) to process tungsten and molybdenum billets for subsequent conversion to wire. This application continues in current use in the refractory metals industry. A semiautomated process for production of ceramic parts using the dry-bag technique was patented by B. Jeffrey of the Champion Spark Plug Company in 1942 (U.S. Patent 2,290,910).

During World War II, the use of CIP was broadened to include applications in the pressing of explosives, ceramics, beryllium, and other special defense-related materials. In the postwar period, larger and higher pressure vessels were constructed to facilitate powder-based processes in metals and ceramics. In 1970, a vessel operating with a working chamber of 61 cm (24 in.) in diameter, 2.45 m (96 in.) long at a pressure of 551 MPa (80 ksi) was placed in operation in industry for processing beryllium powder. This vessel is still in commercial operation after transferring to new ownership

and location. Currently, there are a number of primary metals and metal part production processes that utilize CIP as an essential process step. Applications include processing tungsten, molybdenum, beryllium, tantalum, tungsten carbide/cobalt, P/M high-speed steels, and P/M composites. These materials cannot be melt processed if desired manufacturing response and end-point functional properties are to be maintained. The historical foundation of the current process has been described in the literature (see the "Selected References" at the end of this article).

Cold Isostatic Pressing

Process Characteristics

Unique aspects of CIP, as compared to die compaction, for P/M parts include:

- Hydrostatic application of pressure over all surfaces of the mold produces uniform powder density for simple and complicated shapes. Die-wall friction is not a factor in the densification process because of the elastic behavior of the mold.
- Organic binder or lubricant additions to the metal powders are not required to achieve useful green strength. In fact, these materials are detrimental because of the adverse influence on metal chemistry and related mechanical properties for many of the reactive metals commonly processed by CIP if all these materials were present.
- Shapes with high ratios (greater than 10) of length to characteristic diameter, can be densified and handled.
- Parts with reentrant and three-dimensional curved geometries can be made.
- Elastomer tooling can be combined with metal tooling inserts to exactly control certain part dimensions such as cylinder bores or outside diameters.
- Thin-walled sections and parts can be pressed.
- Parts so large that comparable uniaxial die pressing capacity does not exist in industry can be made because of the large area by pressure product available in the largest CIP vessels. For the 24 by 96 in. by 80 ksi vessel mentioned above, this maximum product is 818 MN (92,000 tons).
- Elastomer tooling costs are low.

Recognized limitations of the process include:

- Dimensional control is generally less precise than with metal die compaction because of the absence of exactly dimensioned reference surfaces and variability of the local poured powder density within the mold.
- Surface finish of cold isostatically pressed parts is rough compared to die-compacted parts except for areas in contact with hard tool inserts in hybrid molds.
- Production rates are low compared to metal die compaction.
- Elastomer molds have a relatively short life because of abrasive wear.
- Leakage of a mold in the CIP vessel due to mold tearing or poor closure and sealing practice results in loss of material due to contamination by the working fluid. With reactive fine powders, such as aluminum, in large molds water leakage into the mold can produce a hazardous exothermic reaction.
- Not all metals and alloys of interest are readily available in the suitable particle size distribution and shape for application in the process.

Process Equipment

Equipment for the process includes a pressure vessel with design pressures ranging up to 758 MPa (110 ksi), fluid reservoir, low-pressure transfer pump, high-pressure intensifier, fluid filtration equipment, automatic and manual high-pressure valves, pressure gages, safety-relief valves, and a control system. The process flow diagram for a modern CIP system is shown in Fig. 2. Fluid filtration for removal of destructive abrasive metal powder particles is a significant modern improvement aimed at reducing maintenance costs.

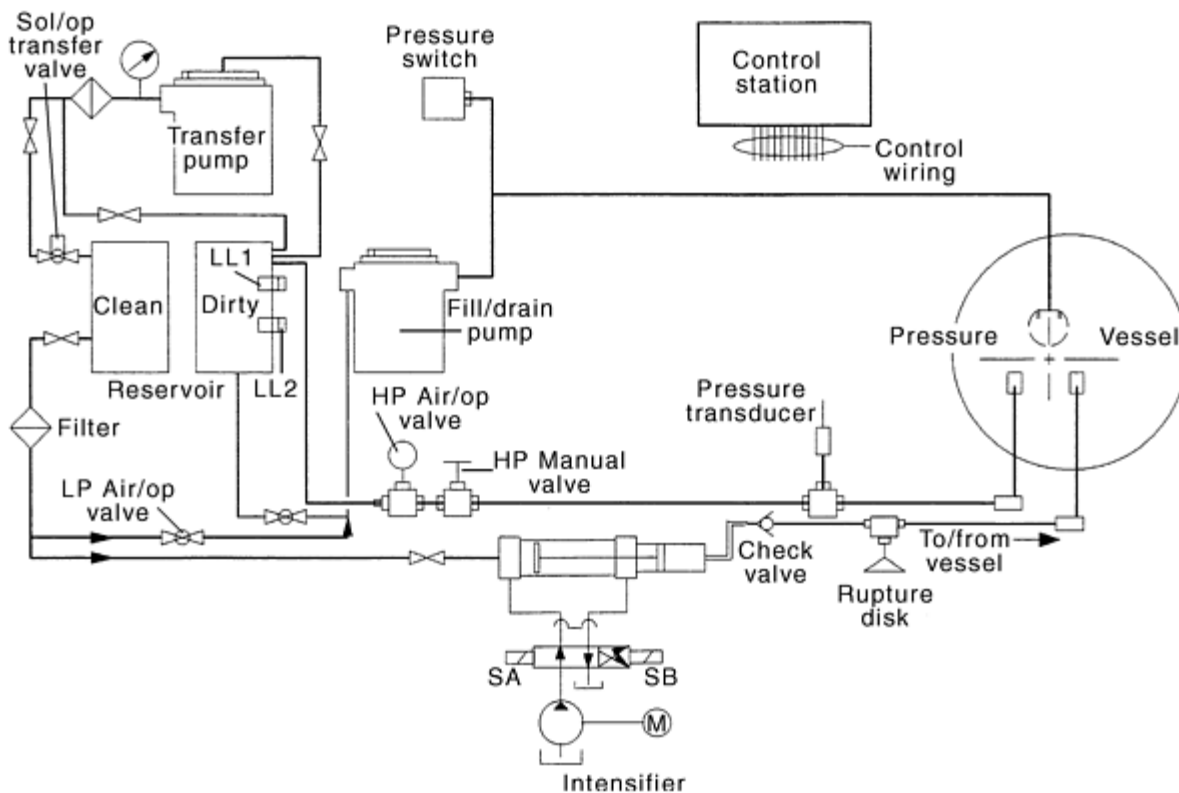

Fig. 2 Process flow diagram of modern CIP system. Source: EPS Inc. LP, low pressure; HP, high pressure; LL, liquid level; SA, side "A"; SB, side "B"; SOL/OP, solenoid to open; AIR/OP, air to open

Pressure Vessels. The pressure vessel is a unique and major component of the CIP system for powder metals. It is designed to meet all applicable engineering and regulatory codes for the size and pressure of the unit. Due to cyclic loading of the vessel, low-cycle fatigue life is a major engineering consideration, and a trade-off between desired operating life and initial cost is a factor in procurement. Design stress levels can be lowered to give increased operating life by increasing section thickness with consequent increase in cost. High-pressure vessels are manufactured as double- or even triple-shell designs wherein bore stresses are reduced by residual compressive stresses induced by a heat shrink assembly technique. Very large and very-high-pressure CIP vessels can be limited in design by the available manufacturing processes, transportation limitations due to size and weight, and engineering materials properties.

Closures and seals are critical design areas of pressure vessels. Closures may be full threaded, interrupted threaded, full resilient threads, or non-threaded support by an external yoke frame. Thread design, machining tolerances, and machine finish are important factors for long cycle life. For rapid opening, a quarter turn interrupted thread allows quick automated handling of the top closure of the vessel. A small CIP system with a quick opening top closure is shown in Fig. 3. The total length of thread in the interrupted design is approximately double that of the continuous thread design to

accommodate equivalent load-bearing capacity. The bottom closure of a threaded vessel is usually full threaded because it is removed only for maintenance and inspection. A recent trend has been use of a closed-bottom end design even for two shell vessels. This innovation eliminates the need for a bottom-end bore seal, which in P/M processing can be subject to abrasive wear due to unavoidable contamination and settling out at the seal/bore interface crevice of metal powder particles from surfaces of elastomer tooling bags. An alternative to a closed-bottom design is a bottom-pressure seal plate supported by the bottom-threaded end closure. This design allows removal of the plate from the top for cleaning and seal change. All CIP vessels have fill and drain ports in the closures and a top air vent port to allow total displacement of air during fluid fill. Fill and drain ports are at the bottom. The air vent port is required to avoid air trapping that would otherwise result in slow pressurization/pumping cycles due to the air compressibility.

Fig. 3 Small CIP system with quick-opening top closure. Courtesy of EPS Inc.

As an alternative to threaded closures, a yoke frame may be used to restrain end loads on the vessel closure plugs. Opening and closing a yoke frame unit requires moving the frame aside horizontally, extracting the end closure, and moving it aside for access to the working void space. User selection of yoke or threaded designs depends on factors including system size, design pressure, space availability, cost, inspectability, and preference.

Pressure Generators. After a low-pressure fluid-fill operation, pressure is increased in the system by air-driven or hydraulic-driven pumps and pressure intensifiers. Air-driven intensifiers are lower cost and slower than hydraulic units. The air units are used for small working void vessels and low production rates. Plant air is typically used for these pumps. Hydraulic intensifiers are installed for routine production, large vessels, and very high pressures. For wet-bag processing in most P/M applications, the pressurization medium is usually water with corrosion-inhibiting additives. An efficient filtering system is required to scavenge particulate contamination that would otherwise accelerate wear of the seals and pistons of these pumps.

Depressurization Design. The low compressibility of the usual working fluid, water, results in a rapid pressure drop in the vessel during let-down after only a small volumetric outflow. For large or convoluted-shape P/M parts, rapid release of the stored elastic energy and equalization of compressed gases (air) in the pressurized compact may cause fracture of the molded shape. First-stage depressurization is therefore preferably regulated with a manual or automatic control valve. With an automatic valve and computer controls, the depressurization rate can be controlled as a function of pressure allowing both a safe initial depressurization rate for molded parts and an efficient, fast, volumetric outflow rate from the vessel at lower pressures.

Control and Safety Features. The control system of a modern CIP unit functions to actuate the vessel closure, check off the locked condition of the closure, sequence valves, actuate a low-pressure pump for vessel filling, set control valves, accept and operate a pressure/time cycle protocol, actuate a high-pressure intensifier pump, provide information about system status (pumps, valves, pressure, etc.), and produce an analog/digital record of the process cycle. With a system with an automatic high-pressure control valve, the pressure let-down can be controlled according to cycle protocol. In addition to design and manufacture according to industry and regulatory standards of the vessel, valves, fittings, lines, and other items in the high-pressure flow path, safety-release overpressure rupture disks, analog and digital pressure indicators

at the control station and at the equipment (analog type), closure lock indicator, instrument air supply indicator, and parallel/series manual valves for pressure let-down in the case of electrical or air supply outage are standard components of a modern CIP system.

Tooling. The simplest form of cold isostatic tooling is an elastomeric material mold or "bag" shown schematically in Fig. 1. The cavity dimensions of the mold take into account the volume of poured and loosely settled powder required to produce a compacted part. The mold cavity may be considered a three-dimensional equiaxial expansion of the cold isostatically pressed form. Additional complexity can be introduced into the tooling by use of inside-diameter, outside-diameter, or special-shape hard-tooling inserts in the bag to provide hard reference surfaces, shapes, and dimensions for the metal powder during compaction. With hybrid tooling, that is, elastomeric bags with hard tooling inserts, defined dimensions and shapes are produced from the "reference" surfaces, while the dimensions and surface smoothness of the "free" surfaces in contact with the elastomer are less exact. To prevent sag and bulging of large molds due to the weight of contained metal powder, external conformal support fixtures are used. Compression of powder can be either "outside-in" (collapsing-bag technique) or "inside-out" (dilating-bag technique). With the dilating-bag technique, there are stops or expansion limiting hard tooling components such as the inside diameter of a steel tube to define the limits of the mold cavity.

Tooling Material. Elastomer tooling is subject to abrasive wear and tearing. Tearing of a mold in the CIP vessel is a serious operational difficulty due to possible spillage of metal powder into the pressure vessel and subsequent introduction into the seal areas, valves, fittings, pumps, and filters. In such an event, immediate steps to drain, inspect, strip, and clean the system are required to avoid costly wear of critical system components. A control system for monitoring mold usage and condition as well as appropriate selection of mold material can prevent such failures. Molds can be manufactured from a variety of elastomers including natural rubber, butyl rubber, polyvinyl chloride, polyurethane, neoprene, nitrile, and silicone rubbers. Abrasion resistance, hardness, and resilience are properties that are adjustable in the elastomer formulation. Polyurethane rubber meets these requirements well and can be produced in a variety of hardness or durometer specifications. Custom molds can be manufactured by commercial sources. Alternatively, a rubber formulation, dipping, and curing operation can be set up in-house when many and varied molds are required using commercially available materials and equipment.

Cold Isostatic Pressing

Wet-Bag Isostatic Pressing

In wet-bag pressing, the mold is filled, evacuated (if this step is used), and sealed outside the pressure vessel. Because these operations occur in a powder-handling area, contamination of external mold surfaces with metal powder can easily occur. Introduction of dirty molds into the vessel results in working fluid contamination with long-term effects similar to mold tearing and gross metal powder spillage. Thorough mold washing as an integral part of the process flow chart is necessary to keep the process fluid system clean. Filled molds are stacked on a rack that serves as handling tooling for loading molds into the vessel. In normal practice, the vessel is not fully emptied of working fluid (most commonly water with corrosion preventative additive) between pressurization cycles. This means that even with an external filtering system for that portion of the working fluid that is cycled in and out of the vessel, a major fraction of the working fluid remains in the vessel and may accumulate traces of metal powder introduced in each process cycle. Depending on usage rate, periodic complete draining and cleaning of the vessel is necessary to maintain the highest level of working fluid cleanliness.

The wet-bag process is flexible in that it can be adapted for large shapes limited only by vessel dimensions or multiple small shapes that can be stacked in a loading rack for a single process run. With a given metal powder that establishes the required process pressure, a mix of mold sizes and shapes can also be processed as a single batch, thereby utilizing the flexibility of the process. The requirement for mold support tooling must be determined for each configuration. Currently, when CIP is used for P/M applications the wet-bag process is usually selected.

Cold Isostatic Pressing

Peter E. Price, Consultant

Part Size and Shape

The upper limitation on the size of a P/M part is the diameter and internal height of the available CIP pressure vessel minus the dimensional space required for the rack tooling required to lift the mold (plus mold support tooling) into and out of the vessel. Alternatively, multiple small shapes can be processed using stacked layers of parts on rack-type tooling.

Billets are simple shapes including cylinders, rectangular solid slabs, and sheet bars. After CIP, these shapes undergo further processing including typically sintering, hot deformation, and cold deformation with intermediate annealing for conversion to final form.

Forging preforms have a shape related to the final forging shape depending on whether it is a closed-die or open-die forging. The preform must have sufficient total mass to fill the closed-die cavity or finish the open-die part with sufficient excess stock to clean up in machining. Sintering following CIP is necessary to ensure metal flow without premature fracture. The advantage of a forging preform is elimination of one or more intermediate forging steps, particularly in closed-die applications. Forging acts to increase the density of the preform, refine the sintered grain structure, and produce deformation texture allowing production of a part with mechanical properties dependent primarily on chemistry and heat treatment. Both forging preforms and near-net-shape parts produced by CIP facilitate production of prototype parts with reduced initial tooling costs.

Near-net shapes are produced using elastomeric molds with and without hard tooling inserts. The mold cavity is dimensioned so that after CIP and sintering final dimensions require only a minimal amount of finish machining. The utilization of expensive metal powders is efficient. Blends of powders with disparate properties such as melting point can be processed by CIP to produce unique functional properties. Also, blends of powders with significantly different mechanical properties, that is, soft and ductile versus hard and brittle can be cold isostatically pressed to net shape to produce parts that could not otherwise be produced by deformation processing. Sintering can produce parts with densities in the range 90 to 97% of theoretical, which is sufficient for designated applications. Intentionally low-density net-shape parts for applications such as filters can be produced by selection of CIP pressure and sintering schedule. Alternately, for select metal powders such as titanium and its alloys CIP to net shape followed by sintering to a closed-pore condition allows a final step of hot isostatic pressing to be employed to produce substantially fully dense parts. Shrinkage allowances for CIP compaction, sintering compaction, and hot isostatic compaction must be factored into the CIP mold design to realize optimal material utilization and minimal final machining. Final dimensions of sintered or sintered and hot isostatically pressed near-net-shape parts depend critically on mold dimensions, powder properties, and the thermal process cycle.

Powder Properties

Metal powder characteristics directly determine the parameters of the CIP process. In mold filling, particle size distribution and particle shape are controlling factors in determining tap density of the filled mold. For billet molds, where final shape is determined by deformation processing operations, exact fill is not as important as in near-net-shape parts. Nevertheless, reproducible particle size and shape factors would be required to ensure repeatable post-CIP processing. In the case of net-shape parts, the mold must be filled to a uniform and repeatable tap density at all locations in the mold to yield predictable green part dimensions. This requires exact control and reproducibility of the above-indicated factors. German (Ref 1) has presented the existing knowledge base covering particle packing characteristics. In the case of blends of powders with disparate characteristics, that is, tungsten plus copper, for example, particle characteristics including size, shape, and density control the extent of separation during handling and mold filling (Ref 1).

Powder blending represents the most adaptable method for creating alloy compositions using CIP. Elemental powders can be blended with master alloy powders to create ranges of compositions. Separation of the blend must be avoided by selecting appropriate size and shape factors for the constituents (Ref 1).

In CIP compaction, a series of events takes place including particle rearrangement, localized deformation, homogeneous deformation, and elastic bulk compression. These phases of compaction depend on yield strength, strain hardening rate, and elastic properties, all of which are generally inferred from bulk properties of the related metal or alloy. Hardness is a shorthand indicator of compaction response because it is a property derived from the plastic flow properties of the bulk material. The softer the bulk metal is, the lower will be the required compaction pressure. With blends of powders with dissimilar properties, that is, hard and soft, compaction response is governed by the constituent with the greatest connectivity, that is, that phase of the blend for which a continuous path between like particles can be traced throughout the structure without intersection in the alternate phase.

Although produced regularly in tonnage quantities in a variety of compositions, powders atomized from the melt have a generally spherical particle shape and have been found difficult to use in CIP processing. This behavior is attributed to absence of shear and interlocking mechanisms during compaction, processes that occur in chemically produced metal powders with irregular shapes. Atomized powders can be altered in particle shape by mechanical processing such as milling or attrition.

Process Parameters

Figure 4 outlines a simple flowchart for the CIP process. Critical elements of the overall process for producing uniform and reproducible parts include: part design, mold design, reproducibility of metal powder density in filled mold, mold support, and CIP pressure. Operations that can lead to process failure if not properly executed include mold closure, mold sealing, evacuation, sealing of mold evacuation port, depressurization rate, and handling.

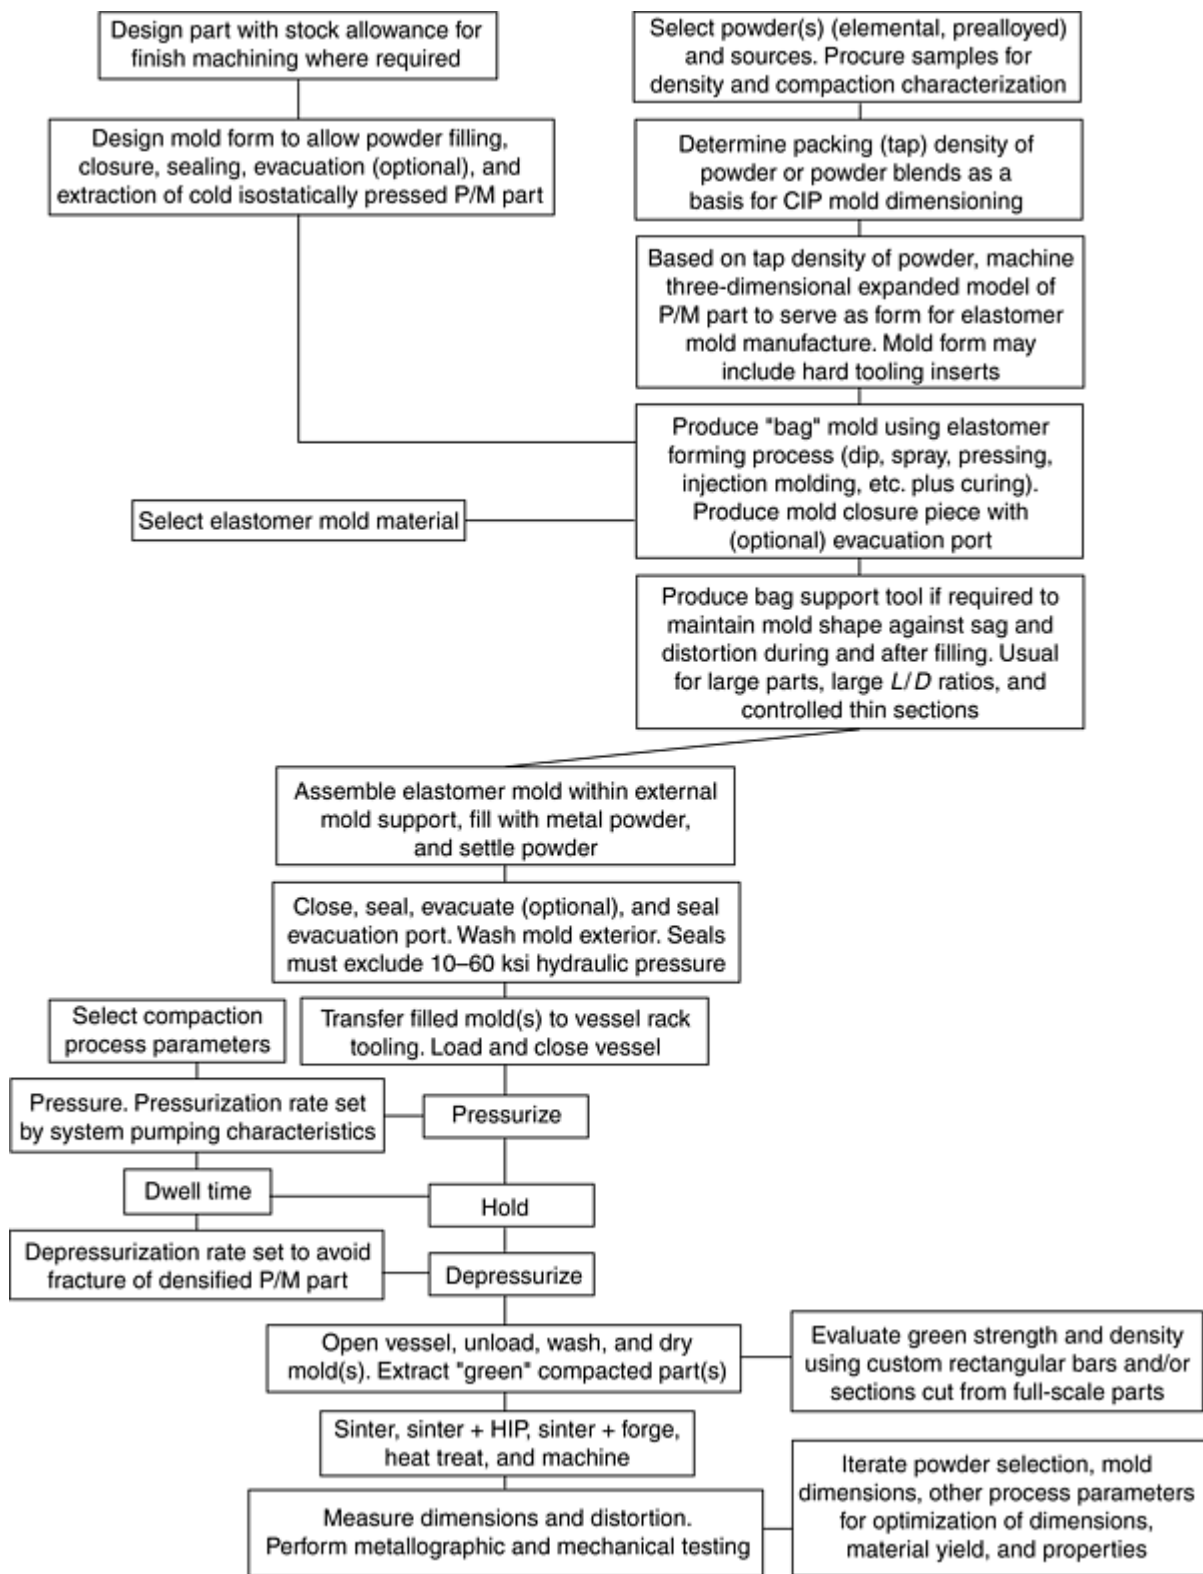

Fig. 4 Process flowchart for production of cold isostatically pressed parts

Dwell pressure for producing "green" strength that allows handling after CIP and maximum density if full density (as opposed to intentionally porous) parts are desired is determined by metal and powder type. Typically, pressures in excess of 200 MPa (30 ksi) are required for the process. Applicable ranges of dwell pressures for a variety of powder metals are:

Powder	Pressure range	
	MPa	ksi
Aluminum	55-140	8-20
Copper	140-275	20-40
Iron	310-415	45-60
High-speed tool steel	240-345	35-50
Stainless steel	310-415	45-60
Titanium	310-415	45-60
Tungsten	240-415	35-60

For isostatic compaction, lower pressures are required than for die compaction due to the absence of die-wall friction effects. Nominal CIP pressure for a metal powder is also substantially independent of part size, again because of the isostatic nature of the process. Figure 5 shows density as a function of pressure for select cases of isostatically and die-compacted powders.

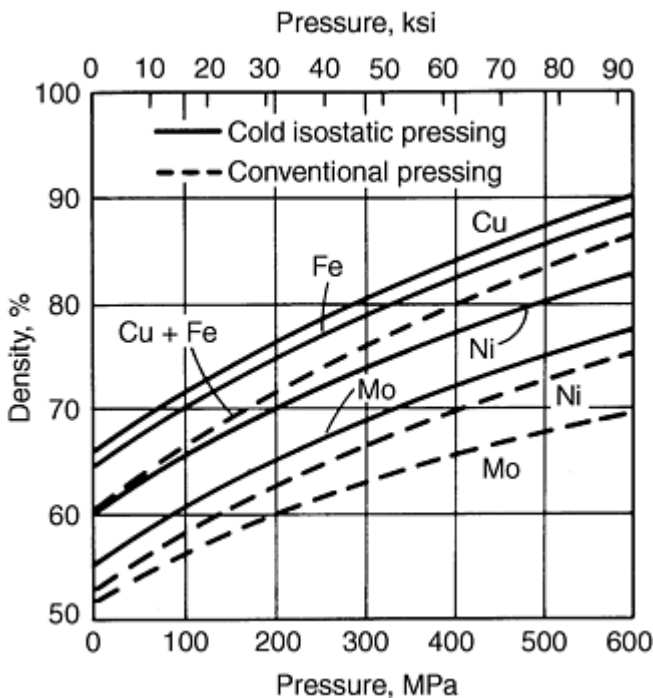

Fig. 5 Density as a function of pressure for cold isostatically pressed and die-compacted parts

Dwell time is generally only a few minutes for the process. At room temperature (the usual process temperature), there is negligible time-dependent particle deformation for the materials listed above. Thus, density follows pressure very closely in time, and no further increase occurs at constant pressure.

Depressurization rate is a unique process parameter for CIP. Under full process pressure, the densified metal part stores elastic strain energy in the solid and the $P \cdot V$ (pressure \cdot volume) energy due to compression of air and gases entering into the mold in the void space of the low-density metal powder. Rapid release of process pressure can result in cracked parts. Entrapped gas can be eliminated by evacuation and sealing of the filled mold, but this process option, which adds complexity to the process and mold design, is frequently bypassed. Because of the relatively low compressibility of water (most frequently used pressurization medium), a very small volume release at high pressure causes a large pressure drop in the CIP system. Therefore, controlled depressurization is achieved by use of a high-pressure flow-control valve in the overall system. A depressurization schedule that avoids part cracking should be determined experimentally.

Evaluation of green strength and density of a cold isostatically pressed part may be carried out for a given metal powder and process cycle in the development or qualification phase of a powder and/or part by molding rectangular bars and carrying out three-point bend tests according to the protocol of ASTM B 312 (1997). These same bars may be measured and weighed before the bend test to determine approximate green density. Because the mold is elastomeric and not a hard die as specified in the ASTM procedure, oversize parts can be produced and machined green to standard dimensions for the development and control tests. Uniformity of density and green strength for larger parts can be determined using cut-ups taken along various directions of interest.

Thermal processing of cold isostatically pressed parts usually starts with sintering. Sintering cycles may be designed to maximize density or produce a specified percentage of porosity. Sintering atmospheres are based on metal chemistry requirements and include vacuum, reducing, and chemically active atmospheres such as carburizing and nitriding. Full density of cold isostatically pressed and sintered P/M parts can be achieved by hot isostatic pressing following sintering if a closed-pore condition can be established. This is common for titanium alloy parts and metal compositions that can be liquid-phase sintered such as tungsten carbide/cobalt, iron-bonded TiC, and tungsten/copper. Low-pressure liquid-phase sintering can be used as a complete alternative to HIP for selected materials. More complicated thermal processing sequences can be invoked such as sinter plus HIP plus forge to produce a fully dense forging with desired grain flow structure. This sequence is material efficient and eliminates the requirement for multiple forging steps, dies, and reheats.

Cold Isostatic Pressing

Peter E. Price, Consultant

Applications

Parts that are candidates for application of CIP originate within the sets (not all inclusive). They are expensive materials such as titanium, tungsten, molybdenum, and tantalum; materials difficult to machine such as tungsten carbide/cobalt, titanium carbide/iron, titanium, and tool steels; complex shapes; hybrid structures such as layered structures of multiple materials or combined porous/dense structures; and intersections of the above. Using titanium and its principal alloy Ti-6Al-4V as materials for illustration, application examples of CIP are shown in the following. Figure 6 shows the shape complexity feature of CIP where a nearly axisymmetric part 125 mm (5 in.) in diameter with round and rectangular inside-diameter features was produced using hard-tooling core mandrels and a net-shape external elastomer mold. The hard-tooled surfaces have evolved as smooth compared to the elastomer mold interface surfaces following CIP plus HIP. The surface produced by the elastomer mold reflects the particle size of the blended powder. In Fig. 7, CIP has been used with blended elemental powders of Ti-6Al-6V-2Sn and Ti-6Al-4V to produce with high material efficiency a hollow cylindrical cup with isotropic (texture-free) mechanical properties using a hard-tool core mandrel. The part has a high surface-area-to-volume ratio. The alternative to the use of CIP is machining from stock with a resulting low part-weight-to-stock-weight yield ratio. In Fig. 8, a series of parts with variable geometry and integral regions of controlled density have been produced using CIP. Powder size distribution can be selected as well as multiple-step CIP to facilitate production of the design. Porosity can range from zero to slightly greater than one minus the tap density of the metal powder, that is, approximately $1 - 0.55/0.65$, where $0.55/0.65$ is a normal range of powder density, when low-pressure CIP plus low-temperature sintering increases the original powder density slightly. Filters, filter supports, vibration damping, and heat transfer control devices are typical applications for porous parts. Figure 9 illustrates forging preforms in an aluminum alloy (lighter-color part) and a titanium alloy produced by CIP plus sintering. A final part can be produced with a single die set and forging stroke. Preform dimensions can be modified so that the forging operation produces desired effects including: amount and location of plastic strain, final densification, microstructural homogenization, and property enhancement, particularly fracture toughness. In the case of the connecting rods, overall length is maintained in forging. For tubular or solid parts with length-to-diameter (L/D) ratios of 2 or greater CIP can produce parts such as shown in Fig. 10. This part has an L/D of 2.25 with wall thickness of ~ 6 mm (~ 0.25 in.) with a closed bottom. Similar parts such as tubes, pipes, hydraulic pressure fittings, and vessel liners with thin walls, high L/D ratios, tapered wall thickness, and stepped bores are all practical with CIP technique.

Roll Compacting of Metal Powders*

Reviewed by Walter V. Knopp, P/M Engineering and Consulting Co.

Introduction

ROLL COMPACTING, or powder rolling, refers to the continuous compaction of metal powders by a rolling mill. In this process, metal powders are fed from a hopper to a set of compacting rolls that produce a continuous green (unsintered) strip or sheet. These materials undergo further processing by sintering (heating) and rerolling to produce an end product with the desired material properties. Material can be produced fully dense or with a desired porosity and pore size.

Ideal powder characteristics for roll compaction are comparable to those desired in powders for die compaction; flowability is important to ensure consistency in the final product; softness and irregularity of powder particle shape promote green strength; and particle size and size distribution influence green density. Metal powders suitable for roll compacting include elemental powders, blends of elemental powders or elemental and alloy powders that are homogenized during sintering, blends that contain additives that are nonreactive and that cannot be produced by standard melting and casting processes, and prealloyed atomized powders.

Atomization has the capability to produce powder particles that are individually uniform in composition and unique in internal structure. Strip produced by roll compacting of powders subsequently produces materials that are clean and completely uniform throughout the coil, with a fine grain size.

Note

Production Procedures

Roll Position. The type and position of the rolls vary with the type of system chosen to produce the desired finished strip. Rolls can be positioned vertically (as in conventional rolling mills), horizontally, or at an inclined angle, as shown in Fig. 1.

Fig. 1 Typical roll positions. (a) and (b) Horizontal positioning. (c) Vertical positioning. (d) Inclined angle positioning

Roll position selection is determined by several factors: the characteristics of the material, the amount of strip to be produced, the desired end product, and special structural requirements. Horizontal roll position (Fig. 1a) using gravity feed offers the most flexibility in controlling powder feed and is a convenient way of introducing several powders for multiple-layer strip. A conventional vertical mill can also be used to roll compact powder. However, vertical roll position (Fig. 1c) requires a very tall sintering furnace, or the green strip must be turned horizontally to enter a conventional furnace. This action could disrupt green bonds and inhibit sintering. The inclined angle position (Fig. 1d) offers a

compromise between vertical and horizontal roll positions. Using this approach, a conventional mill can usually be used and powder can be gravity fed.

Powder Feeding. The initial step in the roll compacting process is the feeding of powder to the rolls. The green strip should exhibit uniform density from edge to edge; otherwise, problems may be encountered during processing, and nonuniform conditions cannot be rectified. If strip has a higher density on one side, it may exit the re-rolling mill at an angle, exhibiting camber or a long edge. However, if the center of the strip has a lower density, it may crack on re-rolling due to densification and elongation of the edges. If the edges of the strip have a lower density, the higher density center area may densify and elongate during re-rolling, causing edge cracks.

Two methods of feeding powder to the rolls are illustrated in Fig. 2. The powder is fed to the hopper by a belt or a vibrating feeder from the storage bin. During saturated feeding (Fig. 2a), the powder falls directly from the hopper into the roll gap. The head of powder in the hopper should be held constant, because it applies pressure on the powder in the roll gap. A variation in pressure at the gap affects the feed rate of the powder, which results in varying density along the strip length. In the unsaturated, or "starved," feeding system (Fig. 2b), the amount of powder entering the roll gap is controlled by adjustable gates. Variations in compaction density can be made by adjusting the gates. Adjustable gates also can be used for saturated feeding.

Fig. 2 Methods of feeding powder to the rolls. (a) Schematic of roll compaction with saturated feed, rolling mill rolls arranged horizontally. (b) Roll compaction with unsaturated feed controlled by adjustable gates

Cover plates, formed to fit the curvature of the roll diameter, are available in sections so that powder feed can be varied at different areas of the roll surface as required. Figure 3 illustrates a typical powder feeder. This design incorporates a lateral deflector plate that distributes the powder evenly across the powder hopper. At present, strips of any roll-compacted powder can be produced by both saturated and unsaturated feeding in widths up to 53 cm (21 in.) and thicknesses of 2.5 to 3.2 mm (0.100 to 0.125 in.). Lateral deflector plates in the powder feeder are not necessary to achieve these results in all cases.

Fig. 3 Typical powder compaction mill feeder arrangement

Edge Control. The green strip rolled from powder should have uniform thickness and density across the width of the strip, and its edges should be well formed and as dense as the center of the strip. Therefore, a method of containing the powder being fed to the compacting rolls is essential to process control. Without edge control, powder escapes from the roll gap. Consequently, a strip with low-density edges is produced, which necessitates edge trimming after the strip is re-rolled.

Figures 4 and 5 illustrate typical methods of retaining powder in the roll gap. The method shown in Fig. 4(a) uses floating flanges that are attached to one roll and that overlap the other roll. Pressure is applied to the flanges as they approach the roll gap, thus preventing powder loss from the gap. A continuous belt that covers the gap at the edge of the rolls also is effective in preventing powder loss (Fig. 4b and 5). Other systems are available that produce strip with a tight edge that requires minimal edge trimming.

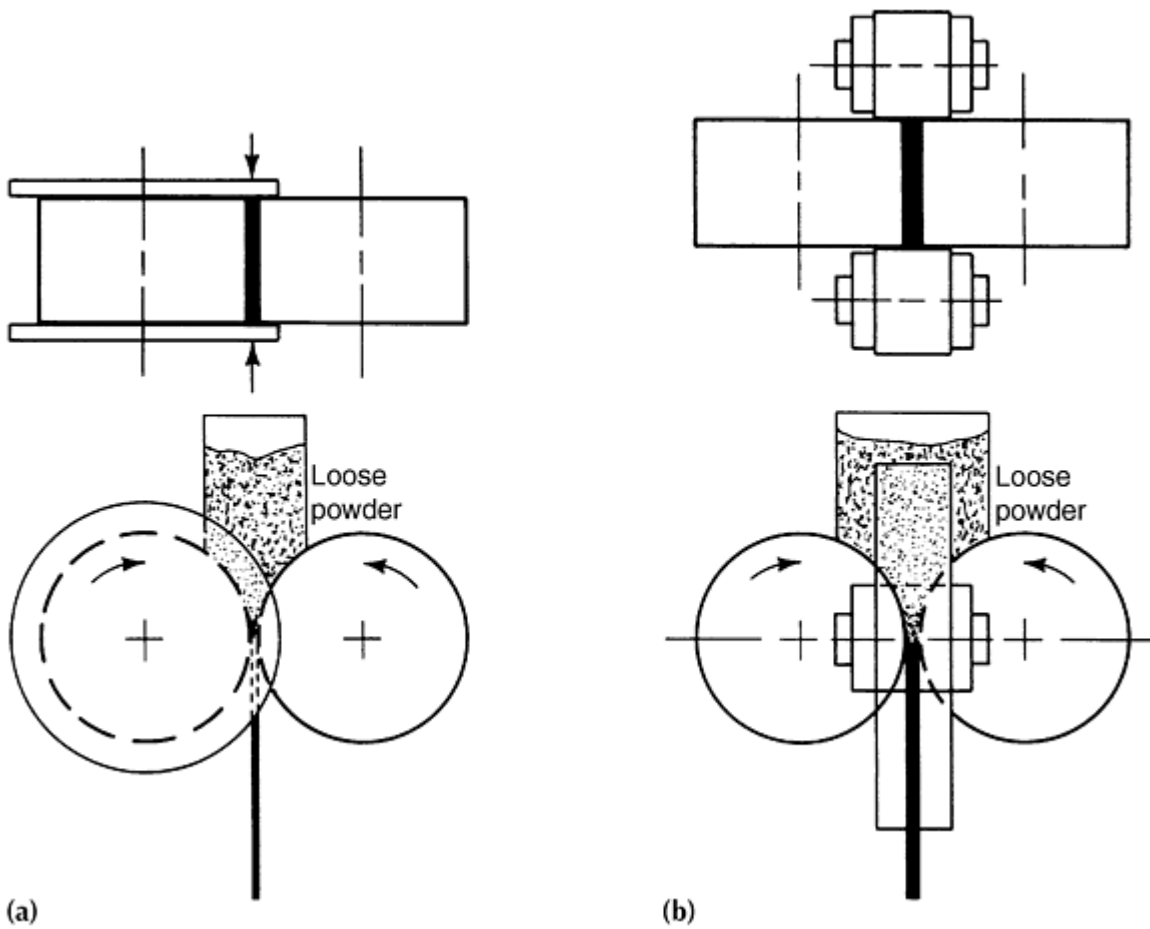

Fig. 4 Methods of controlling powder feed to compacting rolls. (a) Flange edge control. (b) Belt edge control

Fig. 5 Edge restriction device. V-belts and pulleys are used to contain powder at the edge of roll face and in the roll gap of a powder compaction mill

Roll Diameter. In powder rolling, strip thickness is mainly determined by the roll diameter used. Roll diameter varies from 12.7 mm (0.5 in.) to 920 mm (36 in.). Figure 6 illustrates the effect of roll diameter. The nip, or gripping, angle for conventional metal rolling is the same for powder rolling (approximately 7 to 8°). Note that on the larger diameter roll, a larger arc is included by the nip angle on the roll surface. Therefore, a larger amount of powder is pulled into the roll gap than in the small-diameter rolls. For a given powder, a thicker strip can be produced with the larger diameter rolls.

Fig. 6 Effect of roll diameter

Figure 7 shows the strip thickness that can be obtained with different roll diameters with two types of nickel powder. The atomized nickel is soft, while the hydrometallurgical nickel powder is hard. The ratios of roll diameter to optimum green strip thickness vary widely for different powders. They depend on the flow and apparent density of the powder, the coefficient of friction between the powder and roll, roll temperature, and whether the powders produced are hard or soft.

Fig. 7 Effect of work roll diameter on green strip thickness for two types of nickel powder

If the coefficient of friction between the powder and the rolls is increased by roughening the roll surface, a larger amount of powder will be pulled into the roll gap. For the same roll setting, higher compacted densities will be obtained. An increase in roll temperature, achieved through preheating or increased pressure, will also increase the coefficient of friction with the same results.

The roll gap is normally set to provide a green density approximately 80 to 90% of the theoretical density at a thickness that will provide full density when processed to final gage. Hot and cold workability of the material will determine the compacted gage.

Finishing. Uniform green strip produced by the compacting mill must be sintered before further densification. Green density usually is between 75 and 90% of theoretical density. A higher density renders the green strip hard and brittle, while a lower density produces a weak strip that is difficult to handle. Finishing of strip can be accomplished by several methods, depending on the type of material being produced, quantity required, sintering temperature and time, atmosphere requirements, and hot or cold working characteristics.

Figure 8 shows two methods of handling strip when densification is achieved by cold rolling. In Fig. 8(a), strip is coiled green and then sintered in a bell-type furnace. In Fig. 8(b), strip is passed through a sintering furnace, cooled, and then coiled. If necessary, additional sintering and re-rolling steps are completed in the same manner.

Fig. 8 Powder rolling processes. (a) Cold rolled green strip is coiled and then sintered in a bell-type furnace. (b) Cold rolled strip is reeled into individual coils after first sintering treatment

In Fig. 9, strip from the compacting mill is passed through the sintering furnace. While still hot, strip is hot rolled to full density. Strip is then cooled before leaving the furnace and subsequently coiled.

Roll Compacting of Metal Powders *

Reviewed by Walter V. Knopp, P/M Engineering and Consulting Co.

Commercial Production

Powder rolling was described in a number of early patents (Ref 1), but the first in-depth analysis of the process was undertaken by Naeser and Zirm (Ref 2), who documented their work on rolling RZ iron powder into strip. Powder rolling of copper powder is described in Ref 3 and 4.

From 1958 to 1968, powder rolling processes received considerable attention in Great Britain, the United States, Canada, the Soviet Union, and Japan. Principal interest centered around combining low-cost processes for producing metal powders, such as copper, nickel, cobalt, iron, and aluminum, with the powder rolling process to develop methods of fabricating thin sheet or strip more economically.

Nickel Powder Strip. The Sherritt Gordon process of rolling nickel powders into strip and sheet was one result of these efforts (Ref 5). This strip was used to make coinage blanks for the Canadian Mint. Typical mechanical properties of roll compacted nickel strip at various stages of manufacturing are given in Table 1.

Table 1 Typical mechanical properties of hydrometallurgical powder rolled nickel strip

Strip	Strip thickness		Strip density, %	Ultimate tensile strength		Yield strength		Elongation, %
	mm	in.		MPa	ksi	MPa	ksi	
Green strip	4.0	0.158	79	4	0.6	4	0.6	0
Sintered strip	4.1	0.161	79	138	20	136	19	0
Hot rolled strip	2.1	0.084	100	358	52	165	24	38
Cold rolled strip	1.3	0.052	100	579	84	572	83	5
Annealed strip	1.3	0.052	100	362	53	83	12	48

After nickel powder is compacted into a green strip, the strip is sintered between 1000 and 1200 °C (1830 and 2190 °F) in a muffled furnace. Hydrogen, dissociated ammonia, or even less reducing gases provide a suitable atmosphere. Strip is conveyed through the furnace on a mesh belt or rollers.

Densification of the roll-compacted nickel strip can be achieved by hot or cold rolling. Hot rolling of nickel strip is performed above 800 °C (1470 °F), with a reduction in thickness of approximately 50%. Because of its porous nature, the sintered strip should be protected from oxidation when heating for hot rolling. This can be accomplished by using an inert or exothermic atmosphere.

Cold rolling and annealing cycles also may be used to densify the sintered strip. To be successful, sintering must be performed at 1100 °C (2010 °F) or higher. Limited reduction is achieved on the first cold mill pass. The strip must then be fed directly to a furnace without coiling, where it is annealed and cold rolled to full density. Reductions in excess of 35% are necessary to achieve full density.

Several advantages are gained from producing high-purity nickel strip by roll compacting. Lower electrical resistivity is possible (73 to $79 \times 10^{-6} \Omega \cdot \text{m}$, or 44 to $48 \Omega \cdot \text{cir mil/ft}$). Stability can be maintained at $\pm 2\%$ throughout the coil and from heat to heat. Wrought nickel offers an erratic $\pm 6\%$ tolerance. Work hardening rates for roll-compacted nickel strip are 25% less than for wrought nickel strip.

The lower softening (annealing) temperature coupled with high purity makes this nickel useful in clad metal combinations. In these applications, low and closely controlled annealing temperatures are required to minimize interdiffusion and to prevent incipient melting reactions.

Finished nickel strip produced from powder is virtually indistinguishable from strip produced from an ingot. Differences in physical properties are the result of compositional variances, rather than the method of fabrication. Typical physical properties for strip made from nickel powder are:

Density	8.90 g/cm³
Coefficient of thermal expansion at 20-100 °C	14 $\mu\text{m/m} \cdot ^\circ\text{C}$
Coefficient of thermal expansion at 20-500 °C	15 $\mu\text{m/m} \cdot ^\circ\text{C}$
Thermal conductivity	86.23 W/m · K (0.206 cal/cm · s · °C)
Cold working capacity	Good
Hot forming capacity	Good
Hot work temperature	800-900 °C (1470-1650 °F)
Annealing temperature	700-900 °C (1300-1650 °F)
Magnetic properties	
Curie temperature	353 °C (667 °F)
Initial permeability	130
Maximum permeability	1240
Saturation induction	6.05 T
Remanance	3.25 T
Coercivity	23.87 A/m
Magnetostriction (soft) 1590 A/m	0.000032 mm/mm

Cobalt Powder Strip. Other metal powders can be roll compacted using methods similar to that of nickel powder. Powder characteristics and material properties alter processing parameters and conditions, however. For example, cobalt has a close-packed hexagonal crystal structure, which changes the surface morphology of the cobalt powder. Roll-compacted cobalt powder produces a green strip that is stronger and denser than the comparable green nickel strip. Typical mechanical properties of powder rolled cobalt strip at each stage of the production process are given in Table 2.

Table 2 Typical mechanical properties of hydrometallurgical powder rolled cobalt strip

Strip	Strip thickness		Strip density, %	Ultimate tensile strength		Yield strength		Elongation, %
	mm	in.		MPa	ksi	MPa	ksi	
Green strip	2.1	0.084	86	22	3	22	3	0
Sintered strip	2.1	0.084	86	201	29	195	28	5
Hot rolled strip	1.2	0.048	100	758	110	413	60	15
Cold rolled strip	0.9	0.036	100	1103	160	1100	159	1
Annealed strip	0.9	0.036	100	793	115	345	50	20

Note: Compacting roll diameter, 254 mm (10 in.). Roll speed, 6.0 rpm. Roll gap (green strip), 1.5 mm (0.06 in.)

After sintering at 1100 to 1150 °C (2010 to 2100 °F), cobalt may be densified by hot or cold rolling. Cold rolling of pure cobalt is inhibited by the close-packed hexagonal crystal structure, which characteristically produces rapid work hardening and restricts cold reduction to approximately 25% between anneals.

The use of high-purity cobalt powders for the feed to a powder rolling mill results in a relatively ductile strip. Use of controlled conditions during annealing results in increased amounts of cubic phase (usually associated with cobalt above 445 °C, or 835 °F), which is retained at room temperature. The retained phase is stable and shows little tendency to transform to the hexagonal structure at room temperature.

The rapid work hardening characteristics of cobalt make it an ideal candidate for powder rolling. The initial strip can be rolled to a thickness very close to the required final gage. Because initial strip thickness is thin (1.5 to 2.0 mm, or 0.06 to 0.08 in.), cold rolling is minimized. Typical physical properties of powder rolled cobalt strip are:

Density	8.85 g/cm³
Coefficient of thermal expansion at 20-100 °C	13 $\mu\text{m/m} \cdot ^\circ\text{C}$
Coefficient of thermal expansion at 20-500 °C	14 $\mu\text{m/m} \cdot ^\circ\text{C}$
Thermal conductivity at 70 °C (160 °F)	115.9 W/m · K (0.277 cal/cm · s · °C)
Cold working capacity	Poor
Hot forming capacity	Good
Hot work temperature	600-800 °C (1110-1470 °F)
Annealing temperature	800-1000 °C (1470-1830 °F)
Magnetic properties	
(Unworked high-purity powder rolled cobalt strip)	
Curie temperature	1121 °C (2049 °F)
Initial permeability	11.6
Maximum permeability	29.2
Saturation induction	1.9 T
Saturation field strength	310,000 A/m
Remanance	0.3 T
Coercivity	3,600 A/m
Coefficient of friction at 70 °C (160 °F) cobalt/cobalt	0.3

Production of heterogeneous alloys is possible with roll compacting processes. In cobalt-iron materials, for example, the presence of the iron promotes a suppression of the cubic to hexagonal phase transformation in cobalt. The ductility of the cobalt-iron mixture increases with increased iron content. The effects of adding iron powder to cobalt powder on the properties of cobalt strip are shown in Fig. 10.

Fig. 10 Properties of cobalt-iron alloys. Manufactured by powder rolling of blended cobalt and iron powders

Specialty Applications

Roll compacting facilitates the production of small coils in which minor compositional changes can be made during blending. Because roll compacting produces materials with uniform and reliable properties, many specialty materials are produced by these methods (Ref 6).

Specialty P/M strip produced by roll compacting includes various compositions of nickel-iron strip produced for controlled expansion properties and special copper-nickel-tin alloys. The latter must meet stringent property requirements, such as strength, formability, stress relaxation, electrical conductivity, solderability, and corrosion resistance. Casting of this material produces elemental segregation during solidification, which can be avoided by using P/M fabrication techniques.

Typical applications of roll-compacted strip materials include:

- High-purity nickel strip parts for heart pacemaker batteries
- Nickel-iron strip for resistor caps (Fig. 11)
- Nickel-iron lead frames (Fig. 11)
- Ni-Fe-Co cans for glass-sealed electronic parts
- Al-SiC composite strips (Ref 7)
- Ti-Al foils for composite manufacture (Ref 8 and 9)
- Ni-Ti strip for shape memory (Ref 10)

Fig. 11 Typical roll-compacted nickel strip applications. (a) Pure nickel semiconductor caps. (b) Nickel-iron lead frame. (c) Nickel-iron Dual In Line Package integrated circuit. (d) Nickel-iron resistor end caps

Figure 12 illustrates a method for producing porous strip of pure nickel for alkaline battery and fuel cell electrodes. In this procedure, an electroformed nickel screen or mesh is fed into the center of the powder hopper and incorporated into the rolled strip to produce highly porous electrodes with adequate green strength. The same system can be used to feed wires into a green strip for extra strength.

Composite Bearings

Roll compacting also can be used for producing composite, or "sandwich," materials. An example of such a roll-compacted composite material is bimetallic strip used in producing main and connecting rod bearings (Ref 11). A change in automotive emission standards led to the use of these new materials to replace traditional copper-lead sleeve-bearing components. The rolled strip consists of a layer of Al-8.5Pb-4.0Si-1.5Sn-1.0Cu prealloyed powder "sandwiched" to a pure aluminum layer.

The production setup for roll compacting such a composite structure is shown in Fig. 13. Three powder hoppers are required, as well as powder flow blade that controls the flow of the powders into the roll gap. The coil of the composite

strip is then sintered, and eventually the pure aluminum layer is roll bonded to a steel backing material--an operation that is common in the bearing industry.

Fig. 13 Rolling of strip for bearings. Using bonding powder, prealloyed bearing powder, and process powder

Powder Melting. An induction melting furnace is charged with elemental aluminum, copper, and silicon (Ref 11). At an intermediate elevated temperature, lead and tin are added to the melt. Furnace temperature is raised to the single-phase temperature (925 °C, or 1070 °F), and 38 °C (100 °F) of superheat is added to provide a safety margin. The induction current of the furnace creates a stirring action that ensures complete dissolution of the lead and tin to form a true single-phase solution.

From the induction furnace the molten alloy is poured through a launder into a gas-fired tundish furnace. An extension on the bottom of the tundish crucible holds a ceramic nozzle that meters the molten alloy at a controlled rate.

Atomization. The thin metal stream falls vertically into the atomizing chamber, where it is disintegrated into discrete particles and rapidly solidified. Powder particles fall into a 6 m (20 ft) high by 1 m (4 ft) diam collector. They then pass through a cyclone separator to remove the fines and a powder screen to separate oversized particles.

Small, finely dispersed lead-tin alloy particles are contained in a hypoeutectic aluminum-silicon-copper matrix. Because of solubility considerations, the lead-tin bearing constituent remains intact throughout subsequent processing. Controlled distribution of the lead-tin ensures the development of desired mechanical properties.

Consolidation. A consolidation process is selected to produce a strip of prealloyed aluminum-lead alloy that can be ultimately roll bonded to a low-carbon steel backing strip.

Previous experience with wrought aluminum-based bearing materials has proven them unsuitable for direct bonding to a steel liner. Ultimate fatigue resistance of the bearing material depends on both the intrinsic strength of the alloy and the integrity and strength of the bond between alloy layer and steel backing.

When aluminum alloys with soft phases such as lead or tin are bonded directly to steel, the bond interface necessarily contains microscopic discontinuities that occur where lead or tin precipitates are in direct contact with the steel. These imperfections create brittleness in the interface and act as sites for accelerated fatigue crack propagation and bond

separation under service conditions. Consequently, wrought aluminum alloys containing appreciable amounts of soft bearing phase are almost always used with a pure aluminum or nickel bonding layer next to the steel. Powder rolling provides a convenient means of incorporating a pure aluminum bonding layer during the consolidation of the aluminum-lead prealloyed powder.

A third layer on the opposite side of the prealloyed layer from the bonding layer is necessary to ensure that the strip exits cleanly from the rolls of the powder rolling mill. This process layer, which is made from a blend of aluminum and lead-tin particles, is machined off in subsequent bearing finishing operations.

The three distinct compositions are fed into the compacting mill, as shown in Fig. 13. The work rolls compact these powders into a three-layer strip, which is close to 100% of theoretical density as it leaves the roll nip. A flowchart of the fabrication of powder rolled sleeve bearings is shown in Fig. 14. The production mill used to fabricate these bearings resembles a conventional four-high rolling mill (Fig. 1b). A cross-sectional view of the unsintered structure of the aluminum-lead alloy strip is shown in Fig. 15.

Fig. 14 Fabrication of powder-rolled sleeve bearing. (a) Flowchart. (b) Sleeve-bearing component

Fig. 15 Cross section of unsintered powder rolled aluminum-lead strip. Original powder particle boundaries are visible. 25×

Sintering. The green strip is then sintered, which improves the morphology of one of the phases (silicon) and provides the necessary diffusion across particle boundaries to achieve excellent strength and ductility. The finely distributed lead phase is unaffected. Further processing consists of cladding the aluminum strip to a steel backing, followed by blanking, forming, and machining of the bearing halfshells.

Bearing materials must possess a unique combination of properties, including fatigue strength, seizure resistance, wear resistance, and corrosion resistance. The performance characteristics of several bearing alloys are given in Table 3.

Table 3 Typical properties of common bimetal bearing alloys

Alloy composition	Fatigue (Underwood life)	Surface action at 150 °C (300 °F)		
		Coefficient of friction	Wear scar width	
			mm	in.
Al-8Pb-5Si-1.5Sn-2Cu (Clevite 66)	200 h at 49 MPa (7 ksi)	0.21	4.52	0.178
Cu-10Pb-10Sn (SAE 792)	200 h at 69 MPa (10 ksi)	0.22	5.15	0.203
Cu-23Pb-3Sn-2Zn (SAE 794)	200 h at 49 MPa (7 ksi)	0.17	5.08	0.200

Note: The Underwood test simulates the cyclic loading of a rod bearing resulting from the powder stroke in an internal combustion engine. Pressure is based on unit load. Wear scar and coefficient of friction are obtained from the standard LFW-1 test machine,

Recent Developments

Roll compacting of metal powders into strip is a relatively new process. Research and development currently is being conducted on many different materials to produce a superior material as well as to achieve properties not possible with conventional ingot metallurgy (Ref 12).

Roll compacting is especially useful for the continuous and semicontinuous preparation of special-type strip and sheet materials including the following:

- Al-base sheet and strip (Ref 6, 13)
- Ni-base strip applications
- Ti-base sheet and strip (Ref 6 and 10)
- Composites (Ref 7)
- Stainless steel and copper strip (Ref 6)

Iron strip made from high-purity iron powder has produced a low-carbon sheet with properties equivalent to those of conventional low-carbon sheet steel for production of containers for consumer goods. The following are typical properties of thin-gage roll-compacted low-carbon iron powder:

Gage	0.30 mm (0.012 in.)
Yield strength	290 MPa (42 ksi)
Tensile strength	330 MPa (48 ksi)
Elongation	34%
ASTM grain size	11-12
Limiting draw ratio	2.10
Strain ratio	1.3-1.6
Earing	3%
Work hardening exponent	0.220

Spray Forming

Alan Lawley and Roger D. Doherty, Department of Materials Engineering, Drexel University

Introduction

SPRAY FORMING is a near-net-shape solidification process that takes place by capturing a spray of gas atomized metal or alloy droplets on a moving substrate. The metal flow rates are high, typically 0.2 to 2.0 kg/s, and multiple sprays produce even larger rates. On the basis of experimental studies and process modeling (Ref 1), it is known that at the moment of impact the heat content of the spray is equivalent to a solid fraction in the range 0.5 to 0.8. This is material, in the form of small droplets, that has been rapidly solidified by high velocity gas while in flight to the substrate in a few milliseconds. If the process is performed correctly, a large fraction of the sprayed material, typically 0.8 or more, is captured on the substrate where it forms a deposit with the geometry of a billet, tube, sheet/plate, or other shape with dimensions ranging from a few to hundreds of millimeters. The remaining solidification then occurs within the deposit at a much slower rate over times that correlate with the size of the deposit, ~10 to 100 s or more (Ref 1, 2). The resulting

as-sprayed deposits exhibit low porosity and a homogeneous, fine-grained structure. Given appropriate control of the spray and substrate movement, deposits with well-controlled shapes can be produced (Ref 3). Thus, the technology is capable of producing shaped castings with microstructures comparable to or superior to those characteristic of wrought ingot alloys.

Grant (Ref 4) provides an overall review of all aspects of the process and Lavernia and Wu (Ref 5) give an extensive overview of both atomization and deposition, the two major processes integral to spray forming. Their monograph provides a complete coverage of publications in the area up until 1995. The reports of three international conferences on spray forming (Ref 6, 7, 8) give an account of the range of application of the process and show how the subject has evolved in recent years with increasing sophistication of process modeling.

In this article, a description is given of the spray forming process and the attendant metallurgical characteristics of the product. This description is followed by a review of the commercialization and application of spray forming illustrated in terms of several product forms. The article concludes with a detailed analysis of modeling and evolution of microstructure in spray forming.

Spray Forming

Alan Lawley and Roger D. Doherty, Department of Materials Engineering, Drexel University

Process Description

In spray forming in the Osprey mode, a source of molten metal is converted into a spray of droplets by gas atomization. The droplets are collected on a substrate where they aggregate to form a high density preform (Ref 5, 9), as shown in Fig. 1. The preform can be used in the as-sprayed condition or after conventional working operations. The production of billets, strip, and tubing by spray forming is illustrated schematically in Fig. 2.

Fig. 1 A schematic of spray forming in the Osprey mode

Fig. 2 A schematic of the production of billet, strip, and tubing by spray forming

For commercial viability in spray forming in the Osprey mode, close tolerances in shape and dimensions, consistency in microstructure, and a high product yield are essential. This viability requires an understanding of and control over the effects of several independent process parameters: melt superheat, metal flow rate, gas pressure, spray motion, spray height (distance between the gas nozzles and the substrate), and substrate motion (substrate rotation speed, withdrawal rate, and tilt angle). Several parameters can be selected prior to, but not during, the process, such as the diameter of the metal delivery nozzle, the atomizer design, and the substrate material.

Primary process parameters that can be changed during the operation (i.e. on-line) are listed in Table 1. Advantages and disadvantages of the Osprey process are cited as follows:

Advantages

- Densities >98% of theoretical
- Fine equiaxed grains
- No macroscopic segregation
- Absence of prior particle boundaries
- Enhanced mechanical properties
- Material/alloying flexibility
- High rate of deposition, ≤ 2 kg/s

Limitations

- Overall yield
- Shape control

- Compositional control in microalloying

Table 1 Representative on-line parameters in Osprey spray forming

Melt superheat, °C	10-200
Melt flow rate, m ³ /s	10 ⁻⁵ -10 ⁻³
Atomizing gas	N ₂ , Ar, He, or mixed gases
Gas pressure, MPa	0.5-1.0
Scanning frequency, Hz	0-10
Spray height, mm	≥350

Metallurgical Characteristics

Metallurgically, the mechanical properties of spray cast alloys normally meet or exceed those of the counterpart ingot alloy (Ref 9). This fact is illustrated in Table 2 for stainless steel tubing in the spray cast condition and after cold working.

Table 2 Tensile properties of stainless steel

	Yield strength N/mm ²	Tensile strength, N/mm ²	Elongation, %
Spray formed (as-deposited)	260	618	57
Ingot metallurgy (as-extruded)	290	632	58
Spray formed (cold Pilger rolled)	980	1058	15
Ingot metallurgy (cold Pilger rolled)	931	1007	17

(a) Sanicro 28: Fe-26Cr-30Ni-3.5Mo.

The advantages of spray forming in its application to aluminum alloys are vested in low oxygen and hydrogen levels and a refined uniform microstructure (Ref 9). In the absence of oxide films or particle boundaries, minimal hot working is required to optimize mechanical properties. In the standard 2000 and 7000 series aluminum alloys, spray forming enhances damage tolerance. This is attributed to refinement of the grain structure ($\sim 50 \mu\text{m}$) and of the primary phase distribution ($\sim 1 \mu\text{m}$), particularly in alloys that are sensitive to the presence of iron-containing intermetallics or to the distribution of transition element phases. This refinement results in attractive increases in ductility, toughness, and fatigue resistance. Fracture toughness data for spray formed 7075, as a function of yield strength, are given in Fig. 3; corresponding data for the direct chill (DC) cast alloy are included for comparison.

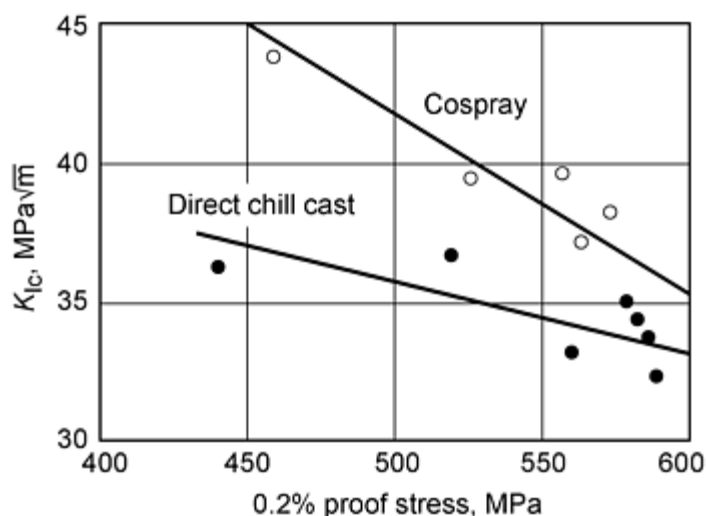

Fig. 3 Fracture toughness of 7075 aluminum alloy as a function of strength and mode of fabrication. Source: Ref 9

Alloy modification via spray forming has led to further strengthening of the 7000 series aluminum alloys (Ref 9). For example, strengths from 700 to 800 MPa have been achieved by increasing the levels of zinc and magnesium. In the T6 condition, fracture toughness is 27 to 32 MPa√m, with attendant improvements in fatigue resistance compared to 7075. Significantly, a 30% increase in strength has been achieved with this new alloy composition compared to 7050 at the same toughness level. Thus the new alloy has the potential for replacing 7075 and 7050 extrusions and 7050 forgings.

Spray Forming Applications

Metallurgically, the benefits of spray forming in the Osprey mode can be realized commercially only if the resulting products are cost effective in the marketplace. To this end, research and development programs have focused on technical improvement and cost reduction in spray forming (Ref 10, 11). To compete with conventional fabrication technologies (ingot casting, forging, rolling, etc.) spray plant throughput has been maximized, and process efficiency has been improved (Ref 11). Throughput has been improved via a larger melt size and preform size, higher production rates, and increased productivity. Improved process efficiency is reflected in lower gas consumption rates, higher yields of deposition, and improved dimensional control in spray formed products.

A review of the commercialization of spray forming in the Osprey mode is given here for several product forms.

Rolls

Sumitomo Heavy Industries Foundry and Forging Company (SHIFF) has been manufacturing spray formed rings in high-chromium cast irons and high-carbon, high-speed steels since 1991. After downstream processing, the rings are fitted to a

roll mandrel for use in round bar, flat bar, wire rod, and section mills, and in finishing or intermediate stands. The rings exhibit a fine, rapidly solidified carbide microstructure leading to improved thermal fatigue resistance and a longer life compared to conventionally cast products. Examples of spray formed rolls are given in Fig. 4; roll sizes up to 800 mm diam by 0.5 m length have been fabricated.

Fig. 4 Spray formed rolls. Source: Ref 11

More recently, interest has centered on the direct manufacture of large clad rolls for use in hot and cold strip mills. Participants in this joint project, funded partially by the U.K. Department of Trade and Industry, were Forged Rolls (U.K.), British Rollmakers, Sheffield University, and Osprey Metals. Arbors up to 400 mm diam by 1 m length have been clad with cold and hot mill roll alloys and with high-speed steel. Figure 5 illustrates the facility with a hot spray clad roll in place. Key to the process is a sound metallurgical bond at the arbor-spray deposit interface.

Fig. 5 Plant for spray forming clad rolls. Source: Ref 11

Tubing

In Sweden, Sandvik produces stainless steel tubes up to 400 mm diam by 8 m length with a wall thickness ≤ 50 mm by spray forming. The spray process configuration for tube fabrication using a single atomizer is shown in Fig. 6. By using multiatomizers, it is possible to minimize porosity on the internal bore of the tube. Spray cast tubes of In625 are shown in Fig. 7.

Fig. 6 Tube fabrication by spray forming. Source: Osprey Metals, Ltd.

Fig. 7 Spray formed tubes of In625 alloy. Source: Osprey Metals, Ltd.

A potential market exists for bimetallic tubing with a corrosion resistant layer sprayed onto the outside of a collector mandrel. Projected applications include boilers, incinerators, and waste heat recovery plants. To this end, Sandvik has developed a corrosion-resistant spray forming alloy Fe-Cr-Ni-Mo (Sanicro 65) for service in waste incinerators.

Rings

In the United States, Howmet operates a plant capable of spray forming superalloy ring blanks up to 800 mm diam by 0.5 m length. These are used for ring/casing components in high thrust gas turbine engines. A study of Udimet 720 has shown that the ring preforms can be processed subsequently by ring rolling or hot isostatic pressing.

Billets

Round billets can be fabricated by spray forming in vertical (Fig. 8) or horizontal (Fig. 9) plants. The two techniques differ only in relation to the collector movement, which is either vertical or horizontal. The former is used currently on aluminum and copper alloy billet plants. Osprey Metals utilizes the horizontal configuration for processing high alloy steels.

Fig. 8 Vertical mode billet fabrication by spray forming. Source: Osprey Metals, Ltd.

Fig. 9 Horizontal mode billet fabrication by spray forming. Source: Osprey Metals, Ltd.

With a melt size of 1.2 tonne, tool steel and precipitation hardened stainless steel billets have been sprayed at diameters up to 400 mm by 1.2 m length (Fig. 10). Significant cost reductions have been achieved by the use of twin atomizers, higher metal dispensing rates, a reduction in gas consumption, and an increase in yield of the deposit.

Fig. 10 Horizontal mode spray formed tool steel billet. Source: Ref 11

Aluminum alloy billets are normally spray formed in the vertical mode (Fig. 8); Sumitomo Light Metals (Japan) uses this configuration on a commercial scale. The spray formed billets are subsequently extruded or forged into the final product configuration. Current billet size is 250 to 400 mm diam by 1 to 1.4 m length. Smaller diameter billets can be extruded without machining because of the tight tolerances achieved. Primary applications for spray formed aluminum-silicon alloys are in the automotive field (e.g., cylinder liners, pistons, connecting rods).

Other spray formed aluminum alloys in billet form are at an advanced stage of development. These include aluminum-zinc alloys, ultralow density aluminum-lithium alloys, and Al-Si-X ternary alloys, which exhibit a low coefficient of thermal expansion (Ref 11).

Copper alloy billets up to 300 mm diam by 2.2 m length are being spray formed on pilot plants in operation at Wieland (Germany) and Swissmetal (Switzerland). Production levels are not high because the emphasis has been on alloy development. Swissmetal produces Cu-Ni-Sn alloys that combine high strength with acceptable levels of electrical conductivity, copper-bronzes with a high tin content that exhibit enhanced levels of hot and cold workability, Cu-Cr-Zr alloys for high-temperature stability, and copper-carbon alloys in which the graphite particles enhance wear properties.

Spray Forming

Alan Lawley and Roger D. Doherty, Department of Materials Engineering, Drexel University

Modeling and Microstructure

The process of spray forming involves a series of steps in which a molten alloy at a selected superheat is disintegrated by high velocity gas atomization into a spray of rapidly cooled droplets possessing a range of sizes and thermal conditions. These droplets then impact on a substrate to give a high yield of a partially solid deposit of controlled shape. This deposit is cooled by the gas stream, and solidification is completed at much slower rates (comparable to those in ingot casting) than the initial cooling rates in the spray. The steps in the process are complicated, and many of them are not yet fully understood, which makes them unpredictable at least from first principles. The process has, however, been modeled, and some understanding of the microstructure characteristics of spray formed alloys has been obtained (Ref 2).

The successful models, which include those of Mathur et al. (Ref 1, 12), Lavernia et al. (Ref 13, 14), Trapaga et al. (Ref 15), Tsao and Grant (Ref 16), Grant et al. (Ref 17, 18) and others (Ref 19, 20, 21), combine detailed numerical models (for those processes in which the physics is well understood) with empirical input parameters for the other processes or steps that cannot, as yet, be modeled. The model developed at Drexel University is illustrated in Fig. 11 (Ref 3, 12). It shows the preset process parameters (e.g., metal superheat, gas pressure, metal flow rate, and gas to metal ratio [GMR]) and the measured (empirical) parameters (e.g., the gas velocity field, the particle size distribution [PSD], the radial mass flux distribution [RMF], and the droplet sticking efficiency [SE]). At the present time, none of the last four parameters can be predicted reliably from first principles. The atomization stage is similar to gas atomization in powder production and has been reviewed in detail by Lawley (Ref 22, 23), Yule and Dunkley (Ref 24), and Lavernia and Wu (Ref 5). Modeling methods are available for predicting gas flow fields using numerical techniques (Ref 19); physics-based methods are available for estimating the mean particle size in gas atomization (Ref 25); and empirical methods are available for predicting the PSD, such as those of Lubanska (Ref 26). However, these methods, when tested in spray forming studies, do not appear to be sufficiently reliable to be useful in modeling the detailed thermal processes intrinsic to spray forming. In addition, the current models of gas atomization do not address the angular dependence of particle density in the spray.

Fig. 11 Flow chart of the Drexel University model of spray forming illustrating empirical inputs and predicted outputs. Source: Ref 3

To overcome these difficulties, it has been found necessary in experimental studies of spray forming to measure all the required empirical parameters in gas atomization. One such parameter is the gas velocity field in the spray chamber, usually determined by Pitot tube measurements in the absence of a stream of molten metal (Fig. 12). Results of empirical determinations of the measured PSD and RMF of the alloys investigated at Drexel University and at the Naval Surface Warfare Center (NSWC) were reported and analyzed by Cai et al. (Ref 3, 27). The method used was to spray the alloys (nickel-base alloy In625, high-strength low-alloy steel, and Cu-6Ti) under a range of gas pressures, metal flow rates, and superheats in a modified Osprey facility at NSWC. The height of the chamber was extended to ensure that solidification of the largest droplets was complete before capture in a series of concentric tubular collectors (Fig. 13). Concurrently, this experiment yielded measurements of the RMF (Ref 3). Analysis of these observations showed a general tendency for the mass mean particle size to fall with increased radial distance from the axis of the spray, as shown in Fig. 14 (Ref 27). Empirical results such as these can then be fitted to descriptive equations in order to model the spray conditions of the alloys in the same facility at NSWC and in a similar facility at Drexel University. A comparable experimental investigation of PSD and RMF for tin, steel, and copper was conducted by Uhlenwinkel and Bauckhage (Ref 28).

Fig. 13 Schematic of system for collecting fully solidified particles from a spray cone for measurement of radial mass flux and particle size distribution. The distance of fall (standoff distance) has been increased from that used in spray forming to ensure a fully solidified spray at the collector. Source: Ref 3, 17

Fig. 14 Measured mass median particle diameter and standard deviation of the log normal distribution as a function of radial distance for Cu-6Ti sprayed at a GMR of 0.68, metal flow rate of 0.32 kg/s, and superheat of 120 °C. Source: Ref 27

With current heat and mass transfer techniques, it is possible to predict the velocity and cooling rate of an individual droplet of a given size in flight to the substrate (Fig. 11) (Ref 5, 6, 7, 8, 12, 13, 14, 15, 16, 17, and 18). By integration of the resultant heat content of all the droplets in the PSD, it is then possible to calculate the enthalpy of the spray at the moment of impact onto the growing deposit. If it is assumed that thermal and chemical equilibrium are achieved rapidly

after deposition, an equivalent value of the effective fraction of liquid in the spray, $f_i(s)$, can be calculated. This calculated value of $f_i(s)$ is a more meaningful physical parameter than the integrated enthalpy in the spray from which $f_i(s)$ is derived. With the use of empirical values of the PSD and gas flow fields, the predicted values of $f_i(s)$ should be reliable. The fraction of liquid on the surface of the deposit, $f_i(d)$, under the spray for a billet shaped preform is predicted to be very close to the calculated fraction of liquid in the spray. However, for other geometries such as tubes, the fraction of liquid on the deposit can be less than that in the spray by virtue of cooling of the deposit when it rotates out of the spray and into the gas stream.

To calculate the rate of growth of the deposit, various inputs are needed. The first of these is the rate of arrival of metal from the spray at each point on the substrate surface. Cai and Doherty (Ref 3, 29) have developed a full three-dimensional shape model that can predict the rate of growth at all points on the deposit, assuming a known sticking efficiency. Examples of the predicted shapes are reproduced in Fig. 15. The shape model can be developed further to delineate the substrate motion required to give specific shapes—including those of complex geometry such as a curved tube where, by altering the substrate motion, a uniform wall thickness was designed (Ref 3, 29). These predictions do, however, require a knowledge of the sticking efficiency of the droplets onto the deposit.

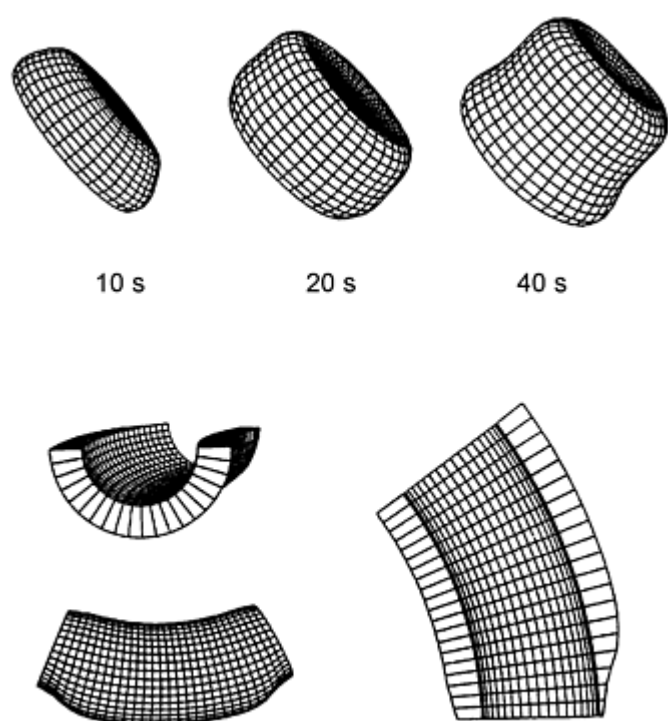

Fig. 15 Predicted shapes for spray deposited billets as a function of deposition time and for a curved tube sprayed onto a 100 mm diam mandrel with appropriate substrate motion using the three-dimensional shape model. Ref 27

Deposit Cooling and Solidification

One of the early predictions of the spray models was the result that successful spray deposition requires a partially solid-partially liquid spray in which $1 \geq f_l(s) \geq 0$ (Ref 1). The droplets arriving at the surface of the deposit at velocities ~ 50 to 100 m/s are predicted to be fully solid if small, fully liquid if large, and for the majority of the mass of the spray of intermediate size, partially solid and partially liquid on impact. Given the high thermal conductivity of metallic alloys, rapid thermal equilibration of all the deposited droplets is expected with a partially solid and partially liquid structure on the surface of the deposit. Initial models of the thermal behavior of the deposit were one dimensional and predicted that after deposition of the partially molten alloy, most of the subsequent cooling was caused by the high velocity gas, with only limited cooling taking place through the substrate--at least for material deposited some distance away from the substrate. The model predicted complete solidification times (10-200 s), that were confirmed by embedded thermocouple measurements (Ref 5). Later models, such as those of Grant et al. (Ref 17, 18) and Cai et al. (Ref 3), confirm the qualitative form of these results, as shown in Fig. 16 and 17. Models of thermal deposition were two dimensional, incorporating gas cooling from the side and top surfaces of the deposited billets (Ref 3, 29). For billets, the two-dimensional thermal models appear to capture the major features of the cooling and solidification process (Ref 29). After a short period of deposition, the temperature at the top surface of the deposit achieves a value corresponding to a partially molten surface. The depth of this incompletely solidified region increases, and at the center of the billet time required for complete solidification is tens of seconds. There is, however, a critical need for a three-dimensional thermal model for more complex shapes, such as a rotating tube (Ref 27, 29). In tube deposition, which is one of the major commercial applications of the technology (Ref 6, 7, 8, 9, 10, and 11), the thermal conditions are complex because the tube is subjected to additional cooling as it rotates into and out of the spray in the presence of the cooling gas stream. As a result, it is expected that for the same enthalpy in the spray, $f_l(s)$, there will be a lower fraction of liquid on the surface of the deposit during spray forming of tubes than of billets.

Fig. 17 Predicted temperature contours for a Cu-6Ti cylindrical billet as a function of deposition time. The enthalpy of the spray corresponds to a fraction of liquid (f_l) in the spray of 0.19. Note the depth of the partially solid region. Source: Ref 27

An initial two-dimensional model for the spray forming of tubes (Ref 27) captured one significant aspect of this geometry. In addition to the usual buildup of surface temperature with time after overcoming the initial chilling effect of the substrate, there was a second but opposite effect in the tube. As the length of the deposited tube grew, the cooling effect of the gas stream on the as-deposited tube resulted in a decrease in the surface temperature under the spray with time as shown in Fig. 18 (Ref 27). Also shown in Fig. 18 is the chilling effect of the tubular substrate, which causes rapid cooling of the deposit in contact with the mandrel even after extensive deposition. The limitations of the two-dimensional model for this geometry are clear from Fig. 18. The thermal model of a billet shows that the fraction of liquid on the surface of the deposit, $f_l(d)$, approaches that in the spray, $f_l(s)$ (Fig. 17).

Fig. 18 Isotherms modeled for In625 tube under a fraction of liquid in the spray of 0.46. Limitations of the two-dimensional model are clear, and acceleration of cooling in the later stages of deposition (due to the cooling effect of the gas stream on the as-deposited tube) are seen from the rapid decline of the partially solid region, even before termination of the spray which occurred after 64 s. Source: Ref 27

It should also be noted that with a rapidly rotating substrate, particularly in tubes, embedded thermocouple measurements are difficult to make (Ref 5). However, for plates sprayed under linear nozzles, embedded thermocouple measurements can be made, and these show close agreement with the thermal model (Ref 30) shown in Fig. 19 and 20. In particular two features of the process are shown in Fig. 20. First, the cooling rate in the solid-liquid phase field in the presence of a preheated steel substrate (to offset the chilling effect of a cold steel substrate) is low. The second feature is the thickness in the deposit (10% at 400 °C and 40% at 30 °C) during which the chilling effect of the substrate causes the deposit to form without the temperature rising above the solidus temperature. Under these conditions, the only liquid present is the transient liquid in the spray as it arrives at the surface of deposition. This transient liquid will disappear rapidly during thermal equilibration with the deposit, and the partially liquid region at the deposit will form only after the deposit is relatively thick (Fig. 18). This result is of major significance in the formation of a deposit of low porosity. Although this study pertains to continuous deposition, the experimental and modeling methods are applicable if the spray is oscillated in the growth direction, thereby allowing for additional cooling at the deposit surface when the spray is temporarily elsewhere. Similar conditions are inevitable in the manufacture of other shapes, most significantly tubes.

Spray Forming

Alan Lawley and Roger D. Doherty, Department of Materials Engineering, Drexel University

Consolidation at the Surface of the Deposit

The two critical unknowns in understanding the spray forming process are the sticking efficiency of droplets onto the growing deposit and the level of porosity in the final deposit (Fig. 11). As discussed, the droplet velocity and thermal models of the conditions in the spray can predict the velocities and the enthalpies of the individual droplets at the moment of impact. In most of the present models, the enthalpy of the spray is averaged over the full radial angle of the spray, ignoring the slightly different gas velocities and droplet size distributions in different radial directions. A correction for the different values of $f_i(s)$ at different angles from the spray axis could be handled in the numerical models, but to-date, the resulting improved predictions have not been readily usable given the difficulties of experimental observation. Thus, although reasonable insight into the thermal condition of the spray is available, at present there is no physically based model that attempts to describe the complexity of the impact of a very high density of high-velocity, partially liquid droplets onto a similar partially liquid surface.

How much of the material arriving at the surface of deposition will stick? Also, how will the sticking efficiency vary with droplet size, impact angle, and the thermal condition (fraction of liquid) of the individual droplets and of the deposit surface? Other important and incompletely answered questions include what determines the resultant microstructure of the deposit, in particular the level of porosity and the grain size? These parameters are likely to be determined, at least in part, by the processes occurring during impact of the high velocity spray onto the deposit surface. Although not yet predictable, each of these phenomena are capable of investigation experimentally.

Sticking Efficiency

Because of the fine partially molten dendritic structure in the majority of the particles, it is believed that dendrite fragmentation will occur, breaking up the solid into small pieces, such as one to a few dendrite arm spacings (Ref 2, 3, 4, and 5). Typical solidification and flight times in spray deposition are only a few milliseconds and from the standard model of dendrite arm coarsening this leads to a dendrite arm spacing (cell size) of $1 \mu\text{m}$ (Ref 31, 32). This result is characteristic of the fine scale in the dendritic microstructure observed in fully solidified powder droplets, such as the overspray particles that failed to hit or stick to the deposit (Ref 2). Fragmentation of the dendrites in the partially molten droplets as they impact the growing deposit at velocities of 100 m/s appears to provide the basis for the fine grain structure characteristic of spray formed materials (Ref 2, 3, 4).

This grain fragmentation process produced by high velocity impact is probably similar to that found in stircasting (rheocasting) (Ref 33). In stircasting, solidification of the dendritic structures under high shear rates causes break up of the dendrites to give small rosettelike particles or with faster stirring and longer times, spherical particles. The model for dendrite fragmentation found to be valid for stircasting is plastic deformation of the dendrites via dendrite arm bending, based on the low yield strength of low solute metal at temperatures close to the liquidus of the alloy. Under this condition, when dendrite arms are bent through large angles ($>20^\circ$) at high temperatures, rapid dislocation recovery occurs producing high angle grain boundaries. These high angle grain boundaries are then wetted by liquid causing separation between the grains because, as shown by Gundoz and Hunt (Ref 34), the energy of a high angle grain boundary, γ_{gb} , with a misorientation of 20° or more, is equal to that of two solid liquid interfaces, $2\gamma_{\text{sl}}$. Clear evidence for this phenomenon was shown in stircast aluminum alloys (Ref 33), and a similar process has been proposed for spray casting (Ref 35). Thus the fragmentation of metallic dendrites appears to occur not by fracture but by deformation, recrystallization, and melting.

Irrespective of the microstructural origin of the fine spherical grains found in most spray formed deposits, the partially solid material at the surface of the deposit is expected to exhibit thixotropic mechanical properties (Ref 33). These properties include a large increase in viscosity in semisolid metallic systems when the stirring rate falls. In consequence, the behavior of the material can change rapidly from fluidlike to that of a solid as bonds build up at grain boundaries between the particles (Ref 33). For spray formed materials, this suggests that, at the deposit surface with its high frequency of high velocity impacts ($\approx 100 \text{ m/s}$), the material will be rather fluid. This fluidlike character will, however, decay rapidly at a given position as the deposit grows and the material just below the surface is no longer agitated by the spray. Videotapes of the surface of aluminum deposits at high liquid fractions (Ref 36) do show rapid surface movement similar to that seen in puddles during a heavy rainfall. This liquidlike behavior at the surface should terminate rapidly beneath the surface of the deposit where mixing by droplet impact will not penetrate deeply into the viscous semisolid material. The strength of the deposit is confirmed by the fact that, even with high rotation rates in spray formed billets and tubes, the shape of the deposit usually remains stable. If this were not the case, the process would be unworkable.

With reference to Fig. 11, the three parameters have been examined (Ref 37) in which the thermal model of the process was used to design and analyze a set of experiments which attempted to understand the process parameters that control the resulting output parameters. In performing these experiments, it was assumed that the enthalpy of the spray at the moment of impact on the deposit (usually expressed as the equivalent fraction of liquid in the spray, $f_l(s)$) was likely to be the critical control parameter. A series of experiments were run on copper-titanium alloy billets, and previous data on In625 tubes (Ref 38, 39, 40) were reanalyzed using the model. For the billets, the process parameters were selected using the model to design experiments with a wide range of $f_l(s)$ in the spray. For the tubes, the experiments were analyzed to determine the operating values of $f_l(s)$ in the spray at the moment of impact. In addition, using Fig. 11, the final size and shape of each spray formed billet and tube were predicted assuming 100% sticking efficiency (SE) (Ref 3, 27). The sizes predicted were then compared with the measured deposit sizes to give a first estimate of the sticking efficiency. These estimated values of SE were then used in revised runs of the three-dimensional shape model, and the comparison was repeated until, for each spray formed deposit, the predicted and measured shapes of the deposit agreed with the fitted value of SE.

Figures 21 and 22 show the resulting measured values of SE in the two studies as a function of the modeled values of $f_l(s)$. The two plots show optimum values of $f_l(s)$ to achieve maximum sticking efficiency but at very different values in the two experiments. For the copper-titanium billets, the highest SE was 0.9 (by weight) at an optimum $f_l(s)$ of 0.3. In contrast, for the In625 tubes, the optimum SE occurred at a much higher value of $f_l(s)$: namely 0.5. The sticking efficiency for the In625 tubes was also enhanced by reducing the centrifugal force, resulting from a slower substrate rotational speed (Fig. 22). Some material is spun off from the rotating deposit because the sticking efficiency is decreased at higher rates of rotation. The decrease in SE at fractions of liquid higher than the optimum value is also explained by this effect.

Porosity

The other key characteristic of the spray formed microstructure is a fine scale porosity that, at best, is 1% by volume and exists primarily in the form of small voids ($< 1 \mu\text{m}$) between grains (Ref 2). In cold regions of the deposit, such as against a cold substrate and at the edges of the deposit, larger amounts of interconnected porosity are usually found (Ref 2, 30, 41). In addition, in hot deposits (high fractions of liquid), spherical pores can be found that are much larger than the grain size of the deposit (Ref 2, 5, 41). These three types of porosity appear to originate from different causes.

Interconnected porosity appears to arise when the chilling effect of a cold substrate causes the fraction of solid at the surface of the deposit to approach 100% (Ref 1). Under these circumstances, true spray deposition does not occur because filling of the pores between solid particles by excess liquid cannot take place. Recent thermal modeling studies (Ref 30) demonstrate clearly this idea (Fig. 20). The absence of a calculated solidification cooling rate before 0.4 of the normalized thickness for the unheated steel substrate and 0.1 of the normalized thickness for the heated substrate, reflect the minimum thicknesses modeled before any retained liquid is predicted to occur on the deposit surface. These distances match closely the experimental thickness of the deposit containing a high density of interconnected pores (Ref 30, 41). The results of this study (Ref 30) confirm the importance of achieving a rapid buildup of a partially molten (incompletely solidified) surface on the deposit, if a spray deposit of low porosity is to be produced. The results also confirm a well-established empirical feature of successful spray forming, namely the need to have a deposit surface that does not rapidly chill the spray. Empirical studies have shown repeatedly that it is not desirable to have too fine a droplet size in the spray

because this leads to a rapid buildup of solid in the spray. It is also important to use a thermally insulating substrate, or alternatively, if the substrate is metallic, then it has to be preheated. This requirement is critical in the spray forming of thick coatings on a metallic substrate, such as spraying tool steel onto metallic iron rolls or spraying stainless steel onto mild steel (Ref 11).

It is generally considered, but not completely confirmed, that the fine scale pores at grain boundaries are ubiquitous to spray formed deposits (Ref 2) and arise from trapped gas from the atomization step. Indirect evidence for this comes from the observation that in the deposition of high-temperature alloys such as copper-and nickel-base alloys deposits are either essentially pore-free or become so after light thermomechanical processing. This change only happens if a chemical reaction occurs between the nitrogen (atomization) gas and a reactive nitride forming element in the alloy such as chromium or zirconium in copper (Ref 42) or nickel (Ref 43). Spraying nickel-base alloys with an inert gas such as argon always produces fine scale porosity that is not readily or permanently removed by subsequent processing (Ref 43). Heavy deformation can close up the pores, but if the gas remains unreacted, then the porosity may return on subsequent annealing.

The coarser spherical porosity that is often reported in deposits produced under hot spray conditions with a high fraction of liquid in the spray occurs as spherical pores that are much larger than the grain size (Ref 2, 41). It appears likely that these pores may form by the coalescence of smaller pores in the presence of a high liquid content. This allows more fluid motion, and the growing pores can push the solid particles apart. Irrespective of the mechanism(s) involved, a simple thermodynamic analysis (Ref 41) suggests that growth of the pores will produce a much larger volume fraction of gas. For finely divided pores with a radius of curvature, r , of a few micrometers, the interfacial energy, σ , and induced pressure, ΔP , can reduce significantly the volume of trapped gas. For example with copper ($\sigma = 1.5 \text{ J/m}^2$) and $r = 3 \text{ }\mu\text{m}$:

$$P = 2 \sigma / r = 1 \text{ MPa} = 10 \text{ bar} \quad (\text{Eq 1})$$

When a number, m , of these small voids of initial radius, r_1 , coalesce, the radius increases to r_2 and the pressure falls, giving a larger volume of gas. Use of the ideal gas law ($PV = nRT$) shows (Ref 37) that:

$$r_2 = r_1 \cdot m^{\frac{1}{2}} \quad (\text{Eq 2})$$

and that the volume, V_1 , of the m small pores increases to a volume V_2 , where:

$$V_2 = V_1 \cdot m^{\frac{3}{2}} \quad (\text{Eq 3})$$

Thus, extended coalescence giving the large spherical bubbles ($m \gg 1$) will result in a significant increase in the porosity observed. If, as is often observed, the coarse gas-filled voids are much larger ($r_2 = 60 \text{ }\mu\text{m}$) than the fine grain boundary voids ($r_1 = 3 \text{ }\mu\text{m}$) (Ref 2), then relaxation of the interfacial induced pressure (Eq 1) will for the same volume of trapped gas increase the porosity 20 times (Eq 2). This analysis gives a moderate overestimate of the apparent increase in porosity following coalescence because the model ignores the effect of atmospheric pressure. The large spherical gas voids described in Ref 2 were produced in a copper-titanium billet sprayed under conditions of $f_l(s) = 0.6$, which should allow for more pore coalescence.

Equation 1 also shows how heavy thermomechanical processing can close up the gas pores even with insoluble gases. If deformation fragments the pores, it will reduce the pore size leading to increased pressure and a decrease in gas volume ($m \ll 1$, in Eq 3). However, unless the gas in the very small pores reacts chemically, it is always capable of increasing its volume fraction by coalescence during high-temperature solid state processing.

Recently a series of quantitative studies (Ref 37) confirmed fine scale porosity in copper-titanium and the nickel-base superalloy In625. The average porosity in the deposits was measured in copper-titanium billets and In625 tubes. Additional experiments were also performed on copper-titanium tubes and In625 billets. The billets were sprayed onto oxide substrates with a low thermal conductivity. Figure 23 shows the porosities measured in the copper-titanium billets and in the In625 tubes as a function of the modeled fraction of liquid in the spray (Ref 38, 39, 40).

Fig. 23 Average porosity in billets and tubes of copper-titanium and In625 as a function of fraction of liquid in the spray. Source: Ref 37, 38, 39, and 40

A steady fall in the level of porosity with increased values of the fraction of liquid in the spray $f_l(s)$ can be seen. The two alloys show very similar results, but the behavior is very different in the two geometries. The billets show porosity levels only as high as 8 vol% in very cold sprays ($f_l(s) = 0.1$), falling to 1 vol% as $f_l(s)$ reached 0.55. In the spray formed tubes, there is a decrease in porosity from a very high value of 25 vol% at a $f_l(s)$ of 0.25 to porosity levels 2 to 3 vol% at high values of $f_l(s)$, such as 0.5 to 0.6. Lavernia and Wu (Ref 5) reviewed the published data on porosity and, as with the results reported here, found high levels of porosity in sprays deposited under cold conditions; the level of porosity decreased as the temperature of the spray increased. Results have also been reported showing the opposite effect. An increase in porosity at high fractions of liquid (Ref 2, 4, 29, and 30), particularly in aluminum alloys (Ref 29, 30) and in alloys sprayed with an inert gas in which there is no interaction between the gas and the alloy constituents has been shown. A minimum in porosity is indicated and present results suggest that this may occur at 0.3 fraction of liquid in the spray in billets (Ref 4). Clearly the optimum value of $f_l(s)$ is higher for tubes than for billets.

The different results between the levels of porosity in billets and tubes show clearly that to obtain equivalent behavior in terms of sticking efficiency and porosity, the spray must be much hotter for tubes than for billets. The difference between these two geometries arises because in billets the surface of deposition remains essentially under the spray at all times. As shown in Fig. 17, the thermal model predicts that the fraction of liquid on the billet surface under the spray rapidly approaches the fraction of liquid in the spray, $f_l(s)$. The geometry of tube spraying requires that the deposit rotates into and out of the spray with each revolution. Thus, at most, deposition occurs 50% of the time, and the rate of arrival of the spray falls to zero at the "3 and 9 o'clock" orientations. At these positions, high velocity gas is sweeping past the deposit surface, and the mean fraction of liquid on the surface of the deposit, $f_l(d)$, should be significantly less than that in the spray, $f_l(s)$. The difference suggests that the control parameter is likely to be the fraction of liquid on the surface of the deposit under the spray, $f_l(d)$, rather than the fraction of liquid in the spray. Since deposition involves both the spray and the deposit, it is possible that some combined parameter involving both $f_l(d)$ and $f_l(s)$ is critical. At present, no reliable three-dimensional thermal models of tube deposition are available. Given such a reliable and validated thermal model, $f_l(d)$ can be modeled along with the modeled values of $f_l(s)$, and the experimental results on sticking efficiencies and porosity can be correlated with these two parameters. The current results suggest that the thermal conditions in the spray and the deposit are the critical parameters in controlling sticking efficiency and porosity. A wider range of studies is needed, particularly for other geometries such as sheet and plate and with other atomization geometries such as the linear nozzle (Ref 27). The current results do, however, illustrate the value of combining experimental studies with modeling.

Grain Structure in Spray Formed Deposits

The defining feature of the microstructure of spray deposited materials is the fine equiaxed grain structure with minimum solute segregation (Ref 2, 3, 4). It is generally agreed that the fine grain size arises from dendrite fragmentation on impact of the spray followed by grain coarsening during solidification. The times for solidification increase with the fraction of liquid in the spray at a given geometry (Fig. 24). However the coarsening is slower than that predicted using standard coarsening theory, which results in a small grain size (Fig. 25). A detailed investigation of coarsening under conditions of spray forming was carried out by Annavarapu and Doherty (Ref 32) using aluminum AA2014 (Fig. 26) and copper-

titanium (Fig. 27) reheated into the solid-liquid phase field. It was found that the measured coarsening rates were much slower than those expected for dendritic structures, and the coarsening rate fell as the fraction of solid in the mixture increased. This is in qualitative but not quantitative agreement with the experimental results for copper-titanium (Fig. 14). Other studies on grain coarsening in spray formed structures (Ref 44, 45) yield similar results. Slower coarsening in solid-liquid mixtures with increasing solid fraction is, however, in direct conflict with experimental studies (Fig. 28) and modeling of coarsening in high purity two phase solid-liquid systems (Ref 32). In these studies, coarsening is accelerated as the volume fraction of solid increases due primarily to shorter diffusion distances. At the highest volume fraction of solid where the liquid is present as small droplets trapped at the boundaries, coarsening is controlled apparently by the drag of these droplets (Ref 32). This conflict appears to arise from the presence of solid second phase impurity particles in the spray formed material which inhibit grain boundary movement (Ref 32, 45). Currently this is established qualitatively, and a detailed quantitative investigation of this phenomenon is required to allow the thermal modeling of deposit solidification to yield reliable predictions of the resulting grain size in different parts of the deposit. Figure 29 shows the result of an experimental study of the grain size variation in a spray formed deposit (Ref 37).

The physical processes that give rise to the fine grain structures in spray forming also give rise to another desirable characteristic, low microsegregation and macrosegregation. Insights into these phenomena were reviewed by Biloni and Boettinger (Ref 46). Rapid solidification to a high fraction of solid (giving fine scale solid particles that are then allowed to cool more slowly with significant coarsening) is expected to result in decreased microsegregation. In addition, the fact that the deposit forms with a high fraction of solid reduces significantly the solidification shrinkage within the deposit, which combined with the restricted permeability of the fine structure, should limit severely the fluid flow processes that cause macrosegregation. These ideas appear to fit qualitatively with the experimental observations of homogeneous spray formed deposits (Ref 4). However few attempts have been made to test the ideas of the expected reduced microsegregation and macrosegregation quantitatively. This is an area that needs additional study.

Spray Forming

Alan Lawley and Roger D. Doherty, Department of Materials Engineering, Drexel University

Modeling: Current Status and Future Needs

Current models of the spray process, which rely on a combination of empirical inputs and physically modeled processes, appear to describe the shape (Ref 3, 27) of all types of spray formed deposits and the thermal conditions in billets (Ref 15, 27) and plates (Ref 27). The modeled thermal conditions in the spray have been found to control the two major unknowns in the process: sticking efficiency, which determines the yield, and trapped gas porosity, which is the major structural defect (Ref 34). These successes were achieved by use of carefully and expensively measured intermediate process parameters--notably the gas velocity field, PSD, and RMF (Ref 3, 27). If each modeling attempt requires this level of prior investigation, then the models will probably have limited application. Renewed experimental and theoretical studies that can lead to reliable predictions of these parameters in different spray forming chambers and with alloys of interest in spray forming are needed. It may be possible and more desirable to make progress directly in such studies by direct investigative techniques in actual gas atomization sprays. Techniques using lasers (Ref 47, 48), high-speed photography, and thermal imaging (Ref 15) appear to offer potential for direct measurements of droplet sizes, velocities, and deposit temperatures from which a process model should be able to back-calculate the needed process parameters and their variation with process variables, such as atomization, gas pressure, and metal flow rate.

The three-dimensional shape models need to be developed further to give thermal models that, once tested and validated, will facilitate improved process design to avoid undesirable features, such as near substrate porosity, and to promote finer and perhaps more uniform grain sizes. The features that limit grain coarsening in the high solid fractions of spray formed deposits also need further study. This is desirable both as a scientific puzzle (Ref 29) and as a potential means of further refining spray formed grain sizes. Given the growing commercial successes of the process (Ref 1), further detailed scientific analysis of all aspects of spray forming is warranted.

Thermal Spray Forming of Materials

Richard Knight and Ronald W. Smith, Center for the Plasma Processing of Materials (CPPM), Drexel University, Philadelphia, PA

Introduction

THERMAL SPRAY is a "family" of particulate/droplet consolidation processes capable of forming metals, ceramics, intermetallics, composites, and polymers into coatings or free-standing structures. During the process, powders, wires, or rods are injected into combustion or arc-heated gas jets, where they are heated, melted or softened, accelerated, and directed toward the surface, or substrate, being coated. On impact at the substrate, the particles or droplets rapidly solidify, cool, contract, and incrementally build up to form a deposit. The thin "splats" undergo very high cooling rates, typically in excess of 10^6 K/s for metals (Ref 1).

Increased attention is being paid to thermal spray processes today because of their ability to consolidate virtually any material that has a stable molten phase, producing coatings or deposits exhibiting relatively homogeneous, fine-grained microstructures (Ref 1, 2). Thermal spray is very versatile and has also been proposed for several new applications, including rapid part prototyping (Ref 3), production of fiber-reinforced intermetallic-matrix composites (IMCs) (Ref 4), and for producing so-called "functionally gradient materials" (FGMs) (Ref 5). Thermal spray is, nevertheless, a mature process technology, having been established now for more than a century as an economic, efficient method for coating and recoating surfaces, repairing worn components and spray forming. The latter has been practiced for at least 50 years as a means of producing ceramic crucibles for the containment of molten or reactive metals, nozzles for hot gases (Ref 6), production of forging dies (Ref 7), and the structural forming of difficult-to-process particulate materials such as high-temperature alloys, refractory metals, intermetallics, and ceramics (Ref 8). Thermal spray processing has become an important powder consolidation technique, and new developments are resulting in more novel material synthesis routes and processing of unique material combinations. This article reviews thermal spray processing advances made in the last 25 years, focusing on the recent innovations that are driving its application in metallic-, ceramic-, and intermetallic-matrix composites (Ref 9), materials synthesis, and FGMs. Thermal spray processes and their characteristics are described, together with descriptions of the properties and characteristics of thermally sprayed materials. The first part describes the different classes of thermal spray processes and the materials systems that can be processed, either as coating or as spray-formed deposits. The second part focuses on thermal spray forming techniques and applications.

Thermal Spray Forming of Materials

Richard Knight and Ronald W. Smith, Center for the Plasma Processing of Materials (CPPM), Drexel University, Philadelphia, PA

Thermal Spray Processing--Introduction

The term "thermal spray" describes the family of four or five processes that use the heat energy generated by chemical (combustion) or electrical (plasma or arc) methods to melt, or at least soften, and accelerate fine dispersions of droplets to velocities in the range 50 to >1000 m/s. The high particle temperatures and velocities achieved result in significant droplet deformation on impact at a surface, producing thin layers or lamellae, often called "splats," which conform and adhere to the substrate surface. Solidified droplets build up rapidly, particle by particle, as a continuous stream of droplets impact to form continuous rapidly solidified layers. Individual splats are generally thin (~ 1 to $20 \mu\text{m}$), and each droplet cools at very high rates ($>10^6 \text{ K/s}$ for metals, Ref 1) to form uniform, very fine-grained, polycrystalline coatings or deposits. Figure 1 shows a schematic of a generic thermal spray powder consolidation process, illustrating the key features and a typical deposit microstructure.

Fig. 1 Schematic representation of a typical thermal spray powder consolidation process

Sprayed deposits usually contain some level, typically between 0 and $\sim 10\%$, of porosity, some unmelted or partially melted particles, fully melted and deformed "splats," and varying amounts of other phases--as a result of oxidation of some hot particles traveling in the spray jet due to entrainment of, and reaction with, the surrounding air.

Thermal spray jets heat large numbers (millions) of particles simultaneously, and because of the nonuniform temperature distributions of the spray jets used, and differing particle sizes, many particles do not experience the same degree of

heating. Some may be completely unmelted and can cause porosity or trapped "unmelts" in coatings. The level of these coating defects varies depending on the particular thermal spray process used, the operating conditions selected, and the material being sprayed, as described later. Figure 2 shows a photomicrograph of a thermally sprayed (high-velocity oxygen fuel, or HVOF) 80/20 NiCr alloy coating showing the characteristic lamellar splat structure. The splats and coating layers were built up as each droplet impacted at the substrate. The microstructure in Fig. 2 includes partially melted particles and dark, oxide "inclusions" that are characteristic of many metallic coatings sprayed in air. As described later, the thermal spray process selected for spraying a material can have a significant effect on the microstructure and composition of the resulting coating and hence on its properties. Figure 2 also shows the characteristically wide range of variation in oxide content, structure, and porosity that can be obtained for the same material as a function of thermal spray technique.

Fig. 2 Photomicrograph showing the microstructure of a thermally sprayed 80/20 NiCr alloy

Thermal spray consolidation of particulate materials, as described above, is essentially a thermomechanical forming process, involving a combination of solid (unmelted or partially resolidified) and liquid phases. Some material may also be vaporized, but this is generally <0.1% by weight. The thermal energy of the process jet heats injected particles close to their melting points and also heats the coating/substrate surface during deposition. Hot working of the particles may also occur owing to the high kinetic energy imparted to the particles by the high-velocity gas jet used to accelerate them, in many cases to velocities exceeding 300 m/s. Consolidation thus occurs through a combination of liquid flow, solid redistribution, solid-phase deformation, recrystallization, and diffusion. In many cases, the continuous bombardment of newly deposited surfaces by subsequent impacting particles locally densifies the underlying deposits through a "peening" process of plastic deformation. All of these consolidation steps are driven by the thermokinetic energy characteristic of the various thermal spray processes. Thermal spray processes are, in practice, microcasting/microthermomechanical forming techniques in which the temperature and velocity of the particles determine the final microstructure and overall degree of consolidation. Unlike other spray casting techniques, thermal spray solidification events are very localized, on the scale of each droplet, and hence there is no long-range solidification structure. Such localized solidification leads to very fine grains, typically 0.1 to 10 μm , and no longer-range segregation.

Thermal Spray Processes and Techniques

All thermal spray methods use chemical or electrical energy to heat feed materials injected into hot-gas jets to create a stream of molten droplets that are accelerated and directed toward the substrates being coated. Figure 3 shows how the various thermal spray processes can be broken down according to the energy source used (combustion versus electrical), feed material form (powdered or solid), and surrounding environment (air, low pressure [vacuum], inert gas, etc.). The thermal spray "family" of processes are typically grouped into three major categories (Ref 10):

- Combustion spray (flame--powder/wire/rod, HVOF)
- Wire arc or arc spray (air or inert gas)
- Plasma (direct current air, vacuum or inert atmosphere plasma spray; RF induction)

Figure 4 shows typical schematics of the major thermal spray processes.

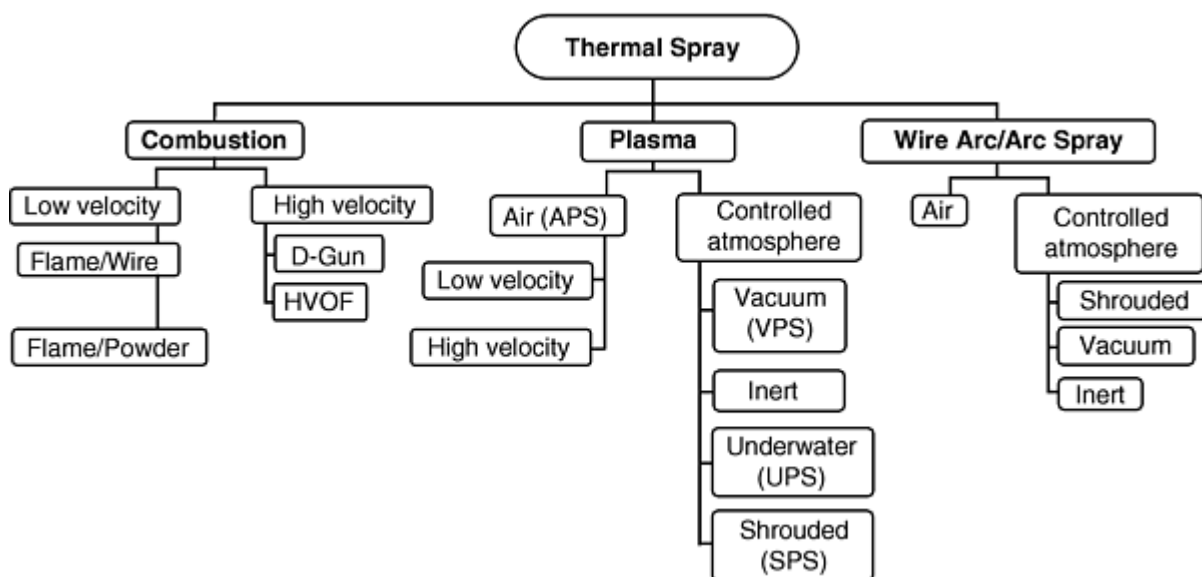

Fig. 3 General types of thermal spray processes

Fig. 4 Major thermal spray processes

Combustion spray burns mixtures of fuels such as acetylene and oxidizing agents (air or oxygen) that are used to subsequently heat and accelerate particles of material injected into the hot expanding gas jets. Combustion spraying has, during the last 15 years, been subdivided into two distinct categories: (a) Flame spray, which uses low pressure (70 to 140 kPa, or 10 to 20 psi) fuel/oxygen mixtures, burning unrestricted and external to the spray gun itself in ambient air, and (b) HVOF spraying, which utilizes internal combustion at higher gas flow rates and pressures (up to ~ 1.5 MPa, or several hundred psi) generating supersonic jet exit velocities. The powder particles are also injected internally in HVOF, such that the heat and momentum transfer to the particles, and hence particle velocity, are substantially higher (>1000 m/s) than in conventional flame spray.

Wire arc spray utilizes two electrically conducting wires as feedstock, rather than powders. A continuous direct current (dc) arc melts the tips of the advancing wires and a high flow (typically >1500 slm) gas jet atomizes the molten material and accelerates the resulting small droplets toward the substrate being coated. A typical wire arc spray gun consists of a nozzle that directs a cool, high-velocity air, nitrogen or, in special cases argon, gas jet at the wire tips and a feedback-controlled wire-feed mechanism that continuously positions and advances the wires. Melt rate and interelectrode voltage determine the arc gap and size distribution of the atomized droplets leaving the tips of the wires and hence affect the final coating microstructure. Because cool gas jets are used to atomize the molten tips of feed wires in wire arc spray, the components being coated are not heated as much as in other thermal spray processes, an advantage when thermally sensitive substrate materials are being coated. Even thin sheets of paper can be coated by the wire arc process. Wire arc spraying is, however, limited to electrically conductive materials (metals) as feedstock, but has the lowest processing temperatures (at the substrate) of all the processes. Particle velocities vary, but are generally higher than in conventional flame spray and lower than HVOF or plasma spray. Plasma spraying (see the section that follows) has the highest particle-heating potential, but its particle velocities, although higher than conventional flame and wire arc spray, are generally lower than those of HVOF spraying. In other cases, accelerating gas cap extensions have been added to conventional wire arc spray systems to increase particle velocity and produce finer droplets, both leading to increased deposit densities, and reduced differences between the microstructures and properties of wire arc sprayed deposits and those produced by other thermal spray processes.

Plasma spray can be broken down into three major categories: (a) air plasma spray (APS), (b) "vacuum" plasma spray (VPS) or low-pressure plasma spray (LPPS), and (c) controlled atmosphere plasma spray (CAPS), which also includes inert gas shrouded plasma jets, depending on the environment used. These distinctions affect the level of interaction

between the process jet and materials being sprayed with the surrounding atmosphere and thus control the microstructure and properties of the sprayed materials. All current commercially significant plasma spray processes use a nontransferred (i.e., no arc is established to the workpiece or substrate) dc electric arc to heat gases to peak temperatures in excess of 25×10^3 K, producing jets of ionized "plasma" with temperature ranges of 3×10^3 to 15×10^3 K. At these temperatures, the plasma gases (Ar, H₂, He, or N₂) are dissociated and ionized into an equilibrium mixture of positive ions and electrons as energy is pumped into them by the confined arc discharge. The plasma state gives the process both its name and its ability to melt any material exhibiting a stable melting point. A typical plasma spray device consists of a cylindrical, thoriated tungsten cathode, which emits electrons when heated by an electric arc, located concentrically and coaxially inside a cylindrical water-cooled copper nozzle. Electrons emitted from the cathode flow to the nozzle anode wall under the influence of the applied electric field, typically 30 to 80 V. Gases injected into this interelectrode region are heated, dissociated, and ionized by the electric arc and subsequently expanded to atmosphere through the nozzle as a subsonic or supersonic plasma jet, depending on the nozzle design and pressure ratio. The gas velocity may, in some cases, exceed 1.5×10^3 m/s, depending on the power input, nozzle design, gas composition and flow rate. Powders are injected into the plasma jet as fluidized streams of "carrier" gas and powder, either externally, by means of a tube that directs the stream of powder particles radially into the hot gas jet immediately after it exits the nozzle, or internally through powder feed ports through the nozzle wall itself. Internal injection produces longer particle heating or "dwell" times and improves melting efficiency, enabling higher melting temperature materials to be sprayed.

Plasma spray devices generally use argon or mixtures of argon plus helium, hydrogen (H₂), or sometimes nitrogen (N₂) to generate the hot plasma jets used for spraying. Coatings sprayed at low pressures (VPS), in inert atmospheres in an enclosed pressure vessel, or using an inert gas shroud, have very low oxide inclusions and porosity levels. This is achieved by eliminating interaction between the molten particles and oxygen being entrained into the jets from the surrounding air. The sprayed coatings generally exhibit low oxide content, such that in many cases VPS materials have the same, or better, properties than cast materials. This characteristic has enabled VPS processes to be used to spray form net shapes of "difficult-to-process" materials, including ceramics, refractory metals, intermetallics, and composites.

Inert gas shrouded plasma spray has the potential of achieving vacuum plasma quality coatings under air plasma spray conditions, thereby lowering the total processing cost. Several effective inert gas shroud designs have been developed and reported, including porous metal nozzle inserts (Ref 11) and discrete, multijet, parallel flow designs located downstream of the nozzle exit on a conventional plasma spray gun (Ref 12).

As stated above, the structures and properties of sprayed materials can vary widely, depending on the process used, classes, and the processing conditions. The different processes each result in different thermal and velocity histories for the injected particles. Particle melting and deformation are thus different in each thermal spray class, leading to the differences observed in the performance of spray deposited materials. Key features of the different processes are as follows:

- Conventional flame spray has the lowest heating potential and lowest mean particle velocity of all thermal spray processes, but is nevertheless used in many applications.
- High-velocity oxygen fuel processes typically have the highest particle velocity, but its gas jet temperatures limit the maximum attainable particle temperatures.
- Wire arc spray has lower processing temperatures and produces intermediate particle velocities, but--owing to its low gas temperatures--can be used to coat thermally sensitive substrates.
- Plasma spray, with the highest processing temperatures, is most flexible with respect to materials selection, and because of its ability to operate under inert gas conditions, is commonly chosen for consolidating oxidation-sensitive and reactive materials.

Thermal spray has been defined as a particulate/droplet consolidation mechanism capable of processing virtually any material and most materials combinations. Despite the widespread use of thermal spray to produce coatings, and, to a lesser extent for spray forming, thermal spray has not been widely used for the synthesis and production of advanced materials. Developments in thermal spray over the last 25 years, including controlled atmosphere plasma spraying, HVOF, reactive plasma spraying, improved wire arc spray methods, new material and powder production methods, and particularly improved process controls have, however, resulted in many new opportunities for the technology in the area of powder consolidation.

The range of materials that can be sprayed, their possible structures, and the application of thermal spray processing are limited only by the imagination of the users and the economic viability of the application. Thermal spray can process many materials, in many forms, to produce deposits on many substrate materials, thus making thermal spray an ideal technique for processing many advanced materials and structures. Many challenges, however, still remain:

- Cost/economics
- Compositional and structural control
- Deposition rate
- Control of deposit properties

Thermal spray is now, owing to recent advances in materials, powder production techniques, process understanding, and control, at the leading edge of novel powder consolidation methods. Some recent advances are reviewed below that present the current state of the technology for implementation as a viable powder consolidation process.

Thermal Spray Forming of Materials

Richard Knight and Ronald W. Smith, Center for the Plasma Processing of Materials (CPPM), Drexel University, Philadelphia, PA

Materials for Thermal Spray

Thermal spray is capable of processing materials with jet temperatures ranging from 500 to 15×10^3 K, which enables virtually any material, or combination of materials, to be processed. Because only small volume powder particles are heated in a given time and because, on solidification, only small volumes, typically 5 to 100 μm in diameter, are being cooled, segregation is not a limiting factor. On the other hand, residual stress can have detrimental effects on the properties and performance of sprayed coatings, its significance varying from process to process and material to material. Also, because materials are deposited in relatively thin (12 to 50 μm , or 0.0005 to 0.002 in.) layers, many unique combinations of materials can be produced.

Three characteristic types of deposit can be sprayed: (a) Monolithic materials, such as metals, alloys, intermetallics, ceramics, and polymers; (b) composite particles such as cermets (WC/Co, $\text{Cr}_3\text{C}_2/\text{NiCr}$, NiCrAlY/ Al_2O_3 , etc.), reinforced metals, and reinforced polymers; and (c) layered or graded materials. Some examples of these, and their particular advantages and associated technical challenges, are described below.

Monolithic Materials

Metals. Tungsten, molybdenum, rhenium, niobium, superalloys (nickel, iron, and cobalt base), zinc, aluminum, bronze, cast iron, mild and stainless steels, NiCr and NiCrAl alloys, cobalt-base Stellites, cobalt/nickel-base Triballoys, and NiCrBSi "selffluxing" Colmonoy have all been successfully thermal spray consolidated either as coatings or structural deposits. Recently Tribolite (FeCrNiBSi) and AmaCor (amorphous) alloys have also been developed for spraying and exhibit excellent wear and corrosion resistance (Ref 13). Monolithic alloys have advantages due to their similarity to

many base metals requiring repair, their high strength, and their corrosion, wear and/or oxidation resistance. Applications include automotive/diesel engine cylinder coatings; piston rings or valve stems; turbine engine blades, vanes, and combustors; protection of bridges and other corrosion-prone infrastructure; petrochemical pumps and valves; and mining and agricultural equipment. Except in the case of controlled-atmosphere spraying (VPS, inert chamber, and shrouded jets) thermally spraying these metals and alloys produces microreinforced composites of monolithic alloys due to their varying levels of oxide inclusions. Figure 2 shows a range of microstructures for thermally sprayed monolithic metals. These coatings exhibit characteristic lamellar microstructures with the long axis of impacted splats oriented parallel to the substrate surface, together with a distribution of similarly oriented oxides. Oxide content varies from relatively thick layers to finely distributed, particulate, intersplat phases, depending on whether the coatings are wire arc, plasma, or HVOF sprayed. The progressive increases in particle velocity of these processes leads to differing levels of oxide, and differing degrees of oxide breakup on impact at the surface. Oxides may increase coating hardness and may also provide lubricity. Conversely, excessive and continuous oxide networks can lead to cohesive failure of a coating and contribute to excessive wear debris. It is thus important, when selecting materials, coating processes, and processing parameters, that oxide content and structure be controlled to acceptable levels.

Thermal spray coatings may, depending on the spray process, particle velocity and size/size distribution, and spray distance, also contain varying levels of porosity and unmelted particles. High levels of porosity may lead to early deposit failure owing to poor intersplat cohesion. Conversely, low levels of porosity (<5%) may be beneficial in tribological applications through retention of lubricating oil films. Lamellar oxide layers can also lead to lower wear and friction due to the lubricity of the oxide. The porosity of thermal spray coatings is typically <5% by volume. The retention of some unmelted and/or resolidified particles can lead to lower deposit cohesive strength, especially in the case of "as-sprayed" materials with no postdeposition heat treatment or fusion.

Other key features of thermally sprayed deposits are their generally very fine grain structures and microcolumnar orientation. Thermally sprayed metals, for example, have reported grain sizes of <1 μm prior to postdeposition heat treatment. Grain structure across an individual splat thus normally ranges from 10 to 50 μm , with typical grain diameters of 0.25 to 0.5 μm , due to the high cooling rates achieved ($\sim 10^6$ K/s) (Ref 1). Such rapid cooling rates, known to form fine-grained martensitic microstructures in steels, contribute to the high strengths exhibited by thermally sprayed materials. The "as-sprayed" microstructure of a typical metallic coating is shown schematically in Fig. 5.

Fig. 5 Schematic microstructure of an "as sprayed" thermally sprayed metal deposit

The tensile strengths of "as-sprayed" deposits can range from 10 to 60% of those of the fully cast or wrought material, depending on the spray process used. Spray conditions leading to higher oxide levels and lower deposit densities result in the lowest strengths. Controlled-atmosphere spraying leads to $\sim 60\%$ strength, but requires postdeposition heat treatment to achieve near 100% values. Low "as-sprayed" strengths are related to limited intersplat diffusion and limited grain recrystallization during the rapid solidification characteristic of thermal spray processes. The microstructures of thermally sprayed metals are typically very uniform and exhibit excellent tensile properties. After heat treatment at $>0.8 T_m$ (melt temperature), much of the characteristic lamellar structure recrystallizes, but depending on the alloy, grain growth may be limited to <100 μm . The fine-grained structures, found in highly alloyed, grain-growth-stabilized superalloys, have been found to improve thermal fatigue properties, but to increase creep rates. After postdeposition heat treatment (vacuum or hot isostatic pressing), the high-temperature creep properties of these alloys have been found to be lower than cast alloys due to the fine grain sizes and the oxygen interstitials. In this reported work, final grain size in heat-treated microstructures was found to be substantially retained, due to very stable oxide and/or carbide networks formed during solidification after spraying, many times originating from the alloy feedstock powders. Final deposit ductilities were also lowered by the retention of relatively high oxygen contents originating from the surfaces of the original powders (Ref 14).

On the beneficial side, the addition of nitrogen to steel matrices by promoting, rather than minimizing, atmospheric interactions during air plasma spraying has been shown to increase the strength of thermally sprayed steels and is a viable strengthening mechanism for selected monolithic alloys (Ref 15). Grain nucleation is suppressed in alloys containing high levels of silicon and boron, yielding so-called "amorphous" coatings (Ref 16). These "micrograined" or amorphous microstructures contribute to the high strengths and toughnesses of thermally sprayed metals at low to intermediate temperatures. Fatigue failure is also harder to propagate in such structures, except through coating defects such as oxide inclusions. The role of grain size effects on the wear performance of thermally sprayed coatings is understood, but has not been independently measured; hence it is hard, for example, to determine its contribution to sliding-wear performance.

Ceramics. Oxides such as Al_2O_3 , ZrO_2 (stabilized with MgO , CeO , Y_2O_3 , etc.), TiO_2 , Cr_2O_3 , and MgO ; carbides such as Cr_3C_2 , TiC , Mo_2C and SiC (generally in a supporting metal matrix) and diamond; nitrides such as TiN and Si_3N_4 , and spinels or perovskites such as mullite and superconducting oxides, have all been thermally spray deposited. Sprayed deposits of these materials are used to provide wear resistance (Al_2O_3 , Cr_2O_3 , TiO_2 , Cr_3C_2 , TiC , Mo_2C , TiN , and diamond), thermal protection (Al_2O_3 , ZrO_2 , MgO), electrical insulation (Al_2O_3 , TiO_2 , MgO), and corrosion resistance. With the exception of SiC (which sublimates), diamond, and SiC or Si_3N_4 (which must be in a metallic binder), ceramics are particularly suited to thermal spraying, with plasma spraying being most suitable due to its high jet temperatures.

The processing and materials flexibility and high temperatures gives plasma spraying a leading role in the spraying of thermal barrier coatings (TBCs), although the use of HVOF is also being investigated. Thermal barrier coatings are, after wear and corrosion coatings, likely to be one of the largest growth markets for thermal spray, with increased use in the automotive, metalworking, and chemical industries. Such broad usage, however, will require a more thorough understanding of the behavior of these materials during high-temperature service. Thermal spray processing of ceramic materials that melt, rather than decompose, is essentially the same as for metals; however, the higher mean melting temperatures and low thermal conductivity of ceramics limits the selections of thermal spray processes that can successfully melt these materials. Combustion spray methods generally have insufficient process jet enthalpies and/or particle dwell times to efficiently spray ceramic powders. Most HVOF systems are also limited in their efficient spraying of ceramics, where the powder sizes required are either too small or deposit efficiencies are too low for the processes to be economically viable. Wire arc spray is excluded because it needs conductive materials, leaving only plasma spraying as an economic method for spraying ceramic powders. There are, however, some specialized flame spray techniques such as the "Rokide" process (Norton Company), which uses a combustion jet to melt the tips off pressed-and-sintered ceramic rods and a secondary gas jet that atomizes the molten material from the melting rod tip. Air plasma spraying is, however, most widely used to deposit ceramics, finding applications in TBCs, wear coatings on printing rolls (Cr_2O_3), and for electrical insulators (Al_2O_3).

The microstructures of sprayed ceramics are similar to those of metals, with two important exceptions: grain orientation and microcracking. Rapid solidification of small droplets (generally $<50 \mu\text{m}$) results in very fine grains as in metals; however, owing to the low thermal conductivity of ceramics, multiple grains may exist though a splat thickness, whereas in metals a single grain may cross an entire splat and even grow into an adjacent one. Intersplat and intrasplat microcracking is widespread in ceramic coatings, resulting from the accumulation of highly localized, residual cooling stresses. Figure 6 illustrates the typical microstructure of a thermally sprayed yttria-stabilized zirconia ceramic coating, showing fine grains, characteristic lamellar structure, and a network of porosity and microcracks.

Fig. 6 Typical microstructure of a thermally (plasma) sprayed ceramic (yttria-stabilized zirconia)

Splats normally exhibit through-thickness cracking owing to the very low ductility of most ceramics, but these cracks do not usually link up through the whole deposit thickness, at least not until an external stress is applied. Microcracking of splats is a major contributor to the effectiveness of TBCs, even under high-temperature gradients and moderate strains, conditions under which conventionally formed bulk ceramics would fail.

Intermetallics. Usually produced from powders due to their intrinsically low ductility, intermetallics are generally consolidated either by pressing and sintering or hot isostatic pressing. Over the last 15 years researchers have reported on the thermal spray consolidation and forming of intermetallic powders. The high heating and cooling rates of the thermal spray process reduce the segregation and residual stresses that ordinarily limit the formability of these brittle materials. Thermal spray processes are also able to deposit materials onto mandrels, building up thin layers of material and thus forming near-net shapes and providing the opportunity for "engineered microstructures" and functionally graded structures. Researchers have also reported on the plasma spraying of TiAl, Ti₃Al, Ni₃Al, NiAl, and MoSi₂ with excellent deposit characteristics and properties. Improved ductilities have been obtained, with tensile strengths equal to, or better than, those of materials consolidated by other powder processing techniques.

Thermal spray processing of intermetallics, unlike ceramics, is generally not an application for plasma spraying. Plasma spray in controlled atmospheres is, however, the method of choice for the production of bulk deposits. High-velocity oxygen fuel and other combustion spray techniques are normally only used to spray compatible intermetallics, such as semiconducting, insulating, or corrosion- and wear-resistant coatings. Most intermetallics are very reactive at high temperatures and very sensitive to oxidation, hence the preference for using inert atmosphere plasma spray. Plasma spray forming is also well suited for the net-shape forming of brittle intermetallics. Investigators have found that plasma spray forming can actually *increase* the ductility of intermetallics such as MoSi₂ (Ref 17) and NiAl/Ni₃Al (Ref 18). These improvements were linked to a decrease in grain boundary and/or splat interface contaminants that limit localized plastic flow under an applied strain and lead to early crack linking, thus lowering the overall plastic flow, measured as ductility. It has been shown, for example, that reactive plasma species reacting at the surfaces of MoSi₂ powder particles in flight actually reduce the residual SiO₂ content below that of commercial MoSi₂ powders and hence reduce the SiO₂ "pest" reaction that degrades the properties of pressed-and-sintered or hot isostatically pressed MoSi₂.

The as-sprayed microstructures of thermally sprayed intermetallics are very similar to those of metals. Figure 7 shows the microstructure of thermal spray consolidated MoSi₂, showing the characteristic lamellar structure and fine grains. Intermetallics are generally somewhat more porous than sprayed metals owing to their limited ductility and low plasticity, which translates into a narrower "processing window" of plasma spray parameters for the production of high-density intermetallics, requiring tighter process control than for spraying metals. Higher-velocity plasma spray processes are preferred because the increased particle velocities result in more complete deformation of individual splats and denser deposits overall.

Fig. 7 Microstructure of a plasma spray consolidated intermetallic material (MoSi₂)

Polymers. Polymeric materials can also be successfully thermally sprayed, provided they are available in particulate form. Thermal spraying of polymers has been commercially practiced for 20 years, and a growing number of thermoplastic polymers and copolymers have now been sprayed, including urethanes, ethylene vinyl alcohols (EVAs), nylon 11, polytetrafluoroethylene (PTFE), polyetheretherketone (PEEK), polymethylmethacrylate (PMMA), polyimide, and copolymers such as polyimide/polyamide, Surlyn, and Nucryl (Du Pont), and polyvinylidene fluoride (PVDF). Conventional flame spray and HVOF are the most widely used thermal spray consolidation methods used to date (Ref 19), although use of plasma spray has also been reported. Figure 8 shows a typical dense, well-bonded, HVOF-sprayed nylon coating. Consolidation of polymers to full densities and high cohesive strengths, unlike metals, relies to some

extent on continued heat input to the polymer layers after deposition onto the substrate. This may be due to the more complex, long-range-ordered nature of the molecular bonding in polymers, compared to the simpler, short-range-order bonding in metals. Thermal spray, a high-temperature, rapid-heating/rapid-solidification process, has been found to decompose polymeric materials, lowering the molecular weight and producing "charring." In many cases, however, this does not impair the functionality of the sprayed coating, although it does change certain polymer properties compared to polymers consolidated by conventional means. Despite thermal spraying of polymers having been practiced for more than 20 years, little research into the material structures and properties has been carried out until recently. Commercial interest in this application is growing, for applications such as aqueous corrosion protection and as a solventless processing alternative to environmentally hazardous volatile organic compound (VOC)-based techniques.

Fig. 8 Microstructure of an HVOF-sprayed nylon coating

Composite Materials

Thermal spraying, either as a coating or as a bulk structural consolidation process, has clearly demonstrated advantages for the production of composites. Difficult-to-process composites can be readily produced by thermal spray forming, with vacuum plasma spray being the process of choice for the most reactive matrix materials. Particulate-, fiber-, and whisker-reinforced composites have all been produced and used in various applications. Particulate-reinforced wear-resistant coatings such as WC/Co, $\text{Cr}_3\text{C}_2/\text{NiCr}$, and TiC/NiCr are the most common applications and comprise one of the largest single thermal spray application areas. Figure 9 shows schematically the diverse forms of composites that can be thermally spray formed.

Fig. 9 Schematic microstructures of possible thermally spray-formed composites. (a) Deposit with a particulate-reinforced second phase. (b) Deposit with a whisker-reinforced second phase. (c) Deposit with a continuous-fiber-reinforced second phase

Whiskers of particles can be incorporated using so-called "engineered" powders, mechanical blending, and by coinjecting different materials into a single spray jet. Mechanical blends and coinjection, although useful, have been found to result in segregation of the reinforcing phase and, in many cases, degradation of the second-phase whiskers or particles. Thermal spray composite materials can have reinforcing-phase contents ranging from 10 to 90% by volume, where the metal matrix acts as a binder, supporting the reinforcing phase. The ability to consolidate such fine-grained, high reinforcing phase content materials is a major advantage of thermal spray over other methods used to produce composites.

Thermal spraying of composite materials with discontinuous reinforcements, such as particulates or short fibers, is usually accomplished by spraying powders or powder blends. Investigators have developed techniques for the production of continuous fiber-reinforced materials that overcome the "line-of-sight" limitations of thermal spray processes. This includes "monotape" fabrication techniques, where continuous fibers are prewrapped around a mandrel and a thin layer of a metal, ceramic, or intermetallic matrix material is sprayed (Ref 20). Plasma, HVOF, and wire arc spray have been used, although in the cases of intermetallics and high-temperature alloys, controlled atmosphere plasma spray (VPS) has generally been used. The fibers are thus encapsulated within thin monolayer tapes and are subsequently removed for consolidation to full density by hot pressing with preferred fiber orientations, producing continuously reinforced bulk composites.

Powders for Sprayed Composites

Discontinuously reinforced composites produced using thermal spray techniques use either composite powders or direct reactive synthesis approaches, as described below. Powders can be produced mechanically, chemically, thermomechanically, or by using high-temperature synthesis. "Engineered powders" defines powders in which different phases are incorporated to produce a "microcomposition" of the final desired structure. Typically these powders contain the desired sizes, size distributions, and morphologies of the equilibrium phases. These powders also permit the introduction of higher concentrations of phases than those normally achievable through conventional melt or reaction processing. Figure 10 shows two types of powder that could be produced in this way: short ceramic fibers within a metal matrix and an intermetallic-matrix material reinforced with more ductile phases. The latter has been found to be a viable approach for increasing the fracture toughness (K_{Ic}) of intermetallics. Varying reinforcing phase combinations, compositions, morphologies, and distributions can be produced. The rapid heating and cooling experienced by these powders during thermal spray forming limits dissolution and degradation of the phases, which remain relatively unchanged after consolidation, although some microstructural refinement and solutioning can take place. Generally, more significant changes occur during conventional powder consolidation processes because of the longer processing times.

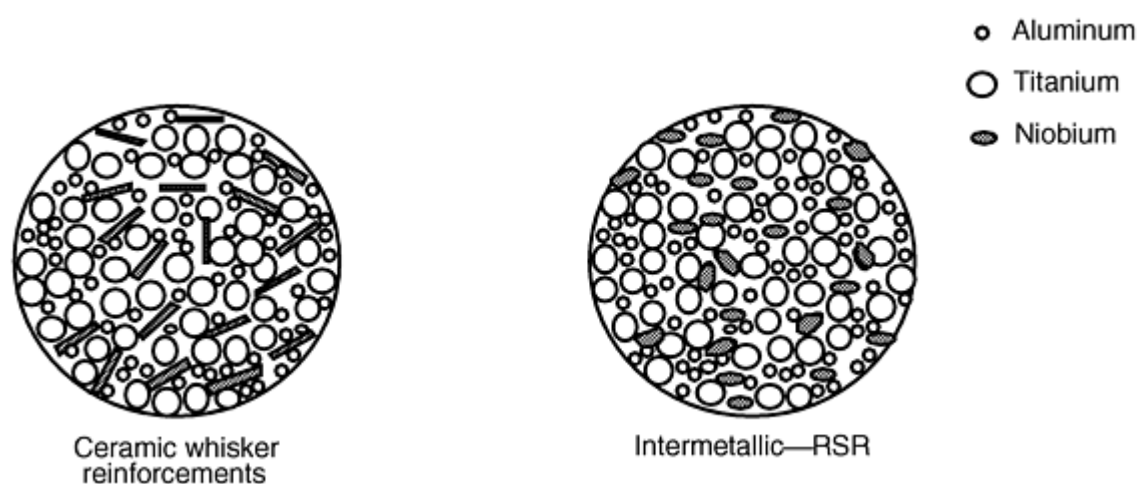

Fig. 10 Schematic representations of typical "composite" thermal spray powders

Mechanical Blends. Blended powders are produced by mixing the required proportions of a binder phase (a metal, an intermetallic, or a ceramic) together with a reinforcing phase. The matrix and reinforcing phases may segregate over time during shipping, handling, and feeding into a thermal spray process and often yield poor "as-sprayed" deposit uniformity. Many mechanical blends can, however, be "agglomerated" and fixed using an organic binder, which reduces their sensitivity to handling. Spherical agglomerates are known to flow and feed better, and spray drying has been used to

produce such materials. Agglomerated powders have enabled thermally sprayed deposits with improved uniformity to be produced, although the high viscosity, shear, and thermal forces acting on injected agglomerated particles tend to break the agglomerates, leading to segregation and direct exposure of the second phase to the thermal spray jet. Physically and thermally stable agglomerates are thus desirable.

Agglomeration, Sintering, and Melt Densification. The mechanical stability of agglomerated composite particles can be improved by agglomeration and sintering, which is a solid or rapid "matrix" melting and cooling process. Metal-matrix/ceramic hard-phase-reinforced powders (e.g., WC/Co, Cr₃C₂/NiCr, NiCrAlY/Al₂O₃, etc.) can be sintered in the solid state by heating in a protective atmosphere furnace, sometimes using a fluidized bed, followed by a gentle milling to break any weak interagglomerate bonds. Agglomerated and sintered powders retain a level of porosity, typically 5 to 10% by volume, depending on the reinforcing phase/matrix combination, the sintering time, and temperature. Retained porosity, although not generally a source of phase segregation in thermally sprayed deposits, can lead to higher as-sprayed porosity and increases the spray jet melting enthalpies required to melt the powders because the thermal conductivity of the individual particles is lowered by the porosity. Melting of metallic binding phases and retention of spherical particle morphologies can be achieved by processing the powders through a thermal plasma jet. Known as "plasma densification," this process produces spherical powders exhibiting near 100% particle density and uniform distributions of reinforcing phases. Plasma-densified powders result in the most uniform thermal spray-consolidated deposits, but at significantly increased cost owing to the additional handling, processing steps, and lower process yields.

Self-propagating high-temperature synthesis (SHS) is a composite powder production method now finding increasing application in thermal spray forming. The SHS process exploits the high heats of formation released from exothermic reactants which, when mixed and ignited, produce a self-sustaining combustion-type reaction that propagates until all reactants are consumed. Self-propagating high-temperature synthesis processing uses mixtures of reactant powders placed in a reactor vessel, generally in an argon atmosphere. The reactant mixture is then ignited using an incandescent filament or laser beam. Self-propagating high-temperature synthesis has been developed to the point where it is now capable of producing composite materials with well-controlled distributions of carbides or other reacted phases in metallic or intermetallic matrices (Ref 21, 22). Self-propagating high-temperature synthesis produces low-density, porous "ingots" that must then be further processed by crushing, milling, and screening to yield powders in size distributions compatible with thermal spraying. Researchers have successfully thermally sprayed SHS-produced MoSi₂, SiC-reinforced MoSi₂, FeCr/TiC, and NiCr/TiC materials. The sprayed deposits reportedly yielded equivalent, and in many cases superior, properties to deposits produced from powders produced by other synthesis routes. Some examples of the improved properties obtained include increased wear resistance in TiC/metal-matrix composites and increased fracture toughness in intermetallic composites such as MoSi₂/SiC (Ref 23). Figure 11 illustrates the SHS powder production route, including powder synthesis and consolidation via plasma spray forming.

Thermal Spray Forming of Materials

Richard Knight and Ronald W. Smith, Center for the Plasma Processing of Materials (CPPM), Drexel University, Philadelphia, PA

Thermal Spray Forming

While the thermal spray technology described above originated primarily as a coating or surfacing process, with materials being deposited as thin (<250 μm), nonload-bearing coatings for dimensional restoration, wear, corrosion, and thermal protection, it has also evolved, during the last 50 years, into a process capable of spray forming free-standing materials onto mandrels at thicknesses of >100 mm. Early applications included zirconia λ-oxygen sensors and bulk ceramic materials for crucibles. Historically "difficult-to-form" materials such as the refractory metals tungsten, hafnium, molybdenum, and tantalum; superalloys; and intermetallics have now all been deposited with varying degrees of success, with the ultimate mechanical properties of the sprayed deposit being the main limitation. Process technology advances, such as HVOF, which can produce sprayed deposits with lower tensile stresses and degrees of thermal degradation than other processes and with increased deposit density, controlled-atmosphere plasma spray, and improved powder formulations and morphologies have all contributed to the successful development of thermal spray forming of monolithic and composite materials.

Thermally sprayed coating deposits are usually <1000 μm thick, more typically ~400 μm. Thermal spray forming, however, can yield deposit thicknesses in excess of 25 mm. Free-standing shapes can be produced by spraying onto sacrificial mandrels, which are mechanically or chemically removed after spraying.

The incremental nature of thermal spray processes, using particulate-based feedstocks, and with deposited layers typically ~15 to 25 μm thick, enables graded and laminated structural materials to be formed. Also, because of the high processing temperatures and high localized forming energies (high particle kinetic energies at impact), traditionally difficult-to-form materials can be processed into near-net-shape components. Virtually all common and refractory metals, many intermetallics, ceramics, and combinations of these have been spray formed as "composite" materials. The properties (apart from the ductility of metals) of these deposited materials, after postdeposition heat treatment, have been reported to be close to, if not exceeding, those of cast or wrought materials. The ductility of metals is limited by contamination sources occurring either within the feedstock powders used, or in the spray process itself, due to oxidation of the material during heating under atmospheric conditions. Nickel-base superalloys and other heat-resistant alloys have all been thermally spray formed during the last 20 years, either as preforms or as a component repair technique. Plasma spray in

low pressure inert/controlled atmosphere (VPS) chambers has been found to be most suitable for forming these alloys; however, recent investigations using HVOF have shown that this too may be a viable alternative to plasma spraying in controlled atmospheres, at least for some component repair applications. Despite the technical capability of thermal spray, however, economics and process/coating reliability concerns related to material structure, uniformity, and material properties still limit the use of thermal spray forming.

The current major advantages of thermal spray forming techniques are in the forming of refractory metals, both in graded or layered structures and in composites. Some of the more innovative spray forming application developments are described below, together with some insights into emerging technologies that may ultimately lead to expanded implementation of thermal spray forming as a materials processing technique.

Reactive Plasma Spray Forming

Research in recent years has demonstrated that the synthesis of advanced materials by chemical routes is more promising than many "conventional" processing methods--casting, forming, and possibly powder metallurgy (Ref 24). Plasma spray forming, a rapid particulate consolidation, high-temperature process, has an inherent suitability for chemical synthesis and is thus a strong candidate for synthesizing multiphase, advanced materials. As described in the literature (Ref 25), plasma spray coating and forming have been practiced for many years and are now practical and economical methods for processing difficult-to-form intermetallic, ceramic, and composite materials (Ref 1, 2, 26). The development of plasma spraying in controlled atmosphere chambers (VPS or LPPS) in the early 1970s (Ref 27, 28, 29) was a key factor behind its advancement from a coating to a forming technology. Controlled-atmosphere plasma spraying, adapted for *reactive* plasma spraying, has recently been developed to combine controlled dissociation and reactions in thermal plasma jets, for the in situ forming of new materials or to produce new phases in sprayed deposits. Reactive plasma spray forming is consequently emerging as a viable method for producing a wide range of advanced materials. The process, a logical evolution from conventional plasma spraying, allows "reactive" precursors to be injected into the particulate and/or hot gas streams. These reactive precursors may be liquids, gases, or mixtures of solid reactants which, on contact with the high-temperature plasma jet, decompose or dissociate to form highly reactive and ionic species that can then react with other heated materials within the plasma jet to form new compounds. Figure 12 illustrates the reactive plasma spray concept. Chemical reactions rely on plasma-induced dissociation of the injected precursors, for example gaseous methane (CH_4), which decomposes into elemental or ionic species such as CH_3^- , C^{4+} or even atomic carbon. These species can react with other elements to produce carbides such as TiC and WC, or under certain conditions, diamond or diamondlike carbon (DLC) films. Figure 12 shows the plasma heating of gases, using either a nontransferred electric arc or an inductively coupled plasma (ICP) radio frequency (RF) discharge; injection of reactive precursors into the plasma jet; and injection of powders in a carrier gas stream. Injection locations may vary depending on the materials or reactions desired and can be directly in the plasma generator (torch or gun) or into a reactor located immediately downstream. The primary requirements are that the precursors dissociate into reactive "species" and that the reaction times and temperatures are sufficiently long for the desired products or phases to form. Reactive plasma spray forming has several key components, as shown in Fig. 12:

- A thermal plasma generator
- A method of injecting the reactants or precursors
- A reaction region where compounds can form and nucleate, either on the surfaces of particles or on a substrate
- A gas jet to transport the heated reactants and products to the surface(s) on which the products are formed

Fig. 12 Reactive plasma spray process for the synthesis of composite materials

Reactive plasma spray applications include the synthesis of composite materials, shaped brittle intermetallic alloys, reinforced or toughened ceramics, and tribological coatings with in situ formed hard or lubricating phases. Reactive plasma spray forming enables a wide range of materials to be produced, for example, aluminum with AlN, Al₂O₃, or SiC; NiCrTi alloys with TiC or TiN; intermetallics such as TiAl, Ti₃Al, MoSi₂, and other ceramics with oxides, nitrides, borides, and/or carbides. All of these have been produced in situ in reactive thermal plasma jets.

Figure 13 shows typical microstructures of some reactively plasma sprayed materials, demonstrating the versatility of the process for the in situ forming of metal/carbide, metal/nitride, and ceramic composites.

Fig. 13 Microstructures of reactively plasma sprayed (a) Al₂O₃/SiAlON and (b) MoSi₂/SiC

Research indicates, however, that significant technical challenges still remain because, despite the promises and advantages indicated previously, the yields and quality of the final products depend strongly on the starting precursors,

their injection methods, and the atmospheres in which they are sprayed (Ref 24, 30). Monolithic SiC, SiN, and AlN powders have also been synthesized in plasma jets (Ref 31, 32). The uniformity of these particular materials has considerable variability, however, and has limited the practical use of many plasma spray processes for forming monolithic compounds, although commercial plasma production of ZrO₂ and TiO₂ powders in plasma jets has been reported (Ref 9).

Recent investigations have demonstrated that reactive plasma spray forming utilizing incomplete or nonequilibrium reactions in plasma jets to form mixtures of phases can produce functional composites with the reactant products embedded in metallic, ceramic, and even intermetallic matrices. These materials have been shown to be very hard and have potential application as wear-resistant coatings (Ref 33). These reactively plasma sprayed coatings were, in practice, metal-matrix composites with in situ reacted hard phases formed when the reactive gas mixtures reacted with molten metal particles. Fine TiC, WC, TaC, and other refractory carbides, oxides, silicides, or nitrides have been spray formed in situ as particulate phases in near-net-shape metallic, intermetallic, and ceramic matrices, thus eliminating many difficult post-forming operations. Lightweight structural materials such as Ti₃Al, TiAl, NiAl, and MoSi₂ have also been produced by reactive spray forming. In these cases, aluminum metal powders were injected into TiCl₄ plasmas to produce TiAl. Molybdenum particles have also been injected into plasma jets seeded with disilane (Si₂H₆) to form MoSi₂.

The utility and potential of reactive plasma spray synthesis is further illustrated by two high potential examples presented below. Research and development in these areas is receiving increased attention as the potential of thermal plasma processing of these high value materials is realized.

Spray Forming of Superconducting Oxides (High T_c Ceramics)

Researchers have reported on the deposition and synthesis of high critical temperature (T_c) ceramic superconductors using dc and RF induction coupled plasma jets (Ref 34, 35). Dense, thick deposits have been produced using prealloyed 1-2-3 YBaCu_xO_y powders, although the high T_c phase was only formed after a postdeposition heat treatment in oxygen. Researchers have not yet been able to directly plasma spray form the superconducting phase by dc plasma spraying prealloyed powders because the rapid cooling of the "1-2-3" materials from the liquid state suppresses direct formation of the high T_c phase. The microstructures of the deposits were also found to contain many small grains and pores as well as fine cracks that limited the maximum critical currents to very low values. Researchers at the University of Minnesota have developed a method of overcoming this limitation by using a vapor phase, plasma-assisted, reactive plasma spray process (Ref 34). This system uses an RF, induction-coupled, plasma heater in combination with liquid feeding of oxalate precursors of the copper, yttrium, and barium components. The liquids were ultrasonically atomized to generate an aerosol, subsequently carried by an oxygen carrier gas into the RF plasma jet. The longer heating, dissociation, and reaction times available in RF plasma jets have been shown to be able to produce the high-temperature 1-2-3 T_c phase directly. Thin, epitaxially deposited, films of the "1-2-3" high- T_c superconducting oxides were formed without the need for any postdeposition heat treatments or annealing in oxygen. The films were single crystals that exhibited none of the critical current limitations characteristic of the directly plasma sprayed materials.

Diamond Synthesis and Deposition

Several researchers have synthesized diamonds using either dc or RF thermal plasma jets (Ref 35, 36, 37) and have shown that generation of CH_3^- radicals and ionic hydrogen, which typically occurs under many plasma jet conditions, leads to the formation of diamond films. In these cases, precursor gases such as methane and hydrogen were injected into the plasma jets, where the high temperatures (>10,000 K) produced the required ionic concentrations such that on collision with a heated surface at $\sim 1000^\circ\text{C}$ amorphous carbon and diamond phases were formed. It is generally accepted that the ionic hydrogen assists in preferentially etching away the amorphous carbon phase, leaving diamond as the surface film. High growth rates (>1 $\mu\text{m}/\text{min}$) can be achieved; however, the exact morphology and bonding of the deposited diamond films varies and can be a limiting factor. A wide range of thermal plasma processing conditions with a wide range of environments have now been used to produce diamonds. The critical elements of diamond growth clearly occur in the thin, plasma-enhanced, reaction zone created immediately above the substrate surface when the thermal plasma jet impinges on the substrate surface. The precise formation mechanisms are not yet completely understood, but research is now showing that it is the thermal plasma jet conditions that are primarily responsible for producing diamonds at high rates.

Functionally Gradient Materials

Functionally gradient materials (FGMs) are a rapidly growing application area with significant promise for the future production of (a) improved materials and devices for use in applications subject to large thermal gradients, (b) lower-cost clad materials for combinations of corrosion and strength or wear resistance, and (c) perhaps improved electronic material structures for batteries, fuel cells, and thermoelectric energy conversion devices. The most immediate application for FGMs is in thermally protective claddings, where large thermal stresses could be minimized and component lifetimes improved by "tailoring" the coefficients of thermal expansion, thermal conductivity, and oxidation resistance. These FGMs could, and indeed are, finding use in turbine components, rocket nozzles, chemical reactor tubes, incinerator burner nozzles, or other critical furnace components. Figure 14 illustrates an example of a thermally sprayed FGM proposed for the protection of copper using a layered FGM ceramic structure. Successful fabrication of this would have application as improved burner nozzles, molds, and furnace walls (Ref 38).

Fig. 14 Schematic of a thermally sprayed FGM for burner nozzle applications

Thermally protective FGMs may also be used in applications where reduced weight is needed, for example in aircraft or other transportation systems, or for the thermal protection of lightweight polymeric materials using insulating materials. The economic production of graded metallic, oxide, and intermetallic structures may also enable advanced batteries, solid oxide fuel cells (SOFCs) (Ref 39), and thermoelectric devices consisting of alternating layers of semiconducting materials (FeSi_2) to be produced.

Thermally sprayed graded materials are now also being considered for the production of oxide/metal/air-type electrode/electrolyte systems. This has been proven by research and development on SOFCs and electrode developments (Ref 40) using thermal spray methods. Spray-formed battery cells promise to be both lightweight and significantly more environmentally acceptable than current lead/acid and nickel/cadmium batteries, thus opening up large potential markets in consumer, computer, and automotive electronics. These products would all use FGMs, which promises to increase performance and lower the cost. Thermal spray forming of such gradient structures has been proposed because of the unique ability this approach has of being able to deposit thin, individual layers of a wide range of materials--metals, intermetallics, and ceramics--thereby enabling layered or continuously graded structures to be produced. The forming of composite gun barrels by spraying tubular laminates and superalloy composites (Ref 41), intermetallics, and refractory metals is one example of completed work. Thick thermally sprayed coatings with graded structures are being developed for several commercial applications, including:

- The ceramic outer air seals in aircraft gas turbines and other "clearance-control" coatings in rotating machinery
- Thick, multilayer, TBCs for heavy-duty diesel engine pistons
- High-performance dielectric coatings for electronic devices
- Wear-resistant coatings for diesel engine piston rings
- Oxidation-resistant coatings for high-temperature conditions

Future growth of FGM applications will ensure that thermal, particularly plasma, spray forming will increase and develop, provided that material properties can be controlled and processing costs can be optimized.

Thermal spray forming can produce continuous gradations of metals, ceramics, and intermetallics, either in alternating stepwise layers or as microlaminates. Materials could be sprayed to replicate the mechanical behavior of a material, for example making tungsten shear locally in high-impact applications. Normally under high impact, tungsten and its alloys behave in a ductile fashion, exhibiting significant plastic deformation, or "mushrooming." When localized shear behavior is required, however, very thin, alternating layers of intermetallic materials can be deposited concurrently while spray forming the bulk tungsten alloy. Thermal spray forming thus enables microlaminate structures to be formed that can be used to locally modify the overall mechanical behavior of the system. The same approach could also be used to modify the electrical or thermal properties of a material.

Thermally sprayed gradient structures have also been proposed as strain controlled coatings and/or structures and for electrical devices, as shown schematically in Fig. 15.

Fig. 15 Other examples of thermally sprayed FGMs. (a) Multilayer coating for strain control. (b) Sprayed electrodes for SOFCs. (c) Sprayed alternating layers for thermoelectric devices

The powder production route for materials permits the production of oxides and/or brittle intermetallics that have unique electrical and thermal properties. Figure 15 shows that oxide-based fuel cells can be spray formed by depositing alternating layers of oxide and metal electrodes, and oxide electrolytes. The figure also shows the spraying of alternating layers of thermoelectric materials (FeSi₂) and the concurrent deposition of metallic electrodes. This processing combines the grading capability of thermal spray together with its ability to spray materials with widely varying melting points, thus truly realizing the advantages of thermal spray forming.

Thermal Spray Forming of Tooling

Two growing, and related, areas for thermal spray forming of materials are the direct production of solid free forms and tooling manufacture and repair.

Solid free-form fabrication has been demonstrated using a CAD model in conjunction with thermal spray deposition to fabricate free standing solid parts. Successive planar layers have been deposited using the wire arc spray process to incrementally build up three-dimensional shapes without the need for preformed mandrels (Ref 3). The wire arc spray process has also been used to replicate metallic, wooden or polymeric tool and die patterns produced using CAD/rapid part prototyping techniques such as stereolithography (SLA). Materials sprayed for this application include zinc and aluminum alloys. Zinc is particularly attractive because of its low shrinkage on solidification, but it is limited by compatibility of the final application with relatively soft tooling. More demanding applications require the spraying of tool steel, which can damage thermally sensitive polymeric SLA models. Wire arc sprayed Kirksite-type alloys as the tool surface have also been proposed (Ref 42) as a means of reducing tooling costs for many plastics molding processes, including structural foam, injection molding, compression molding, and vacuum forming. This approach is attractive for short production runs in which the cost of traditionally machined tooling can be very high. Coating thicknesses of 1.5 to 2 mm (60 to 80 mil) are typical, with reported cost savings ranging from a half to a twentieth of that of conventionally produced tooling.

A recent development in this area (Ref 43) was the unique combination of spray forming of tool steel using nitrogen as the atomizing gas with in situ shot peening to incrementally eliminate distortion due to stresses in the sprayed deposit. Tools and dies have been produced from 0.8% C steel, 13% Cr steel, M-2 tool steel, and 18/8 stainless steel using this technique.

Thermal spray forming of materials is also being used for the repair of tooling subsequently used in other metal forming processes. Air plasma sprayed (APS) coatings consisting of 70 vol% yttria-stabilized zirconia + 30 vol% CoNiCrAlY have been successfully applied to the surfaces of cast centrifugal casting molds (Ref 44). Service life was reportedly extended from 20 to 200 runs, with reduced product rejection rate.

Thermal Spray Forming of Materials

Richard Knight and Ronald W. Smith, Center for the Plasma Processing of Materials (CPPM), Drexel University, Philadelphia, PA

Conclusions

Thermal spray is a unique materials processing tool capable of processing the widest range of materials into useful forms: coatings of widely varying thickness, monolithic spray-formed materials, and spray-formed composite or graded structures. Thermal spray processing commonly uses powders as feedstock, and as described here both the form and characteristics of the starting powders play key roles in the development of the final thermally sprayed microstructure. The process heat source, combustion versus plasma, also has a significant influence on the microstructure of the coating or spray-formed deposit. The ultimate properties of sprayed materials, for example in coatings, are quantified in terms of the density/porosity, hardness, wear and/or corrosion resistance, thermal conductivity, and electrical resistivity. Key physical properties of spray-formed structures can also include coefficient of thermal expansion, tensile and creep strength, and fracture toughness. The structures of thermally sprayed materials therefore depend on the materials processing route used, including powder processing, heating rates and dwell times, particle velocity, and on the environmental exposure during processing.

Advances in thermal spray will continue to stimulate its growth as an important powder consolidation technique, especially for difficult-to-form materials. Important advances to date include:

- Emergence of the SHS route as an economical means of producing a wide range of improved composite feedstock materials for thermal spray forming
- Ever-growing knowledge and application bases for reactive plasma spray processing for synthesizing a wide range of advanced materials
- Growth of thermal spray as a method of producing a wide range of FGMs for thermal, mechanical, chemical, and electrical applications

Thermal spraying, developed just over a century ago, is now on the verge of many new and important forming applications. Thermal spray forming is now benefiting from the increased processing and materials knowledge that will allow increased use of its structures and characteristics. Further understanding of the potential for thermal spray consolidation of powders and the potential of this route for forming, however, necessitates that the influences of the processes on material microstructures be studied and understood. The last 25 years of research have been dedicated to this, and now new applications for the forming of materials for molds, dies, tooling, functionally graded structures, refractory metals, and composites are being established. The future challenges facing thermal spray are cost effectiveness, together with improved structure/property control, using highly reliable, repeatable processes. The potential is there, and many recent advances in materials and process control have ensured that industry is using thermal spray as both a coating and a forming process.

Slip Casting of Metals

R.A. Haber and C.A. Paredes, Ceramic Casting Technology Program, Rutgers University

Introduction

SLIP CASTING is a very common process for consolidating ceramic powders. It can be described as the filtration of ceramic particles suspended in a liquid, at room temperature, into a porous mold. The porous mold removes the solvent by means of either capillary forces or an external pressure, leaving the compacted piece in the mold. Figure 1 shows the critical process steps involved in slip casting of ceramics and the different parameters that must be controlled to obtain the best properties of the final product (Ref 1).

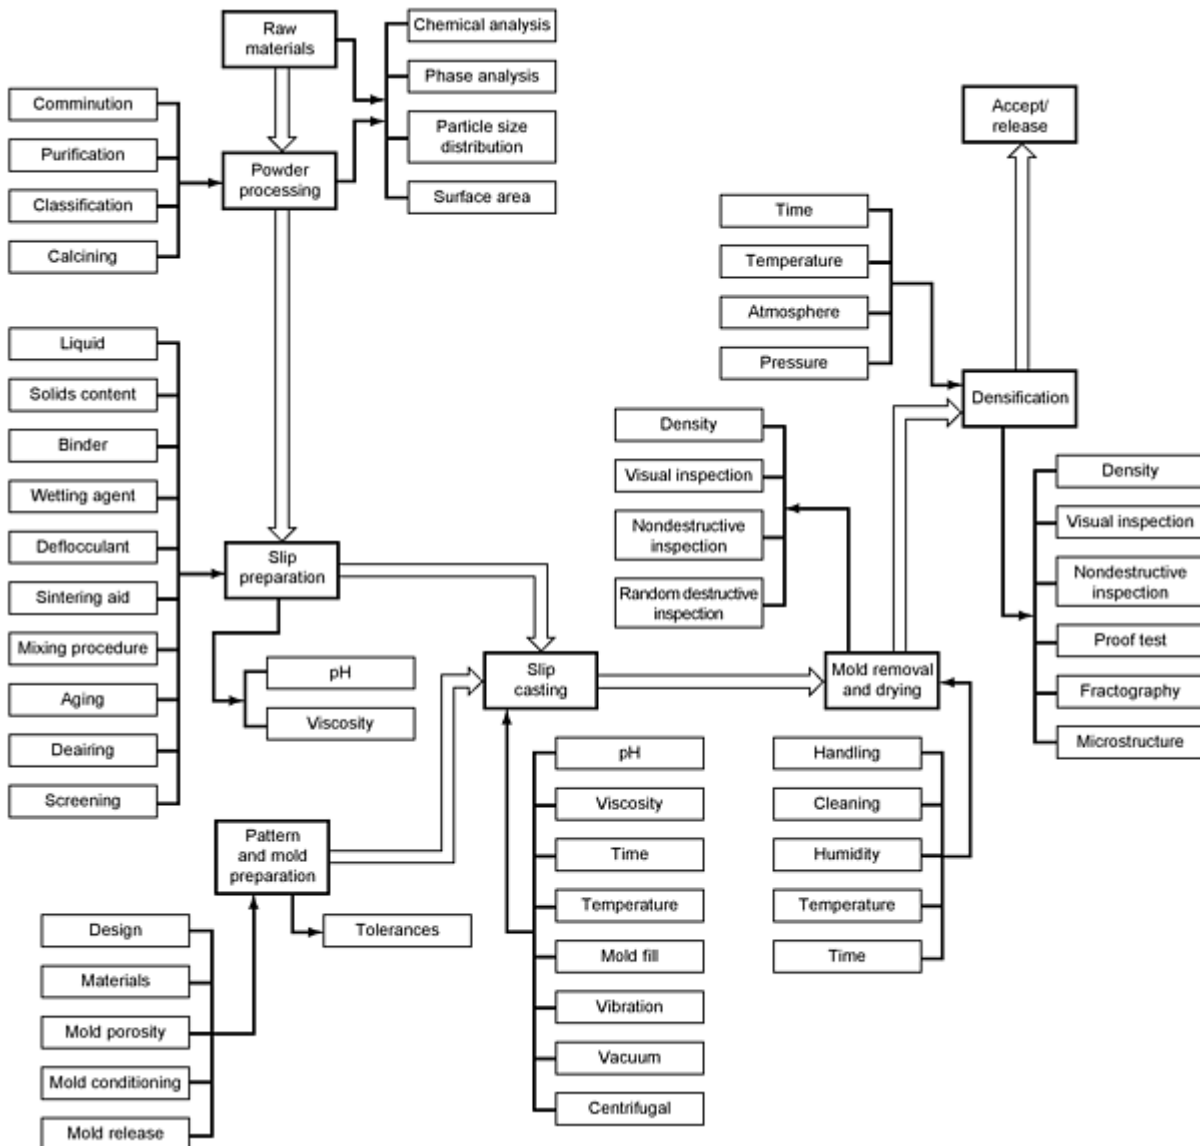

Fig. 1 Process steps in slip casting and parameters that must be controlled. Source: Ref 1

Traditionally, pressure compacting of metal powders has been used to produce metal parts. This technique presents several disadvantages. Hausner (Ref 2) lists some of these disadvantages:

- Restriction on size of parts being made due to capacity limitations of presses and relatively high die cost
- Shape restrictions of complicated pieces due to nonuniform pressure distribution in a mass of metal powders, which is caused by friction conditions prevailing during application of pressure
- Economic restrictions, because this process needs to be a relatively large-scale production due to the relatively high cost of the dies

The earliest reference to slip casting of metal powders is a German patent granted to Reichmann in 1936 (Ref 3). This method consists basically of pouring a suspension of metal powder and water into a plaster mold. The mold has the negative shape of the desired form, and it absorbs all the water from the suspension. The slip should have a low enough viscosity to enable an easy pour into the mold. The green body should be firm enough to retain its shape after stripping the piece from the mold. Figure 2 shows schematic of slip casting of metals (Ref 5). The two most common variations of slip casting are solid casting and drain casting (Fig. 3). Drain casting is a method where the slip is poured into the mold and after a determined time the slip is drained from the mold, leaving a deposited cast layer inside the mold. After some time is allowed for the piece to become rigid, the part is demolded, dried, and fired. Solid casting is similar to drain casting, but the slip is allowed to sit in the mold during dewatering, leaving the solid piece inside.

Slip Casting of Metals

R.A. Haber and C.A. Paredes, Ceramic Casting Technology Program, Rutgers University

Colloidal Stability

Because slip casting of metals is a wet process, some understanding of the interaction between the material and water must be established. Most materials when immersed in a polar solvent become charged. The different mechanisms by which the surface acquires such charge depend greatly on the type of material used. These mechanisms include ion dissolution and ion adsorption (Ref 4, 7). Ionic materials acquire their surface charge through preferential dissolution. A very well known example is AgI, where the solubility product gives the amount of soluble species Ag^+ and I^- . When an excess of I^- ions is present, the colloid is negatively charged, and vice versa. These ions are called potential-determining ions (PDI). For the case of metal oxides, hydronium and hydroxyl ions become PDIs. This process is illustrated by the next reaction:

A material can also gain surface charge by unequal adsorption of ions in the surrounding solution. If a larger quantity of positive ions is adsorbed on a particle surface, then a positive surface charge will result, and vice versa.

Electrical Double Layer. It is necessary to understand the behavior of the potential and charge distribution around the vicinity of colloidal particles. For this reason, it is very important to understand the source of the charge distribution. The electrical double layer is thought to be composed of two parts, the inner portion of the double layer and the diffuse double layer.

Helmholtz was the first to relate the electrical double layer to a metal surface (Ref 7). He assumed that the charge on the particle surface was balanced by an equal and opposite charge located near the particle surface in the surrounding solution. This theory was then modified by French and British scientists and the model was called the Gouy-Chapman model. This model is the simplest quantitative treatment for the diffuse part of the double layer. The assumptions are (Ref 4):

- The particle surface is assumed to be planar with a uniform surface charge.
- Ions of the diffuse portion of the double layer are distributed according to the Boltzmann distribution.
- The solvent is assumed to influence the double layer only by its dielectric constant.
- A symmetrical one-to-one electrolyte is assumed.

A schematic of this model for a particle medium interface is shown in Fig. 4. This model gives the mathematical function that describes the potential distribution at a distance from the particle surface:

$$\Psi = \Psi_0 \exp [-\kappa x] \quad (\text{Eq 1})$$

where Ψ is the potential at a distance x from the particle surface, Ψ_0 is the surface potential, and κ is the Debye parameter, or the inverse double layer thickness. For low surface potential, the potential can be related to the surface charge through:

$$\sigma_0 = \epsilon \kappa \Psi_0 \quad (\text{Eq 2})$$

where σ_0 is the surface charge and ϵ is the medium dielectric constant. The surface potential depends on both the surface charge density and the Debye parameter, which is in turn affected by the ionic strength of the medium. As a result, when the double layer is compressed, κ increases and both the surface charge and the surface potential are affected. Surface charge must increase and surface potential must decrease, respectively, or both can occur.

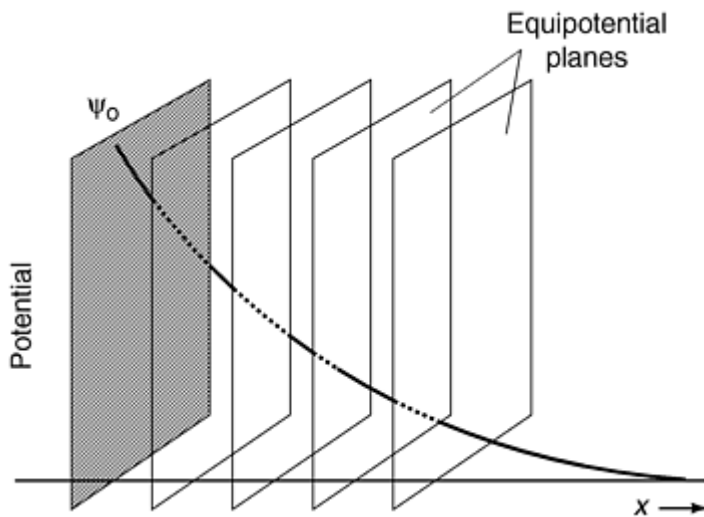

Fig. 4 Electrostatic potential distribution in parallel planes near a metal surface. Source: Ref 7

In the Gouy-Chapman treatment, the ions on the diffuse layer are considered point charges. Stern modified the double-layer theory to account for specific adsorption of ions as well as for the fact that ions have a finite size. This theory proposed a division of the double layer into two parts by a plane called the Stern plane. Ions with centers located within an ionic radius of the particle surface are in the inner part of the double layer. The ions located beyond the Stern plane are in the diffuse portion of the double layer, where the Gouy-Chapman treatment is considered to be applicable. The potential changes from Ψ_0 to Ψ_d . Figure 5 shows schematic of Stern's representation of the electrical double layer.

Fig. 5 Representation of Stern's electrical double layer. Source: Ref 4

In the presence of specific adsorption, either co-ion or counter-ion adsorption can occur. The Stern potential is either reduced or reversed with respect to the surface potential, as shown in Fig. 6. The Stern potential can be determined by electrokinetic measurements. Electrokinetic behavior depends on the potential at the surface of shear between the charged surface and the electrolyte solution (Ref 4). This potential is called the zeta potential [ζ]. The exact location of the shear surface is unknown, but it is accepted that it is located very close to the Stern plane. Therefore, it is usual to assume identity between Ψ_d and ζ . The zeta potential is a property that can be readily measured, while the Stern potential cannot. For this reason, zeta potential values are used in determining material surface properties.

DVLO Theory. The stability of colloidal-sized particles depends essentially on the balance of attractive and repulsive forces surrounding the suspended particle. A quantitative theory enabling determination of stability was developed independently by Deryagin and Landau and Verwey and Overbeek and is called the DVLO theory. According to this theory, the total interaction between particles is the sum of two contributions, V_R , the repulsive part due to the overlapping of double layers, and V_A , the attractive portion resulting from Van der Waals attraction (Ref 4, 7, 8):

$$V_T = V_A + V_R \quad \text{(Eq 3)}$$

Figure 7 shows total interaction energy curves. The repulsive forces are an exponential function that is effective on the range of the double layer. It is positive for all values of distances between the two particles. The attractive forces, on the other hand, decrease as the inverse power of the distance between the particles. At very small distances, the attractive potential becomes very negative, forming the potential energy well described as the primary minimum. When particles lie at this distance, they typically form very strong aggregates that cannot be broken up under normal shear conditions. As the distance between these particles increases, the repulsive forces start taking over and a maximum energy barrier results. The magnitude of this barrier depends on the concentration of electrolyte present. A secondary minimum develops at large separation distances between particles. The attractive forces dominate at this distance, leading to a potential well. In order for flocculation of particles to occur, the energy barrier between particles should be either very small or very big. One way in which an energy barrier may be reduced is the presence of a significant amount of electrolyte that will cause a compression of the electrostatic double layer between particles and allow for Van der Waals forces to dominate between particles. A more detailed review of this theory can be found in Ref 4 and 7.

Slip Casting of Metals

R.A. Haber and C.A. Paredes, Ceramic Casting Technology Program, Rutgers University

Process Considerations: Slip Control

There are variables that should be monitored and controlled at all times to prevent agglomeration of the particles as well as settling. Some of these variables are:

- Water-to-powder ratio (solids loading)
- Type and amount of deflocculant
- Viscosity of the slip
- pH of the slip
- Surface chemistry of the metal particles
- Temperature of the slip

- Particle size distribution

All these factors have a direct effect on the stability of the suspension. The ratio of densities of the metal particles to the fluid affects the nature of the suspension. As this ratio increases, the nonuniform settling rate of the metal particles starts taking place. The various sizes and shapes of the particles also affects the stability of the slip. These settling forces can be balanced by using powders of small and fairly uniform particle size and by increasing the viscosity of the suspension. The use of finer particles has a further advantage because their high surface-area-to-volume ratio causes them to sinter faster.

Two very important processing variables in preventing flocculation mentioned above are viscosity and pH of the suspension. Tamura (Ref 9) reported that slip casting MoSi₂-base heating elements was best achieved using a water-to-metal ratio of 0.180, pH 4.05, and a viscosity range of 1000 to 1800 cp. In 1939, Hauser and Hirshon (Ref 10) suggested that the charge on the particles might originate as a result of either dissociation of different ions for the particle surface or by preferential adsorption of ions from the surrounding medium of the particles. In either case, the charges in the metal surfaces are balanced by counter-ions, which form a double layer. Jones (Ref 11) proposed the mechanism by which the metal particles repel each other. He proposed a formation of either an oxide film or an adsorbed film in the metal surface. The development of either film can be controlled by pH adjustment. Figure 8 shows how viscosity decreases when pH increases up to a minimum value, after which the viscosity starts increasing again. St. Pierre (Ref 12) showed this curve using molybdenum powder suspended in 5% aqueous polyvinyl alcohol solution.

Fig. 8 pH-viscosity relations for a fine molybdenum powder suspended in 5% polyvinyl alcohol solution. Source: Ref 12

Deflocculants are chemical additives used to control the flow properties of casting slips. In ceramics, common deflocculants are sodium silicate, sodium carbonate, and lately polyacrylates. For dispersing nonclay slips, strong acids or strong bases are often used. There is a strong correlation between the water-to-metal ratio and the amount of the deflocculant in the slip (Ref 5). An increase of solids loading requires an increase in the amount of deflocculant necessary to maintain the pH and viscosity. Lidman and Rubino (Ref 13, 14) presented two papers on slip casting of stainless steel powder. The slip was prepared using ammonium alginate for bonding the powder particles, polyvinyl alcohol for elasticity, and water for fluidity. Rempes et al. (Ref 15) conducted slip casting experiments using different powder materials, metals, ceramics, and cermets. They found that for slip casting chromium and stainless steel 302 a combination of a sodium salt of alginic acid (Keltex of Kelco Co., used as a suspension agent and binder) and an acrylic acid polymer (Carbopol 934, Goodrich Chemical Co.) deflocculants was required. For the case of titanium and molybdenum, only a solution of Keltex was necessary to achieve slip stability.

Slip Casting of Metals

R.A. Haber and C.A. Paredes, Ceramic Casting Technology Program, Rutgers University

Mold Control

The main components of the slip casting process are the slip and the mold. Both components play an important part in the production of pieces. Slip casting is a filtration process in which the mold serves as the filter and also is the driving force for filtration. Plaster mold properties are extremely important to the overall casting system. The ideal mold material is one that is inexpensive and can reproduce intricate detail, remain dimensionally stable, and provide good dewatering capacity indefinitely. Gypsum has proven to be the best material for these needs. Norton (Ref 16) lists why gypsum plaster is the best mold material:

- Fine detail may be reproduced.
- The mold is stable chemically and physically.
- The absorption can be varied over wide limits for any desired use. The porosity allows release of the clay.
- A smooth, durable surface can be readily formed.
- Uniform physical and chemical properties can be maintained.
- The pores are not easily sealed by colloids.

- The cost is moderate.

Plaster Production. Gypsum is found in many parts of the world, typically in deposits of marine origin. It is the most valuable and widely used form of calcium sulfate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$). Partially dehydrating gypsum results in the two forms of hemihydrate gypsum, α and β . Both forms are widely used in the production of molds for slip casting because of their ability to rehydrate and form rigid porous molds. Molds made from the α hemihydrate-derived molds are known for high strength, while the β hemihydrates are known for their excellent absorptive power. The primary difference between the two materials is the hemihydrate crystal morphology, as controlled by the calcination process. Table 1 summarizes the known forms of calcium sulfate.

Table 1 Forms of calcium sulfate

Material	Formula	Preparation
Dihydrate	$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	Naturally occurring gypsum rock
α-hemihydrate	$\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$	By dehydrating in saturated steam
β-hemihydrate	$\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$	By dehydrating in dry atmosphere
$\alpha\beta$-soluble anhydrite	CaSO_4	By dehydrating α -hemihydrate
β-soluble anhydrite	CaSO_4	By dehydrating β -hemihydrate
Insoluble anhydrite	CaSO_4	By high-temperature processing

Source: Ref 16

Plaster Setting. The set rate of plaster is important because it can affect the compressive strength of the mold and in turn its durability. The basic driving force for the setting of plaster is the room-temperature solubility difference between hemihydrates and gypsum. The hemihydrate is far more soluble than gypsum. As it comes in contact with water, it dissolves to reach its solubility equilibrium. Simultaneously, gypsum precipitates because its solubility limit is exceeded by a considerable amount (Ref 17). There are two mechanisms regarding the initiation of gypsum crystallization being argued: the growth from colloidal gypsum present due to supersaturation or the growth from gypsum crystal nuclei present as an impurity (Ref 18 and 19). Though only 18.6 g of water per 100 g of hemihydrate is required for hydration from hemihydrate to gypsum, excess water is added to afford fluidity of the suspension. The excess water creates the porosity present after drying. Concentrated suspensions set to form hard masses due to the interlocking of the growing crystals.

Setting expansions are caused by crystal growth, which actually exerts pressure on container walls. The growth of needlelike crystals forms a network where crystals lie against one another, transferring force and displacement throughout the setting mass.

The set time can be affected by different factors such as plaster-to-water ratio and temperature of the plaster/water mixture or through use of set accelerators and retardants. It is clear that control of all these parameters is important for maintaining consistent plaster properties on set time and the resulting microstructural dependence.

Plaster Mold Production. Once the ideal mold properties are obtained, they are only reproducible through accurate control of mold production procedures. Often these procedures are overlooked.

The term consistency is commonly used for the water-to-plaster ratio, or number of grams to 100 g of plaster. It is probably the single most powerful means of adjusting plaster properties. Nearly all the properties that this variable controls can be fine-tuned by proper preparation procedures. Figure 9 shows a plot of strength, density, and total absorption as a function of consistency (Ref 20).

Fig. 9 Variation of strength, density, and total absorption as a function of consistency. Source: Ref 20

Mold durability in casting is influenced by the overall strength of the mold (Ref 21). For this reason, the mold used is one having the maximum strength allowable concurrent with good permeability and capillarity.

Foaming of the plaster slurry decreases the density of the mold while maintaining reasonable strength. Adjustment in particle size of the plaster or by mixing the α and β hemihydrates can result in a stronger mold material.

Mixing of the plaster slurry can be considered the most crucial step in mold production. The reaction of hydration is dependent on solubility, the number of seed crystals, and energy, due to the exothermic nature of the reaction. Vigorous mixing can accelerate solubility equilibrium. Breaking of the dissolving crystals during mixing can increase the hemihydrate surface area, helping also the attainment of the solubility equilibrium. Breaking of gypsum crystals increases the number of nucleation sites and, therefore, the hydration rate. Excessive mix energy can increase the temperature and initiate the related effects.

There are many other factors that should be considered very carefully to obtain the best properties for the plaster mold. Mixing time has an inverse effect on the compressive strength and water absorption rates--the longer the mixing time, the higher the rates. Aging of calcined plaster during storage can also alter the water demand, set time, and appropriate mixing requirements for a given plaster batch (Ref 22). While in storage, the character of the hemihydrate may change to gypsum, affecting the total hydration and the number of nucleation sites. A humid environment may also serve to fuse hemihydrate crystals, lowering crystal disintegration, surface area, and solubility, thereby reducing water demand and set rate.

The drying of plaster molds is very important in the efficient production of pieces by the slip casting process. The ideal mold moisture for casting is between 8 and 17%. A mold that is too dry will cast quickly at first, forming a dense layer that slows further casting. A mold that is too wet will lead to a slow cast and poor dewatering shrinkage, which complicates demolding (Ref 21). Moisture distribution is also important, so the mold must be allowed to equilibrate between casts to prevent moisture concentration at the casting surface, giving a very slow second cast.

Slip Casting of Metals

R.A. Haber and C.A. Paredes, Ceramic Casting Technology Program, Rutgers University

Mechanics of Filtration

Cake filtration involves the separation of fine solid particles from liquid in which they are dispersed by collecting the solid particles on a surface of a medium that is permeable only to the liquid. In slip casting, the filter medium is either a gypsum or synthetic mold. As the casting process continues, additional particles are collected on the surface of the initial layer of solids, thereby building up a cake. At any instant of time during the casting of a cake, the liquid will flow through the previously deposited solid layers.

The driving force for slip casting in plaster is the capillarity of the mold. The opposing force in the system is the resistance of both the mold and the cake to the flow of water. Permeability is the inverse of the resistance.

Plaster molds absorb water according to the parabolic rate law where the rate of absorption decreases linearly with the square root of time. Assuming a constant driving force, the decreasing rate is caused by the increasing volume of the mold that is being penetrated, thus contributing to the resistance. This balance of forces in the mold leads to an increase in absorptive rate with increasing porosity. The decrease in mold resistance outweighs the decrease in capillary suction (Ref 23).

Addition of a cake to the system yields a more complex relationship where the absorptive rate is inevitably decreased dramatically. There is a new balance between the one driving force and two resisting forces.

Mold and Cast Cake Permeability. Though the mold and cake are both permeable, the permeability values are low enough to serve as the resistance to capillary suction of the mold. Deeg first modeled slip casting as a diffusional process, and later it was more correctly described by Deen as a filtration process (Ref 24).

Flow through a porous material was first quantified and described by D'Arcy, who noted that the rate of liquid flow through a sand bed was proportional to the pressure gradient across the bed. Kozeny then related the flow rate per unit area to the viscosity, porosity, and internal surface area of the porous medium. Carman combined these analyses and related the properties to the permeability (Ref 25, 26). Adcock and McDowall (Ref 27) bridge the gap between ceramics and this area of fluid mechanics. Ceramists now use the Adcock and McDowall equation for permeability:

$$K = \frac{\eta \, dv/dt \, L}{PA} \quad (\text{Eq 4})$$

where dv/dt is the volumetric flow of the filtrate having a viscosity η , as forced through a bed of thickness L and area A , by the pressure gradient P .

The permeability equation is commonly used to calculate the permeability of the cast cake, and more recently the plaster mold. Dal and Berden incorporated the permeability of the plaster into D'Arcy's equation:

$$\frac{dv}{dt} = \frac{PA}{\eta[(L_c/K_c) + (L_m/K_m)]} \quad (\text{Eq 5})$$

where the subscript c stands for the cake and m for the mold. Now it is apparent that the volumetric flow is dependent on both permeabilities, as a pair of resistance in series (Ref 24).

The casting rate is dependent on both the volumetric flow rate and the total porosity of both the cake and mold. A mold of low porosity will have the highest penetration distance of the waterfront, representing the effective thickness, L . Consequently, the greater effective filter thickness and the lower permeability as dictated by the lower porosity will reduce the rate of fluid flow. The casting rate and cake permeability are similarly dependent on the void fraction of the cake.

Slip Casting of Metals

R.A. Haber and C.A. Paredes, Ceramic Casting Technology Program, Rutgers University

Pressure Casting

Pressure casting is rapidly being implemented in the production of different components. The need for shorter casting times, reduced costs, and improved physical properties of the cast has contributed to its development. However the level of science and fundamental knowledge is still quite limited. Most of the factories run a pressure casting machine at the suggested pressures and cycle times specified by the supplier of the equipment. Little variation is usually done in either the cycle time, ramping rate, and pressure levels.

Basically, pressure casting refers to the application of pressure to the slip to increase the casting rate. Originally, plaster molds were used for this purpose, but because of its lack of strength and limitation of the applied pressures, porous plastic molds are used now. Development of these molds allowed the pressure to be increased tenfold. Blanchard (Ref 28) reported results for different bodies for a 6 mm thick compact. He observed a decrease in time from 45 to 15 min by increasing the pressure from 0.025 to 0.4 MPa for a porcelain formulation.

There are two types of pressure casting systems: medium pressure (0.3 to 0.4 MPa) and high pressure (up to 4 MPa). Pressure casting is currently being used in different applications such as in sanitaryware in the case of medium-pressure systems and dinnerware in the case of high-pressure systems.

There are several advantages of pressure casting over slip casting. Complex shapes become easier to cast with applied pressure because the quality of the greenware is improved and the fluctuations reduced. The filtration rate of plaster molds used for slip casting is slow, thus requiring a large number of molds and available space. The casting cycle using pressure casting is shorter, reducing labor costs and improving productivity.

Powder Metallurgy Methods for Rapid Prototyping

Introduction

DIRECT FABRICATION is a manufacturing innovation whereby engineers integrate design and manufacturing operations for structural materials via computer software to fabricate components in an automated fashion. Several techniques are under development, and their use for rapid prototyping (RP) can eliminate the need for costly redesign after a part has gone into full-scale production. Traditional prototyping can itself be costly and time consuming, often delaying product introduction. Rapid prototyping technologies were developed in response to increasing competitive pressures to bring quality products to market quickly. A key element in any RP process is the use of sophisticated computer codes used to generate computer numerical control (CNC) motion and process control data from "slices" taken from solid models.

The following section in this article summarizes the principal RP methods. Later sections provide more detailed information about the following P/M RP methods: soft tooling, low-pressure molding, selective laser sintering, and laser-based direct fabrication.

Powder Metallurgy Methods for Rapid Prototyping

Rapid Prototyping Methods

Leander F. Pease III, Powder-Tech Associates, Inc.

If every designer had immediate access to the required raw material, computer-controlled machining centers, and the facilities for heat treating and finishing parts, the prototype process would already be irreducibly short. It is the real-world lack of immediate access to raw material and machining that has inspired the search for desktop manufacturing (DTM). In its most elegant form, the engineer's CAD system drives a clean, quiet machine in the corner of the office to produce the required prototype part the same day, and, for some classes of plastic materials, this kind of system is in use today. A laser system traces out the part in a bath of photocurable plastic. In the past, it was not common practice to machine a plastic prototype part from a monolithic block. Rather, the usual procedure was to build tooling and then injection mold the part, a process that could take up to 12 weeks.

The rapid development of laser-processed plastic prototypes has inspired the search for a similar system to work with metals. The output of such a system might be fully dense parts to simulate the product of ingot metallurgy, or it might be less than fully dense materials that simulate P/M components. Whatever the system, it must offer advantages over the current machining methods. Such advantages can be in saving development time or reducing machining costs. It is important to understand the current methods used in P/M part prototyping so as to be able to assess the real value of the developments in DTM.

Powder Metallurgy Methods for Rapid Prototyping

Powder Metallurgy Prototypes

Powder metallurgy prototypes are now produced either by building hard tooling and making limited runs of parts or by machining the prototypes from monolithic blocks of the required sintered materials (Ref 1). The hard tooling route requires 4 to 12 weeks, a few thousand dollars worth of tooling, and then the use of valuable production press time to make the parts. If the design must then be changed, the whole process must be repeated. Alternatively, blocks of the required P/M materials are readily available from P/M parts producers. Such prototype materials are produced in all the alloy designations found in MPIF Standard 35, ASTM B 783 or ISO 5755, using powders in inventory. They are available in two days to two weeks. The P/M blocks have the same density and mechanical and physical properties as the materials listed in the standards. Just as in the case of ingot-based metals, the P/M materials are then fashioned into prototype parts on machining centers or by wire electrical discharge machining. The parts have the required tolerances and surface finish. Heat treating is performed subsequent to the machining. The time required for the machining operation depends on the facilities at hand: a captive model shop may be available, or an outside custom machine shop used. The times range from a few days to a few weeks.

Realistically, the new rapid-prototyping systems must compete with the existing P/M methods. This means that in some cases, the machined P/M prototypes will be available in as little as 1 week, and they will meet the drawing requirements for material properties, dimensions, and surface finish. Figure 1 shows an actuator insert electrical discharge machined and further machined from a simple block of P/M material such as those shown in Fig. 2. In one version of the insert, the 32 teeth were wire electrical discharge machined at a cost of \$192. In a second version, the teeth were ground, requiring 1.5 h.

Soft Tooling. The fabrication of conventional tool steel molds for metal injection usually requires 10 to 12 weeks. The use of soft tooling allows limited numbers of metal-injection molded (MIM) parts in only 1 to 2 weeks. Soft tools are constructed of cross-linked polymers such as epoxy resin for rigid tooling and silicone for resilient tools. The rigid materials withstand metal/binder injection at a few thousand pounds per square inch while the silicone tools are used for low-pressure molding.

To create a rigid tool, a model of the proposed part is first machined. The part is covered in a parting agent and cast in epoxy resin. The resin may be reinforced with fillers. The model must have a parting line film or sheet attached, so as to create the two halves of the mold. Prior to curing, the epoxy is de-aired by vacuum. After curing, the model is removed from the two mold halves. The molds can be used in the MIM process to make 10 to 1000 pieces.

Soft tooling also refers to tooling machined from aluminum, which can run up to 50,000 pieces at normal injection molding pressures. Such tools can be made in 2 to 4 weeks.

Ink-Jet Technology. In this process, an ink-jet printer (Ref 2) deposits 80 μm droplets of liquid acrylic copolymer binder onto a bed of metal powder. At each pass of the print head, a bonded path 175 μm (0.007 in.) wide and 75 μm (0.007 in.) deep is created. The printer follows computer-generated instructions to construct a part layer by layer. After one layer is bonded, the powder bed is lowered and a new 175 μm (0.007 in.) layer of powder is rolled into place. This layer is then bonded to the layer below, gradually building a three-dimensional object.

In making injection molding tooling, internal water passages are created that conform well to the shape of the cavity. Such carefully placed water passages provide optimal cooling during MIM and result in faster cycle times and less residual stress in the molded part. There are no ingot-based metallurgical or machining techniques that can create arbitrary cooling passages inside an object.

When the object is complete, it is removed from the bed and the loose powder blown off and collected. The powder inside the cooling passages is removed by water immersion of the green part. The part is then heated at 100 °C (212 °F) to cure the acrylic and strengthen the structure. The acrylic is removed in a thermal debinding step, and the part is then easily handled.

In an example with 60 μm (0.002 in.) stainless steel powder, the debound part is placed on a stainless steel substrate, which in turn rests on zirconia pellets in an alumina crucible. A piece of 90/10 Cu/Sn bronze is placed on the substrate adjacent to the porous part. In a furnace containing argon + 5% H₂, the temperature is raised to 980 °C (1795 °F). The bronze melts, wicks along the stainless substrate, and enters the side of the porous part. This continues until the bronze fills all the pores by capillary action. The zirconia pellets keep the stainless steel substrate from being brazed to the alumina crucible. The stainless substrate is machined off the bottom of the fully dense mold. The cores and cavities are then machined and polished as necessary.

Other materials produced in the same fashion include iron, stainless steel, tungsten, tungsten-nickel, tungsten carbide, and tungsten carbide cobalt. It is possible to locally alloy a part by depositing fine metal powders along with the acrylic binders. The fine powders then diffuse into the base metal during the sintering cycle. In terms of capital cost, thermal printers are much less expensive than lasers. One can imagine a whole room full of printers constituting a small factory for low-volume production runs.

Selective laser sintering (SLS) was developed by DTM of Austin, TX (Ref 3) and uses laser energy to transform metal powders into useful tooling and parts. A CAD model of the part is numerically transformed into thin slices. Loose, polymer-coated 55 μm (0.002 in.) metal powder is laser fused into the required shape, as it traces out the area of the computer-generated slice. The workstation lowers this fused layer by 75 to 250 μm (0.003 to 0.10 in.), and a new layer of powder is rolled into place, atop the fused layer. Laser fusing of this second layer bonds the particles to each other and to the layer below. In this way, a part is built up, layer by layer. Molds 15 by 25 cm (6 by 10 in.) by a few inches thick have been produced by this method.

After the fusing step, the part has a green strength of about 2.7 MPa (400 psi) and requires care in handling. The unfused powder falls away from the fused part and is recycled. The fused green part is impregnated with acrylic resin containing a cross-linking polymer and then dried at 50 °C (112 °F). The dried part is placed on an alumina plate in a graphite crucible, and the porous preform is infiltrated with molten copper, in an atmosphere-controlled furnace. The furnace then returns to room temperature, and the assembly is removed.

The infiltrated part contains about 60% Fe, 39% Cu, and 0.8% C. During infiltration, the part shrinks 2.5% linearly, and this is compensated at the initial part design. The infiltrated parts have a tolerance of ± 0.25 mm (± 0.010 in.) over distances of 13 cm (5 in.).

In all, the process takes about 5 days and results in a mold that is ready for plastic injection molding or metal injection molding. Such a mold can produce 50,000 plastic parts. The main use for SLS via the DTM process is making tooling for the injection molding of plastics. The infiltrated material so produced does not conform to MPIF Standard 35 and so could not be used in functional prototypes.

In principle, other alloy steels could be SLS to form 60% dense preforms that could then be sintered and shrunk to the correct density to serve as P/M prototype parts. This would involve linear shrinkages of 7 to 10% with difficulties in maintaining tolerances. In general, parts sintered to such a degree would not have the same mechanical properties as the standardized P/M grades.

Direct Laser Sintering (Laser Free-Form Fabrication). A method has been devised to directly laser sinter metal powders and intermetallic compounds, without the use of a polymeric binder film (Ref 4). They use a three-axis machine to aim both a fiber-optically guided Nd-YAG laser beam and a stream of metal powder at a substrate as shown in Fig. 3. The laser is under computer control to develop the part as a series of layers. The powder falls into the focal zone of the laser where it sinters to itself and to the underlying layer. This is done in an atmosphere of argon with < 5 ppm oxygen.

The original machine creates $2\frac{1}{2}$ dimensional parts in an envelope of 9.5 by 9.5 by 38 mm ($\frac{3}{8}$ by $\frac{3}{8}$ by 1.5 in.) high. These are thin-walled parts 1.5 to 3.2 mm (0.060 to 0.125 in.) wall. The minimum wall thickness is 0.8 mm (0.030 in.). Powder is deposited at a rate of 2 g/min with a 2 kW laser. The powder can be formed into a fully dense object or into one that has controlled porosity. Parts with residual porosity showed particle boundaries, and their mechanical properties are not yet known. A new five-axis machine makes parts within a working envelope of 60 by 60 by 60 cm (24 by 24 by 24 in.). It deposits powder at the rate of 10 to 20 g/min. The powders cool at 100 K/s (180 °F/s) in rod forms and 10,000 K/s (18,000 °F/s) in flat plate forms.

Fig. 3 Laser-sintering apparatus. Courtesy of G. Lewis, Los Alamos National Laboratory

The process is a near-net-shape process with tolerances of $\pm 0.25 \mu\text{m}$ (± 0.010 in.). The first layer of the part sinters to a base plate, which must later be machined off. Thick-walled parts are harder to make because of the longer time needed to make a massive part. Also, it is hard to form sharp corners on thick-walled parts. To a degree, this problem is addressed by the five-axis machine, which can be angled, and is able to make special finishing passes and overhangs. The usual powder is -100 down to -325 mesh, but $10 \mu\text{m}$ (0.0004 in.) powders give better surface finish. Powders processed to date include P20 tool steel, 316 and 410 stainless steels, tungsten, MoSi_2 , and NiAl. No work has been done on low-alloy steels. The carbon must be in solution in the steel, or the laser beam will vaporize it. This suggests that only special prealloyed steel powders with carbon in solution will be used. The excess powder can be recycled and reused. A laser can be used to form powder directly into a part, as shown in Fig. 4. This work (Ref 5) has resulted in usable tool steel molds.

Fig. 4 Laser-sintering apparatus. Courtesy of D. Keicher, Sandia National Laboratory

Free-form laser-sintering work is being researched in order to develop a way to laser sinter titanium alloy powders into the 150 kg (330 lb) bulkheads for F16 aircraft. The starting powder is Hunter-Kroll unpurified sponge titanium fines at -40/+100 mesh and vanadium-aluminum master alloy. The powders are in a bed fluidized by argon with <15 ppm oxygen. The original chamber is 0.3 by 0.3 by 0.3 m (1 by 1 by 1 ft) and is for concept demonstration. Laser-sintered titanium samples that weighed about 454 g (1 lb) were produced to determine mechanical properties.

The laser is 7 kW with a spot size of 12 mm ($\frac{1}{2}$ in.). This results in the melting of the titanium and the alloying of the vanadium and aluminum master alloy. The melting tends to create a flat surface. At the same time, with one or two passes, any residual chlorine or sodium in the Hunter-Kroll fines is evaporated. Kroll fines, which are made by reducing $TiCl_4$ with Mg, are undesirable as a feedstock because residual Mg salts have been observed in the pores of laser deposited material. Hydrogen levels are low, but can be further reduced by vacuum annealing after laser forming. The first layer is attached to a striking plate, and the object is built up layer by layer. The fluidized bed allows one layer to be submerged in the bed, in preparation for the next layer to be sintered. The final object is usually machined 3 mm ($\frac{1}{8}$ in.) on each surface. The striking plate tends to warp about 3 mm ($\frac{1}{8}$ in.) in 100 mm (4 in.). Because the object is almost, but not completely, pore-free the part is subsequently hot isostatically pressed without a can or forged to full density.

The second-generation machine has a working area of 3 by 3 m (10 by 10 ft), and a bed depth of 1 m (3 ft). A 14 kW laser rides on a gantry. This allows the manufacture of an F16 bulkhead that is 3 by 1 by 0.1 m (9 by 3 ft by 3 in.) thick. A finished bulkhead weighs about 150 kg (330 lb). The laser covers 45 cm² (7 in.²) to a depth of 1 mm (0.040 in.) in 1 min. This is 4.6 cm³/min (0.28 in.³/min), and for titanium at 4.5 g/cm³, 20.6 g/min (0.05 lb/min).

Table 1 summarizes the capabilities of several free-form fabrication processes in terms of tolerance, size, and speed. Current applications of laser-sintered metal powders are injection molding tools. Expected applications include laser-sintered titanium alloy bulkheads, tooling, prototype parts, and one-of-a-kind or short runs. A shipboard manufacturing center that will use computer-stored information on part geometry to laser sinter and manufacture replacement parts while at sea is also expected as well as other, similar objectives. Laser sintering could fabricate some interesting composite materials and might be a production manufacturing method rather than just the prototype method. One example might be intermetallic valves for automotive engines.

Table 1 Comparison of P/M-based rapid-prototype/DTM processes

Tolerances ^(a)		Surface finish		Size		Deposition rate		Materials	Ref
μm	in.	μm	in.	cm	in.	mm ³ /h	in. ³ /h		
± 50 X-Y and ± 375 Z	± 0.002 X- Y and ± 0.015 Z	4 RMS	0.00016 RMS	7.5 × 10 × 15	3 × 4 × 6	16	1	Full density	5

RMS, root mean square.

(a) For dimensions up to about 15 cm (6 in.)

It seems likely that laser free-form fabrication using metal powders will provide a rapid progression from design to prototype parts. The process readily makes fully dense objects. It must be determined if the tolerances so produced are adequate for fit and function tests, or whether additional machining will be needed. In some cases the machining might be minimal, but in other cases it might be more cost effective to start with a simple block of material and machine it all over. The laser-formed materials will have advantages when working with expensive or difficult-to-machine raw materials.

For less than fully dense P/M prototypes, of the type covered by MPIF Standard 35, the utility of the laser free-form fabrication process is yet to be determined. In addition to competing with the tolerances and surface finish of parts machined from simple blanks, there is the difficulty of matching the physical and mechanical properties of P/M parts. Many P/M materials are essentially composites, rather than homogeneous alloys, for example, nickel steels and diffusion alloys. The most common P/M material is FC-0208, iron + 2% Cu + 0.8% combined C. Laser sintering does not work well with loose graphite, so special prealloyed Fe-0.8% steels would have to be produced. The copper could not be prealloyed because normal P/M sintering practice does not diffuse copper to the center of the iron particles.

Low-pressure molding (LPM) is done at <0.7 MPa (<100 psi), usually in soft tools. To obtain a low viscosity that will pour into tooling, the mixtures are prepared under conditions of low shear rate, which lowers viscosity by tenfold. The mixtures solidify in the molds, and after removal, parts are thermally debound and then sintered. There are two classes of binder materials: dilute polymer solutions and polymerizable systems.

Dilute polymers consists of 0.5 to 5.0% aqueous solutions of polysaccharides, vinyl polymers, waxes, alginates, and so forth. The mixtures are poured into porous molds and dried at room temperature (slip casting). As dried, the parts are already 99% debound, and the remaining binder is removed thermally at 500 °C (932 °F) in protective atmosphere. In one example, stainless steel is sintered to 96% of the pore-free density. In another dilute polymer method, Quickset (Ref 8), the mixture of powder and dilute polymer is frozen. The water is then removed by sublimation. The binder comes out during vacuum sintering.

An example of a polymerizable system is furfuryl alcohol and powder. It is poured into the mold, and heat and catalysts are applied. In 1 to 5 min, it cross links and hardens. The water is expelled as gas, leaving a porous skeleton that later allows for the removal of the rest of the binder, at 400 to 500 °C (752 to 932 °F). In a variant called gelcasting, 10 to 20% acrylamide in water is mixed with metal powder. The mixture is poured into soft tools and allowed to gel for 10 to 60 min. After removal of the part, it is dried for a few hours. It is debound at 350 to 500 °C (662 to 932 °F). After high-temperature sintering and substantial shrinkage, 17-4 PH steel reached 7.5 g/cm³.

Soft Tooling

S.V. Atre and J.A. Thomas, The Pennsylvania State University

Soft tooling is a general term that is used to describe molds fabricated from polymers. The principle utilizes the low viscosity of polymer precursors to accurately form the reverse pattern of a given desired shape. The solidified reverse pattern can then be used to replicate the original shape many times.

The development of soft tooling gained impetus as a consequence of the material and labor shortages during World War II. However, its widespread acceptance has only occurred more recently as the economic benefits of reduced lead times from "art to part" have become apparent. This increased awareness has coerced dramatic changes in the field, to the extent that physical reverse patterns can now be directly created from virtual desired shapes stored in a computer. To date, the development of soft tooling can be attributed to traditional manufacturing techniques such as injection molding and thermoforming for plastics, sheet metal forming for metals, and hand lay-up for composites (Ref 9). The current accelerated growth of binder-assisted P/M forming techniques has made it crucial for the parts manufacturer to take advantage of the quickly fabricated, low-cost, lightweight tooling obtained from polymers. This section outlines the materials, methods, attributes, and applications of soft tooling.

Soft-tooling materials are usually cross-linked polymers (Ref 10). They can be categorized on the basis of the consistency of their final structure under two classes: rigid and resilient materials.

Rigid materials include thermosetting resins such as epoxies, polyesters, phenolics, and polyurethanes. Epoxy resin is the most common resin used for constructing rigid molds. The mold is shown in Fig. 5. It is used for fabricating M2 tool steel parts by MIM.

Fig. 5 A rigid mold fabricated from filled epoxy for the production of M2 tool steel parts. Courtesy of J.A. Thomas and A. Griffo, The Pennsylvania State University

Resilient materials include thermosetting resins such as silicones, polysulfides, polyurethanes, and polyureas, as well as aqueous network structures such as biopolymer gels based on agar or gelatin. Silicone is the most commonly used class of materials for constructing resilient molds. The mold is shown in Fig. 6. It is used for fabricating 316L stainless steel watch cases by LPM.

Fig. 6 A flexible mold fabricated from RTV silicone. Clockwise from bottom left: master model, top half of mold, bottom half of mold and green part, final part after debinding and sintering. Courtesy of C.D. Turner, The Pennsylvania State University

The mechanical properties and tooling performance of the polymers are dependent on their physical and chemical structure as well as fabrication conditions. As a result, considerable property variations occur even within a given class of polymers. Resin manufacturers usually provide detailed information on the properties of the polymers to aid the tooling engineers in the selection of the correct material for their application. The hardness of the common resins used in soft tooling (Ref 9, 11, 12) and metals (Ref 12, 13) used in traditional "hard" tooling are given in Table 2. The much lower hardness observed for polymers is the rationale behind the use of the term "soft" tooling.

Table 2 Materials used in fabricating molds, arranged in order of decreasing surface hardness

Material	Surface hardness ^(a)
G30 cemented carbide	71 HRC
Steel, nitriding	>68 HRC
Steel, carburizing	60-65 HRC
D3 tool steel	62 HRC
Nickel-cobalt alloy	45-52 HRC
Copper-beryllium 275	46 HRC
Aluminum bronze	188 BHN
Steel, low alloy and carbon	180 BHN
Kirkcote	80-105 BN1
Brass	50 BN1
Sprayed metal	<50 BN1
Epoxy, metal filled	85 Shore D
Epoxy, unfilled	85-90 Shore D
Polyurethane, hard	70-85 Shore D
Polyurethane, soft	40-65 Shore A
Silicone rubber	15-65 Shore A

Methods. Figure 7 outlines the key steps involved in the manufacture of parts from a soft tool. A master model is fabricated by machining or other rapid-prototyping methods.

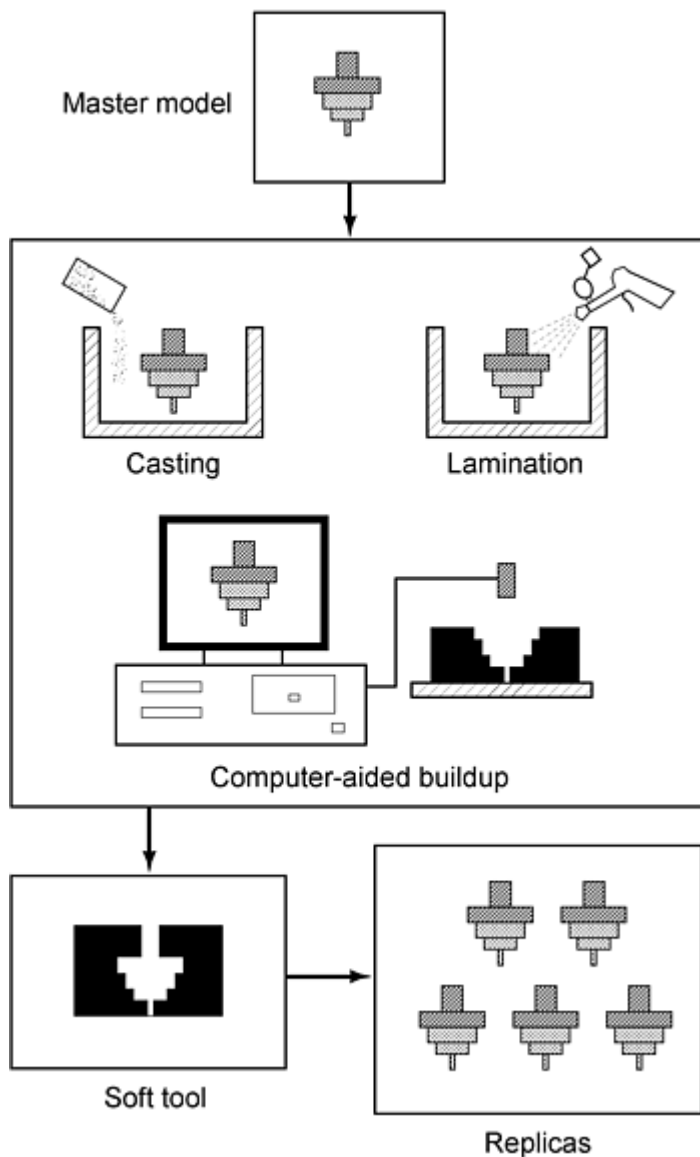

Fig. 7 An outline of the soft tooling process

Recent developments directly use a CAD file stored in the computer to be used as the master model (Ref 14). Using the master model, a soft tool is fabricated from procedures such as casting, lamination, and computer-aided buildup.* The master is separated from the cured tool and is used to make replicas by a forming technique of choice.

Several rapid-prototyping techniques for fabrication of plastic objects have been covered elsewhere in this Volume. Casting is briefly described in this section. Most thermosetting materials used in casting are also excellent adhesives. Therefore, a release or parting agent must be applied to the master model before application of the tooling resin. Particulate fillers such as aluminum, silicon carbide, and sand are often added to the resin in order to increase thermal conductivity, improve surface hardness, and reduce costs, respectively. The high viscosity of filled suspensions makes it important to ensure the removal of air bubbles entrapped during the mixing or pouring stages (Ref 15). In order to fabricate large tools, the soft tool can be cast onto a core of materials such as stainless steel, aluminum, kirksite, or resin-fiber glass laminates in a procedure known as backing (Ref 9). More recently, an additional stage known as fronting has been developed in order to create a thin metal film on the surface of the soft tool in order to improve thermal properties and hardness (Ref 16).

Attributes and Applications. Complex shapes can be cast or laminated to final dimensions using soft-tooling techniques. Lower costs can be achieved compared to conventional tooling because fabrication times are short and expensive machining is often unnecessary. The time for fabrication is on the order of days as opposed to weeks or months. There are two main limitations of soft tooling. The poorer thermal properties result in an increase in molding

cycle times and impose restrictions on the maximum processing temperature. The inferior mechanical properties, in general, reduce the lifetime of the tooling to the order of 10 to 1000 parts. Table 3 summarizes the comparisons between the attributes of soft tooling and conventional hard tooling.

Table 3 A Comparison of attributes of metals and polymers for tooling

Comparison variable	Result (for polymers)
Capital investment	Favorable
Labor cost	Favorable
Lead time	Favorable
Large tool cost	Favorable
Tool weight	Favorable
Repair and design changes	Favorable
Short runs and prototypes	Favorable
Ease of duplication	Favorable
Corrosion resistance	Favorable
Surface finish	Favorable
Skilled supervision	Approximately equal
Material cost	Approximately equal
Thermal conductivity	Unfavorable
High-temperature strength	Unfavorable
Long production runs	Unfavorable

Source: Ref 9

From the above discussion, it is evident that polymers are most useful for the quick and inexpensive fabrication of tooling for low-volume prototyping runs. Further, the tooling is useful when a high level of surface finish is required. Soft tooling is applicable to binder-assisted P/M forming techniques such as powder injection molding and LPM.

- * Lamination refers to the fabrication of alternate layers of glass cloth or chopped fiber and a resin. Computer-aided buildup is used here to describe all techniques that include a CAD file to directly create a three-dimensional object. Some examples are stereolithography (SL), SLS, fusion deposition modeling (FDM), three-dimensional printing (3DP), and ballistic particle manufacturing (BPM).

Low-Pressure MoldingS.V. Atre, The Pennsylvania State University

There are several shape-forming techniques that utilize powder-binder suspensions (Ref 17). In recent years, a number of methods have emerged in which molding occurs under low shear rate conditions. These methods are collectively referred to as low-pressure molding (LPM). Figure 8 shows the generic steps involved in LPM. A well-mixed feedstock consisting of the powder and binder constituents is introduced into a mold at pressures below 0.7 MPa (100 psi). Generally, the viscosity of the feedstock is such that the material can flow at room temperature (1 to 10^3 Pa · s). The feedstock is solidified in the mold to the desired shape. The green part is removed from the mold and is subjected to thermal debinding and sintering cycles to high final densities (90 to 100% of the theoretical value). The main variations in the process occur in the binder composition and in the solidification stage.

Fig. 8 Flow chart for the LPM process, showing the four major stages and highlighting the important parameters within each

A critical requirement for any molding operation is that the feedstock viscosity allow complete and uniform mold filling (Ref 18). The viscosity of suspensions depend on many variables such as temperature, shear rate, particle characteristics, and solids loading (Ref 19, 20). For example, thermoplastic polymers and waxes soften and flow easily above their melting point. Certain polymers and suspensions display a shear thinning behavior, wherein the viscosity decreases with increasing shear rate. Particle characteristics such as shape, size distribution (mean and width), packing characteristics, and surface chemistry have all been recognized to play a role on the suspension viscosity. A semiempirical equation (Ref 18) relating the suspension viscosity, η , to some of these variables is:

$$\eta = \eta_b A (1 - \phi / \phi_m)^{-n}$$

where η_b is the viscosity of the binder, ϕ is the solids loading, ϕ_m is the maximum particle packing density, and n is a constant usually close to 2. A is a function that accounts for shear rate, temperature, and particle size effects. In principle,

some or all of the above factors can be controlled to allow molding at low shear rate conditions. In LPM practice, however, the suspension viscosity is usually reduced by lowering η_b . Typical examples of LPM techniques are discussed next.

Powder Metallurgy Methods for Rapid Prototyping

Methods

Frequently, LPM methods for shape forming with metal powders are extensions of processes developed for ceramics. The majority of LPM processes can be classified based on the binder system under two categories: dilute polymer solutions and polymerizable systems. Variations under each of these categories are discussed.

Processes Using Dilute Polymer Solutions. A straightforward approach to reducing binder viscosity is to use polymer solutions. The viscosity of a polymer solution is lowered with decreasing concentration and molecular weight of the polymer (Ref 10). Both aqueous and non-aqueous systems have been practiced, although the former is preferred for environmental and safety reasons, provided the metal system is not reactive toward water. Two examples are presented using this method.

Slip casting is a classic example of a forming method used primarily for ceramics (Ref 17). Although the method had been explored several decades ago for metal powders (Ref 21), it was rarely practiced until more recently (Ref 22, 23). Slurries consisting of aqueous polymer solutions as binders and metal powders have been used for slip casting. Polysaccharides, vinyl polymers, waxes, and various organometallic compounds have been used in solutions (concentration varying between 0.5 and 5 wt%) for slip casting (Ref 24). A homogeneous feedstock is obtained by the low shear mixing of the ingredients at room temperature. The viscosity of the feedstock can be reduced by more than an order of magnitude under conditions of low shear (e.g., 450 Pa · s at a shear rate of 40 s⁻¹ for a 316L stainless steel feedstock, solids loading of 60 vol%). The feedstock is then poured into molds at ambient conditions of temperature and pressure and dried before ejection of parts. The use of porous tooling helps achieve green densities in the range of 70 to 74% of the theoretical density (Ref 23). The parts obtained are nearly 99% debound and have a green strength of 9.5 MPa (1380 psi). The remaining binder is rapidly removed in a thermal debinding step (500 °C). Because the amount of carbon in the starting feedstock is low, carbon control, especially for the fabrication of thick sections, is relatively easy. Carbon analysis performed on 17-4 PH stainless steel parts formed by slip casting resulted in 0.045 wt% residue (Ref 23). Final sintering is conducted under standard conditions. Starting with identical powders and solids loading, comparable properties can be obtained for 316L stainless steel parts fabricated by slip casting and powder injection molding (Ref 25), as shown in Table 4. The latter process is an example of a high-pressure molding process. Depending on the mold geometry, pressures in the range of 3.5 to 70 MPa (500 to 10,000 psi) are typical for powder injection molding (Ref 18). In a separate study, a sintered density of 7.74 g/cm³ and hardness of 40 HRC have been reported for slip cast 17-4 PH stainless steel (Ref 23). This powder is unsuitable for use in the fabrication of parts by die compaction due to its hard and spherical nature. Powder injection molded parts for the same material are 7.5 g/cm³ and 35 HRC, respectively (Ref 26).

Table 4 Sintered properties of 316L stainless parts obtained by slip casting and powder injection molding

Property	Slip casting ^(a)	Powder injection molding ^(b)
Shrinkage after sintering, %	14.8	13.3
Sintered density, % theoretical	95.6	91.0
Ultimate density strength, MPa	492	448
Elongation to fracture, %	38	34
Hardness, HRB	59	57

Feedstock: water-atomized 316L stainless steel ($d_{50} = 14.3 \mu\text{m}$) at a solids loading of 62 vol% was used in both processes. The binder system used in slip casting was an aqueous alginate solution. The binder system used in powder injection molding consisted of paraffin wax, polypropylene, and stearic acid. Sintering conditions for both processes: 1350 °C, 1 h, H₂.

- (a) Ref 22.
 (b) Ref 25

The Quickset process is another variation of binder systems using aqueous polymer solutions (Ref 8). Here, the parts are frozen in the mold, and the water molecules are removed by sublimation. Additives are introduced in the feedstock to minimize volume changes during freezing. The residual binder is removed in a thermal debinding step. For Sialon, flexural strength of 975 MPa and Weibull modulus of 19.4 have been reported using the process. Comparative runs with isopressed parts resulted in values of 785 MPa and 8.7, respectively, for the flexural strength and Weibull modulus.

Polymerizable Systems. The viscosity and melting point of a polymer increase with its molecular weight (Ref 10). Therefore, a logical alternative to using polymer solutions is to use low-molecular-weight polymer precursors (referred to as monomers, oligomers, or prepolymers) in order to obtain low binder viscosities at room temperature (typically <1 Pa · s). A catalyst is used to initiate the polymerization reaction, often in combination with heat. The polymers are of the thermosetting type because a cross-linking agent is usually added to the mixture to solidify the part in the mold. This approach owes its origins to fabrication techniques used in polymer-matrix composites. Two examples of this approach are presented.

The debinding reaction injection molding (D-RIM) process uses a low viscosity (0.2 to 1.0 Pa · s), thermosetting liquid polymer to fluidize the powder (Ref 27). Solids loading of 60 to 65% for metal powders can be achieved. The furfuryl alcohol-based polymer undergoes solidification as a result of a cross-linking reaction initiated by the addition of heat or a catalyst. A green strength of 6.5 MPa (950 psi) is typical. Water molecules are evolved in the gaseous state as a by-product of the reaction and leave behind an open pore network. Nearly 50% of the initial binder is removed in this manner at the end of the molding stage. The remaining binder is thermally decomposed in air, hydrogen, or vacuum at 400 to 500 °C. Mold residence times depend on part dimension and typically vary from 1 to 5 min. An important aspect of processes using thermosetting resins is that thermal decomposition occurs without any liquid phase being formed. The porous structure formed in the present process as a result of the condensation reaction provides a convenient pathway for the escape of the gaseous decomposition products. This minimizes the formation of internal stresses that could lead to defects such as cracks and blisters during the thermal debinding stage. Tensile strength for carbonyl iron D-RIM parts was reported to be 215 MPa. A value of 220 MPa reported for powder injection molded processed iron (Ref 26).

Gelcasting is another variation based on the use of cross-linkable monomers (Ref 28). A monomer solution provides a low-viscosity vehicle for suspending the powder. For example, the viscosity of a 62 vol% slurry of alumina has been reported to be 1.8 Pa · s at a shear rate of 10 s⁻¹. The monomers used are a mixture of acrylamides (10 to 20%), and the solvent is usually water (80 to 90%). This is introduced into a mold made of aluminum or polyethylene where it is cross linked to form a solid polymer-solvent gel. The cross-linking reaction can be performed by the addition of heat (50 to 60 °C) and a suitable catalyst. The gelled part can be removed from the mold without distortion and dried to remove the solvent. The mold residence time depends on part geometry and varies from 10 min to an hour. Drying is dependent on the part and occurs outside the mold cavity in a matter of hours. The residual binder was removed at 350 to 500 °C. The process was originally developed for processing ceramics (e.g., alumina and silicon nitride) and has been extended to metal powder systems (e.g., 17-4 PH stainless steel and H13 tool steel). A sintered density of 7.58 g/cm³ and hardness of 37 HRC have been reported for gelcast 17-4 PH stainless steel. Values for powder injection molded parts for the same material are 7.5 g/cm³ and 35 HRC, respectively.

Powder Metallurgy Methods for Rapid Prototyping

Advantages

The lower shear and room-temperature conditions required for the mixing and molding of LPM feedstocks afford considerable savings in equipment and energy costs. In addition, the extent of wear of tooling and equipment is reduced, as is the accompanying contamination problems in the feedstock. Further, the low shear conditions during molding allow the use of inexpensive mold materials such as aluminum, plaster, epoxy resin, and silicone rubber. An added advantage of using soft tooling such as epoxy resin or silicone rubber is that the surface finish of the product is greatly enhanced. The low molding pressures imply that the forces required for clamping the mold are also reduced. Because a major portion (50 to 99%) of the binder removal is accomplished either during the molding cycle or by drying, the problems associated with the storage, handling, and disposal of solvents (in the case of solvent debinding methods) or corrosive acids (as in the case of catalytic debinding methods) present in powder injection molding are completely avoided. The residual binder is rapidly removed in a thermal debinding step. With the ease of debinding, carbon control, especially for the fabrication of thick sections is easier. Density variations of $\pm 0.1\%$ at the 3σ level has been reported for the LPM of silicon nitride in an automated press (Ref 29). Data on dimensional tolerance of parts produced by LPM are limited. One study reports a 3σ tolerance of 0.2 to 0.3% for sintered parts (Ref 8). More work related to dimensional tolerance and surface finish needs to be performed for other LPM methods.

Applications

Low-pressure molding methods can currently use a number of metal powders such as stainless steels, tool steels, composites, and superalloys. In cases where the metal surface is reactive toward the binder components (e.g., iron), a passivating coating using silanes has been applied prior to the mixing of the feedstock (Ref 27). Depending on the extent of automation, LPM techniques are ideally suited for situations involving low- to intermediate-volume runs (1 to 10,000). The rapid production of tooling is a very important application. Figure 9 shows an example of P/M tooling produced by LPM technology. Applications for LPM have been demonstrated in traditional P/M areas such as the aerospace, automotive, microelectronics, biomedical, and consumer industries.

Powder Metallurgy Methods for Rapid Prototyping

Selective Laser Sintering

Leander F. Pease III, Powder-Tech Associates, Inc.

Selective laser sintering (SLS), developed by DTM of Austin, Texas (Ref 3), uses laser energy to transform metal powders into useful tooling and parts. Figure 10 is a diagram of the first part in the process, wherein a loose, polymer coated metal powder is laser fused into the required shape. A CAD model of the part is numerically transformed into thin slices, 75 to 250 μm (0.003 to 0.010 in.). In the machine shown in Fig. 10, a very thin layer of heat-fusible powder is deposited on top of the build cylinder (step 1). Then, the powder layer is fused by the laser, as it traces out the computer-generated slice (step 2). The layer so formed is held together by the strength of the fused plastic coating on the 55 μm (0.002 in.) particles. The work stations lower this fused layer by 75 to 250 μm (0.003 to 0.010 in.), and a new layer of powder is rolled into place (step 3) atop the fused layer. Laser fusing of this second layer bonds the particles to each other and to the layer below. The support platform moves the part downward a layer at a time (step 4), and the process repeats itself until the part is fully formed, that is, built up layer by layer. The chamber size is 38 by 33 by 41 cm (15 by 13 by 16 in.); parts and molds 15 by 25 cm (6 by 10 in.) thick have been produced.

Fig. 10 Process for producing a selective laser-sintered tool. Numbered steps in the figure are described in the text. Source: Ref 3

After the fusing step, the part has a green strength of about 2.7 MPa (400 psi) and requires care in handling. The unfused powder falls away from the fused part and is recycled. The fused green part is impregnated with acrylic resin containing a cross-linking polymer and then dried at 50 °C (122 °F). The dried part is then placed on an alumina plate in a graphite crucible. Blocks of copper are also placed in the crucible to serve as an infiltrant for the porous laser-formed part. The assembly is heated in 70%N₂-30%H₂ at 0.5 °C/min (1 °F/min) to 1120 °C (2048 °F). At 300 °C (572 °F) the polymer burns out, but the cross-linked polymer remains to strengthen the part and prevent slumping. At 700 °C (1292 °F) the iron particles begin to sinter and bond. At 1083 °C (1981 °F) the copper melts and runs laterally into the porous steel preform. It infiltrates from the sides and then runs up into the part by capillary action. There is enough copper present to fill all the pores, but the copper does not adhere to the alumina plate on which the infiltrated part now rests. The furnace then returns to room temperature, and the assembly is removed.

The infiltrated part contains about 60% Fe, 39% Cu, and 0.8% C. Its properties are:

Ultimate tensile strength, MPa (ksi)	475 (69)
Yield strength, MPa (ksi)	255 (37)
Elongation in 25 mm (1 in.), %	15
Hardness, HRB	75
Elastic modulus, GPa (10 ⁶ psi)	207 (30)
Coefficient of thermal expansion, mm/mm · °C (10 ⁶ in./in. · °F)	14.4 (7.99)

The thermal conductivity is important for injection molding tools and is 185 W/m · K (107 Btu/ft · h · °F) or about six times that of P20 steel. During infiltration, the part shrinks 2.5% linearly, and this is compensated at the initial part design by making it over size. The infiltrated parts have a tolerance of ±0.25 mm (±0.010 in.) over distances of 13 cm (5 in.). Walls can be as thin as 1 mm (0.040 in.). All parting lines and shutoffs for molding tools must be machined and therefore have 0.5 mm (0.02 in.) added at laser forming for that purpose. The as-infiltrated surface roughness is 0.25 μm (10 μin.) R_a and may be polished to 2.5 to 25 nm (0.1 to 1 μin.). Some polishing may also be done in the green state.

In all, the process takes about 5 days and results in a mold that is ready for plastic injection molding or MIM. Such a mold can produce 50,000 plastic parts in its useful lifetime. The main use for SLS via the DTM process is making tooling for the injection molding of plastics.

The infiltrated material produced by SLS does not match properties of pressed-and-sintered materials (such as in MPIF Standard 35), and so could not be used in functional prototype parts. In principle, other alloy steels could be selective laser sintered to form 60% dense preforms that would then be sintered and shrunk to the correct density to serve as P/M prototype parts. This would involve linear shrinkages of 7 to 10% with difficulties in maintaining tolerances. In general, parts sintered to such a degree would not have the same properties as the standardized P/M grades. (The prolonged sintering would result in erroneously high elongation and toughness.)

Powder Metallurgy Methods for Rapid Prototyping

Laser-Based Direct Fabrication

Eric J. Whitney, Applied Research Laboratory, The Pennsylvania State University; John E. Smugeresky, Sandia National Laboratories; David M. Keicher, Optomec Design Company

Many rapid prototyping methods are under development, and some use metals or ceramics separately, while others are exploring using metals and ceramics together. In one process, metal powder can be deposited at a rate of about 0.1 to 10 g/min in precise amounts and with positional accuracy such as a net-shape part results. In another process, metal powder is deposited at a higher rate, about 10 to 100 g/min, resulting in a near-net-shape part. Both of the processes are completely computer controlled such that there are no molds used in the fabrication of a shape. Generally, the processing atmosphere is controlled to limit interstitial contamination from oxygen and nitrogen. The processes completely melt and fuse the metal powder, often achieving full theoretical density. These approaches eliminate or reduce the need for nonfunctional prototyping, such as the traditional trial-and-error prototyping approach using wood, clay, or plastic and the new rapid-prototyping (RP) processes that integrate computer-aided engineering, CAD, and CAM techniques with polymer deposition processes. These RP processes are also known as stereolithography or selective laser sintering (SLS).

During the period that RP was being developed, several laser laboratories experimented with using CNC-controlled laser-cladding systems to build structural parts (Ref 30, 31, 32). These laboratories concentrated on obtaining structurally sound material and addressed making only rudimentary shapes. The importance of this early work, however, was the demonstration that structurally useful material could be deposited using laser technology. More recently, several laboratories have taken advantage of the RP software concepts to push laser-based direct-fabrication technology to a much higher level of shape definition (Ref 33, 34, 35, 36, 37, 38). While there are a number of terms used to describe this

technological evolution, for example, rapid manufacturing (RM), flexible fabrication (FF), and solid free-form fabrication (SFF), they are laser-based direct-fabrication techniques for structural rather than model or surrogate materials.

The material deposited by these processes must have structurally useful properties, such as high tensile strength, adequate ductility, good fracture toughness, and good fatigue life. At a minimum, the properties must be equivalent to conventionally cast material of the same composition. The potential of the process, however, is the ability to make materials that have unique characteristics, in shapes that are not constrained to have a single composition throughout the part.

For example, turbine engine parts often operate with severe temperature gradients. The limiting mechanical property in the high-temperature region may be creep while at the lower-temperature region the limiting property may be tensile or fatigue strength. In designing such a chemically homogeneous component manufactured using current processes, a compromise between creep resistance and high fatigue must be made. However, with the laser-based direct-fabrication techniques, parts are formed by depositing a small volume of material and building the part a layer at a time. This allows for composition changes on a scale equivalent to the width and height of the deposit such that gradients in the composition can be intentionally built into the part. Appropriate selection of the composition gradients provides the opportunity to adjust the properties as a function of position, creating so-called functionally graded materials. Thus, a design engineer may be able to increase the life of a component by metallurgically optimizing each region of the part for the anticipated thermomechanical environment. Both thermal profiling and composition profiling, in principle, can be engineered into a part to optimize its design.

Lasers are an ideally suited heat source for laser-based direct-fabrication processes. The laser provides an intense heat source that is easily configured into highly automated systems. Laser-based direct fabrication has much in common with laser cladding and surfacing techniques. Laser power level (energy density), powder deposition rate, and travel speed are parameters that can be scaled to suit the requirements for thermal profiling, size and composition of the deposit to control microstructure, mechanical properties, dimensional tolerances, and surface finish. Figure 11 (Ref 5) shows a schematic of a simple laser-based direct-fabrication setup.

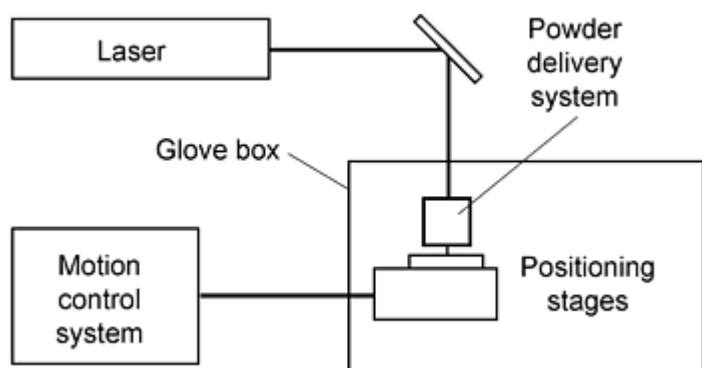

Fig. 11 Basic approach to laser-depositing metallic materials. Source: Ref 5

Many types of lasers can be used, depending on the size and sophistication of the desired part and the type of material being processed (Ref 39). Selection of laser type depends on the light absorption, thermal transport, and thermodynamic properties of the material being deposited. For small intricate parts, a laser power of 1 kW or less can be used (Ref 40). For larger parts, such as those shown in Fig. 12, with thick-wall sections multikilowatt lasers must be used to achieve economical deposition rates. Adjustments to processing parameters are also required to meet dimensional and surface finish specifications.

Fig. 12 Thick-walled Ti-6Al-4V laser-based direct fabrication. Source: Ref 41

Laser-Based Direct Fabricated Microstructures. A wide variety of microstructures, some of which are unique, can be achieved with laser-based direct fabrication, depending primarily on the power level of the laser utilized. At power levels less than about 5 kW, a small molten pool of material is created on a substrate, the added feedstock increases the size of the pool momentarily, and solidification occurs when the laser beam is traversed. Solidification rates are generally high enough, due to the heat-sink effect of the substrate, that metastable microstructures characteristic of rapid-solidification technology are readily generated. This corresponds to ultrafine, extended solid-solution microstructures capable of producing enhanced mechanical properties. In welding terms, cellular dendritic microstructures are produced where the secondary dendrite arm spacing can be used to estimate the solidification rate, with rates of approximately 10^4 s^{-1} being realized. Figure 13 (Ref 42) shows 316 stainless steel produced by two different laser-based direct-fabrication processes.

Fig. 13 Fine-grained ductile 316 stainless steel produced under nonoptimized conditions. Left: optical macrostructure, showing layer geometry. Source: Ref 5. Right: transmission electron micrograph showing ultrafine grain size. Source: Ref 42

In making thick-section parts, high-power lasers in the 10 to 45 kW range are generally used. Here the solidification rates are slower, possibly approaching those of thin-walled castings. Figure 14 shows the microstructure for a laser-based direct-fabrication-processed Ti-6Al-4V using a 14 kW CO_2 laser and a thin-walled conventional casting.

Fig. 14 Microstructure of laser-based direct-fabricated Ti-6Al-4V

The chemical and mechanical properties of laser-based direct-fabricated materials are excellent. The following alloys were deposited and tested: Ti-6Al-4V, Ti-5Al-2.5Sn, 316 stainless steel, alloy 625, alloy 690, alloy 718, H13 tool steel, and nickel-aluminum-bronze. Some representative data are presented here.

Ti-6Al-4V. It is well known that titanium alloys are subject to embrittlement by oxygen and nitrogen, impurities commonly introduced during conventional processing. Table 5 shows a comparison of the composition of laser-based direct-fabricated deposited Ti-6Al-4V and the starting powder composition. The data show that, under properly controlled conditions, the increase in oxygen and nitrogen can be held very low. Tensile and hardness properties of laser-based direct-fabricated Ti-6Al-4V material are also within ASTM B 367 Grade C5.

Table 5 Chemical composition of laser-based direct-fabricated Ti-6Al-4V and starting powder

Sample ^(a)	Composition, wt%					
	O	N	H	Fe	Al	V
Starting powder	0.23	0.032	0.012	0.199	6.01	3.95
Laser-based direct-fabricated material^(b)	0.23	0.048	0.0072	NC	5.83	3.75

(a) Powder sample average of two tests.

(b) Vacuum mill annealed

The data shown in Tables 5 and 6 are from laser-based direct-fabricated Ti-6Al-4V material made from prealloyed hydride-dehydride powder and using a 14 kW CO₂ laser. After forming, the material was heat treated in vacuum at 788 °C (1450 °F) for 2 h. Fatigue testing has shown that laser-based direct-fabricated Ti-6Al-4V is equivalent to cast and hot isostatically pressed material.

Table 6 Tensile properties of laser-based direct-fabricated Ti-6Al-4V

Test	ASTM B 367 C5	Laser-based direct-fabricated Ti-6Al-4V
Hardness, HRC	39 max	36
Ultimate tensile strength, MPa (ksi)	896 (130)	1007 (146)
Yield tensile strength, MPa (ksi)	827 (120)	876 (127)
Elongation, (in 25.4 mm, or 1 in.)	6 min	8.5

Alloy 718 is a widely used γ' -strengthened superalloy that is available in cast and wrought forms. The alloy generally exhibits good weldability. Table 7 shows the 538 °C (1000 °F) tensile properties of laser-based direct-fabricated alloy 718 after postform aging.

Table 7 Tensile properties of laser-based direct-fabricated Alloy 718

Test	Typical cast value	Laser-based direct-fabricated alloy 718
Ultimate tensile strength, MPa (ksi)	860 (125)	931 (135)
Yield tensile strength, MPa (ksi)	725 (105)	793 (115)
Elongation, %	9	15

Alloy 625 and 316 stainless steel are austenitic materials that are based on nickel and iron, respectively. The alloys are available in wrought and cast forms. Alloy 625 is a high-temperature material that is corrosion and oxidation resistant. It is used in the chemical, petroleum, paper, nuclear, and aerospace industries and is generally regarded as the most widely used nickel-base alloy in the world. At lower temperature, 316 stainless steel is used in many of the same industries as alloy 625. Both alloys represent a significant portion of the premium metals market.

Excellent properties for 316 stainless steel, where yield strengths double that of wrought annealed bar with no sacrifice in ductility, are routinely achieved by laser-based direct-fabrication processing (Table 8) (Ref 42). The properties of similarly processed alloy 625 exceed those of annealed bar. Properties are dependent on processing parameters, and work on 316 stainless steel demonstrated that mechanisms as simple as grain refinement over conventionally processed materials lead to Hall-Petch strengthening. Figure 14 shows a grain size of approximately 10 μm compared to 50 μm for wrought 316 stainless steel. Hardness values have been reported (Ref 42) from 180 to 232 on the Knoop scale, equivalent to Rockwell B values of 85 to 96. Rockwell B values in the 80 to 85 range for stainless steels correspond to tensile yield strengths in annealed bar of about 240 MPa. Tensile yield strengths greater than 480 MPa have been reported (Ref 43) for similarly processed material, for samples with Knoop hardness in the 230 to 240 range (96 HRB). In that study, the grain size within the fabricated structures was reported to be on the order of 5 to 10 μm , whereas the grain size for the annealed 316 stainless steel is typically around 100 μm . This difference in grain size is believed to be the primary cause of the improved strengths for the laser-based direct-fabricated structures and is consistent with the Hall-Petch relationship between yield strength and grain size. Consequently, full-size parts can be made with a wide range of strengths.

Table 8 Mechanical tensile test data for laser-based direct-fabricated 316 stainless steel and alloy

Plane orientation with respect to tensile direction	Ultimate strength		Yield strength		Elongation (in 25 mm, or 1 in.)
	MPa	ksi	MPa	ksi	
316 stainless steel perpendicular	790	115	450	65	66
316 stainless steel parallel	805	117	590	86	33
316 stainless steel anneal bar	585	85	240	35	50
Inconel 625 parallel	930	135	635	92	38
Inconel 625 perpendicular	930	135	515	75	37

H13 Tool Steel. The fabrication and maintenance of tools is a huge cost element for many manufacturing operations. Laser-based direct-fabrication of tools is of immense economical importance. Utilizing the unique metallurgical qualities of laser-based direct fabrication to increase the useful life of tools may also reduce costs. H13 tool steels processed by laser-based direct fabrication can have both a coarse and fine structure (Ref 44), depending on processing conditions. Figure 15 shows the tempering response of laser-based direct-fabricated H13 as compared to a conventionally prepared alloy of the same composition.

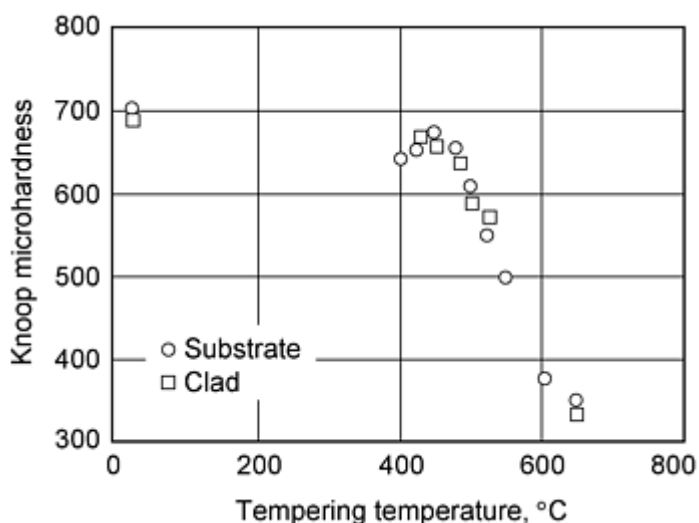

Fig. 15 Tempering response of H13 tool steel

Consolidation Principles and Process Modeling

Revised by Randall M. German, Pennsylvania State University

Introduction

CONSOLIDATION of metal powders generally involves sintering, whereby an assembly of loose or compacted particles metallurgically bond into a coherent body at elevated temperatures. During the process, sintering powder particles form strong bonds and alloy any admixed elements. Temperatures below the melting point of the major constituent are usually used, although liquid phase sintering is the most common technique in production.

Although sintering has been the subject of extensive experimental and theoretical work, there is no universally applicable theory of sintering. Much is not understood about the process, and no single applicable explanation or understanding of the process has emerged. Sintering generally consists of six distinct, but not necessarily sequential, stages:

- Initial particle bonding
- Neck growth
- Pore rounding
- Pore channel closure
- Densification and pore shrinkage
- Pore coarsening

Material transport mechanisms involved include surface diffusion, volume diffusion, evaporation and condensation, and grain boundary diffusion. Several factors affect sintering. However, the most significant are time and temperature, with temperature being the most important single variable. Particle size, compact porosity, and prealloying also affect the sintering process.

Consolidation Principles and Process Modeling

Revised by Randall M. German, Pennsylvania State University

Consolidation Principles

This article discusses the important changes in density, microstructure, and mechanical properties that occur when metal powder compacts in the as-pressed condition (green compacts) are sintered. These changes are described phenomenologically and from the point of view of the driving forces and the material transport mechanisms that are important in the modeling and characterization of changes in density, microstructure, and mechanical properties from sintering green compacts. The mechanisms of homogenization during sintering and of activated and liquid phase sintering also are examined. In addition, process modeling is discussed at the end of this article.

Changes in the dimensions and density of compacts are important considerations in sintering. Changes in density during sintering are primarily due to changes in phases, in alloying, or in volume (dimensions), but changes in mass, which may be caused by the loss of lubricant added during compacting, volatilization of a component such as zinc from brass, and the reduction of oxide skins on the powder particles during sintering should also be considered.

In studies of the fundamentals of sintering, dimensional changes are determined as the difference in dimensions between green and sintered compacts, parallel and perpendicular to the direction of pressing, and are expressed in percent of the green dimensions. From a technological standpoint, the dimensional change during sintering of greatest importance is the difference between the dimensions of the die and the sintered compact in the radial direction, that is, the direction perpendicular to that of pressing.

Another approach to studying shrinkage and densification during sintering is to determine the dimensional changes with a dilatometer. A compact is heated at a constant rate to a given sintering temperature and then cooled at this rate from the maximum temperature to room temperature. For example, a dilatometer curve is shown in Fig. 1. This curve represents the dimensional changes in the axial direction of the same type of copper compacts as Fig. 2. Compacts were pressed at a pressure of 138 MPa (20,000 psi) and were heated and cooled at a uniform rate of 3.9 °C/min (7 °F/min). This type of experiment is particularly well suited for studies of the rate of densification as a function of temperature.

Fig. 1 Dilatometer curve of dimensional changes in a copper P/M compact from sintering. The first portion of the curve up to 315 °C (600 °F) is identical to that of a specimen of solid copper and represents the thermal expansion of the metal with increasing temperature. When sintering begins, shrinkage counteracts thermal expansion, and the curve deviates from that for solid copper. As the temperature increases, the rate of shrinkage increases and the compact contracts. Immediately after reaching the maximum sintering temperature of 925 °C (1700 °F), the compact is cooled at the same rate at which it was heated. During cooling, contraction initially is faster than normal thermal contraction. Eventually, the dilatometer curve slope follows normal contraction. Compacts from $-74+43 \mu\text{m}$ copper powder pressed at 138 MPa (20,000 psi) and heated at a rate of 3.9 °C/min (7 °F/min) to 925 °C (1700 °F) and then cooled at the same rate.

Fig. 2 Shrinkage of copper powder compacts from $-74+43 \mu\text{m}$ sieve fraction. Compacted at 138 MPa (20,000 psi) and sintered at various temperatures as a function of sintering time

Consolidation of Compacts

Consolidation of metal powders generally entails compacting, followed by sintering. However, metal powders sometimes are sintered without compacting, which is called "loose powder sintering." This process is suitable for certain specialized P/M applications such as bronze filters and porous electrodes, as well as for model experiments to study the mechanism of sintering. Additionally, all powder injection molded structures begin sintering from this same condition once the binder is removed.

The simplest type of sintering is for compacts of a single metal powder, or compacts of homogeneous solid-solution alloy powders (alpha brass powder or an austenitic stainless steel powder). However, powder metallurgy alloys also can be produced by blending two or more constituent powders in proportions required to achieve the desired overall alloy composition. Constituent powders of the mixture may be composed of pure elements (elemental powders) or alloys containing two or more elements (master alloy powders). If a homogeneous alloy is to be produced from a mixture of powders, sintering must be controlled to achieve the required degree of homogenization.

Another alloying method is the use of prealloyed powders in which each powder particle has the same composition as the final part produced by compacting and sintering. Such prealloyed powders typically are produced by atomization of a molten alloy by impingement of a high-pressure gas or liquid stream. The fluid disperses the liquid alloy into small droplets to solidify into powder particles.

Homogenization of elemental powders occurs through interdiffusion of the chemical elements among the constituent powders of different composition. Often, it is a solid-state diffusion process. Complete homogenization during sintering is achieved during the sintering of mixtures of iron and graphite powder, where graphitic carbon goes into solid solution in gamma iron (austenite) at the sintering temperature.

Homogenization circumvents some of the disadvantages of prealloyed powder processing. Hardness and strength of prealloyed powder particles result in powder compacts with low densities and low green strengths when pressed at room temperature. Mixture of powder with the major component of the alloy present as an elemental powder (usually soft and ductile) typically exhibit high densities and high green strengths in the as-compacted condition. Furthermore, adjustments to alloy composition can be made readily by varying the proportions of constituent powders in the mixture, thus eliminating the need for additional powders of different composition. Mixtures composed of elemental powders normally can be obtained with high purity. Prealloyed powders, conversely, may contain elements other than the main components of the alloy because of pickup of impurities during melting prior to atomization.

The disadvantages of homogenization processing center around the need to remove compositional heterogeneities by thermal processing (often in conjunction with mechanical working) subsequent to compaction. Homogenization often involves more extensive elevated-temperature exposure than normal sintering; this added processing expense must be minimized by limiting processing conditions to levels that provide the required homogeneity. Also, in many cases, one element diffuses much faster as compared with the other, resulting in swelling and dimensional growth during sintering.

Activated Sintering. Sometimes, compacts pressed from a mixture of a high-melting-point metal with a small addition of a lower melting point metal are sintered, such as compacts of tungsten powder to which small amounts of nickel powder have been added. During sintering at temperatures below the melting points of both metals, the compacts densify at much lower temperatures than those of the high-melting-point metal. This is one type of activated sintering (Ref 2), which is discussed later in this article and elsewhere in this Volume.

Liquid-Phase Sintering. Compacts of mixtures of metal powders also may be sintered at temperatures that form a certain amount of liquid phase. This results in a much faster process, which is very popular in industry, because of the decreased sintering times. The process is widely used in sintering iron, copper, tungsten, cobalt, and cemented carbide compositions. The quantity of the liquid phase must be small enough to be held by capillary force within the skeleton of the remaining solid phase so that the compacts retain their shape. In this process, the liquid phase may be present through the duration of the sintering cycle. This is the case in the sintering of compacts from a mixture of tungsten, nickel, and iron powders (the so-called "heavy alloys"), and in the sintering of cemented carbides (combinations of tungsten and other refractory metal carbides with cobalt). Because the solution of small particles of the solid phase in the liquid and its reprecipitation on the large particles during sintering plays an important role, this method often is referred to as the solution and reprecipitation process of liquid-phase sintering.

In transient liquid-phase sintering, however, a liquid is formed when the compact is heated to the sintering temperature. The liquid is transformed into a solid by interdiffusion while the compact is at the sintering temperature, such as in the sintering of compacts from mixtures of copper and tin powders, in which an alpha bronze solid solution is formed.

Pressure-Assisted Sintering. The simplest form of pressure-assisted sintering is that which occurs by uniaxial hot pressing. A refractory mold (die) is inserted into a furnace, and both the powder and the die are heated while the punches are driven by an external pressure source. Hot isostatic pressing is another widely used process. This process is also called gas pressure bonding, because a high-pressure gas assists densification. In hot isostatic pressing, the powder is enclosed in a thin-walled container that is flexible but pressure-tight at sintering temperatures. A pressurized gas is uniformly applied to the container in a high-pressure chamber. The chamber contains a furnace to heat both the material and the gas. The hot consolidation of metal powders, where sintering and densification are combined by applying pressure to the powder at elevated temperature, is not discussed in detail in this article. Hot consolidation processes are discussed elsewhere in this Volume.

Shrinkage and Densification

During sintering, most compacts pressed from a single-phase metal powder shrink rather than expand. The higher the sintering temperature, the longer the sintering time, the smaller the particle size of the powder from which the compacts are pressed, and the lower the green density of the compacts, the greater the shrinkage. Compacts from powders of body-centered cubic metals (molybdenum and tungsten) of a given particle size pressed to a given density and sintered a given length of time at a given homologous temperature (ratio of sintering temperature to melting temperature of the metals in degrees kelvin) show higher shrinkage than compacts from face-centered cubic metals (copper and nickel) sintered under corresponding conditions.

Compacts made of iron powder generally are sintered in the temperature range where iron has the gamma (face-centered cubic) structure. One reason is because carbon, an important strengthening element, is soluble in the face-centered cubic

form of iron, but is insoluble in the body-centered cubic phase of iron. Compacts made of iron powder with conventional commercial particle size distribution, pressed to green densities in the range from 6.6 to 7.1 g/cm³ and sintered at temperatures ranging from 1100 to 1200 °C (2010 to 2190 °F) for $\frac{1}{2}$ to 1 h, experience minimal shrinkage, often less than 1% with some alloying additions the compacts will expand. Despite this small amount of shrinkage, iron powder compacts are sintered adequately with regard to their mechanical and physical properties. This is important in the fabrication of structural parts from iron and steel because of the need for control of dimensions. Large amounts of shrinkage during sintering may be undesirable, thus rendering control of final dimensions of the sintered part difficult.

Shrinkage of copper powder compacts from a -74+43 μm sieve fraction, pressed at 138 MPa (20,000 psi), as a function of sintering time and temperature is shown in Fig. 2. These compacts were heated rapidly to the isothermal temperature and, after being held at this temperature, cooled rapidly to room temperature. These data represent the "isothermal" shrinkage of the compacts, even though shrinkage during heating and cooling is included. As shown in Fig. 2, shrinkage of the copper powder compacts is primarily a function of sintering temperature. The higher the temperature, the greater the shrinkage. Shrinkage also increases with increasing sintering time. The rate of shrinkage is initially quite high, but then decreases with increasing sintering time. The higher the sintering temperature, the more rapid the decrease in shrinkage rate. Accordingly, high sintered densities can be obtained more readily by increasing sintering temperature than by increasing sintering time.

In other P/M applications, large amounts of shrinkage are desirable to obtain sintered densities near those of the solid metal. For instance, compacts from very small tungsten powder (body-centered cubic) sintered at temperatures near the tungsten melting point increase in density from 11 g/cm³ in the green condition to 18 g/cm³ in the sintered condition; that is, they shrink 15% linearly. Because the sintered compacts are subsequently swaged and drawn into wire, close control of sintered dimensions is not required.

Effect of Powder Size on Shrinkage. Another factor affecting shrinkage is the particle size of the powder. As shown in Fig. 3, an increase in density during sintering of copper powder compacts pressed at 276 MPa (40,000 psi) and sintered at 865 °C (1590 °F) is a function of sintering time. The rate of densification of compacts from -44 μm powder is considerably faster than that of compacts from a -75+100 μm sieve fraction.

Fig. 3 Density of compacts from electrolytic copper powder. Two particle size fractions: -75+100 μm and -44 μm sintered at 865 °C (1590 °F) as a function of sintering time

Effect of Green Density on Sintered Density. A final factor affecting the densification of compacts from a single-phase metal powder is the green density of the compact or the pressure at which the compact is pressed, which determines green density. As shown in Fig. 4, density of compacts from carbonyl nickel powder is plotted as a function of the compacting pressure for green compacts and for compacts sintered at five different temperatures after pressing. The

higher the compacting pressure, the smaller the sintering shrinkage, or the change from green to sintered density. However, the sintered density is much improved by the higher green density.

Fig. 4 Density of carbonyl nickel powder compacts. Sintered at a series of temperatures for 2 h as a function of compacting pressure

Expansion during sintering is common in compacts made of soft metal powders, such as copper, that are pressed at high pressures. This expansion is due to gases entrapped in closed-off pores of the compact. Gases may be entrapped during compacting or may be formed by chemical reactions, such as the formation of water vapor by reaction of oxide skins on the surface of the particles with the hydrogen of the sintering atmosphere which diffuses into the closed pores. Such expansion or growth generally is not observed in compacts that are made of harder metal powders.

Microstructure

The microstructure of green metal powder compacts reveals the outlines of the original powder particles and the pores. Depending on the particle size distribution of the powder from which the compact is pressed, powder particles and pores that are visible in the microstructure may have narrow or wide size distributions. If the powder particles are polycrystalline, grain boundaries may be observed within the particles. Particles may be flattened and distorted, depending on the nature of the powder and the compacting pressure. Typically, uniaxial compaction creates flattened pores that subsequently contribute to anisotropic dimensional change in sintering.

The microstructure of a green compact pressed from copper powder at a pressure of 180 MPa (26,000 psi) in the unetched condition is shown in Fig. 5. This microstructure indicates that the copper powder had a fairly wide particle size distribution and that some of the particles had interior porosity. Most of the boundaries between particles can be readily discerned. When this compact was sintered 15 min at 705 °C (1300 °F), a temperature too low for adequate sintering, the microstructure shown in Fig. 6 was obtained. The principal difference between the microstructures of the green compact and the one sintered at 705 °C (1300 °F) is in the shape of the pores within the powder particles, which have become rounded during sintering. The sintering temperature is too low to produce adequate bonding between powder particles; however, significant strengthening occurs by this temperature.

Fig. 5 Microstructure of green compact. Pressed from copper powder at 180 MPa (2,600 psi). Unetched. 450×

Fig. 6 Microstructure of copper powder compact. Pressed at 180 MPa (26,000 psi) and sintered 15 min at 705 °C (1300 °F). Unetched. 450×

Figure 7 shows the microstructure of the copper powder compact sintered 30 min at 980 °C (1800 °F). The sample was etched to reveal the grain boundaries in the microstructure. Boundaries between particles can no longer be discerned; instead, a network of grain boundaries similar to those in wrought and annealed copper is illustrated. Pores of different sizes filled with the medium used to mount the specimen for microstructural examination are seen. These pores are no longer cusp-shaped and irregular, but have become rounded. In compacts made of small powders, complete spheroidization of the pores often is observed.

Fig. 7 Microstructure of copper powder compact. Pressed at 180 MPa (26,000 psi) and sintered 30 min at 980 °C (1800 °F). Potassium dichromate etch. 500×

The transition in microstructure from that of a green compact to that of a well-sintered compact is a function of sintering temperature and time. During annealing of cold worked wrought material, a recrystallization temperature is reached, where nuclei of strain-free grains are formed that grow into the recrystallized structure. Subsequently, grain growth of the recrystallized structure occurs. This temperature for recrystallization and grain growth is a function of the time during which the cold worked material is annealed and the amount of prior cold work. The temperature range in which the typical microstructure of a well-sintered powder compact is developed is much higher than the recrystallization temperature of the wrought material. Compacting pressure frequently has a relatively minor effect on the temperature range at which the sintered structure is developed.

Development of the typical well-sintered structure of a metal powder compact requires that grain growth occur across prior particle boundaries. This grain growth is restricted until material transport that occurs during sintering has progressed to a point where a substantial increase in the contact area between particles has taken place. This increase in contact area is impeded by the network of pores. It is not responsive to the effects of strain hardening during compacting, which are relieved at temperatures below those at which the development of a sintered microstructure is observed. The principal effect of higher compacting pressures on grain growth during sintering is to facilitate extensive contact between particles.

Mechanical Properties

Mechanical properties of P/M structural materials depend on the composition, density, and heat treatability of the material, as well as processing and design considerations. Final density, which is expressed in g/cm^3 as well as percent of theoretical density--the ratio of the density of a P/M material to that of its wrought counterpart--has the greatest effect on properties of P/M materials. Powder metallurgy parts with theoretical densities less than 75% are considered to be low density, those above 90% are high density, and those in between are classified as medium density. Generally, structural parts have densities ranging from 80% to above 98%. Oil-impregnated bearings have densities of approximately 75%; densities of filter parts can be as low as 35%.

As shown in Fig. 8, mechanical properties generally improve with increases in density. Figure 8 illustrates the effects of density on the mechanical properties of as-sintered nickel steels. The data of Fig. 8 apply only when electrolytically produced iron-base powder is used and the processing includes presintering and repressing of all materials above 6.6 g/cm^3 . Other iron powders and processing methods produce different results. One option is based on specified minimum tensile properties, where the fabrication suppliers may select suitable powders, density, and processing to meet minimum strength levels. The density designations in Fig. 8(b) are defined in Table 1.

Table 1 Typical density designations and ranges of ferrous P/M materials

Density of pure iron is 7.87 g/cm^3 .

Designation MPIF density suffix	ASTM type ^(a)	SAE type	Density, g/cm^3
N	I	1 ^(b)	Less than 6.0
P	II	2	6.0 to 6.4
R	III	3	6.4 to 6.8
S	IV	4	6.8 to 7.2
T	V ^(c)	5 ^(c)	7.2 to 7.6
U	7.6 to 8.0

- (a) ASTM B 426 only; different density ranges used in ASTM B 310 and B 484.
- (b) Density range of 5.6 to 6.0 g/cm^3 is specified.
- (c) Minimum density of 7.2 g/cm^3 is specified.

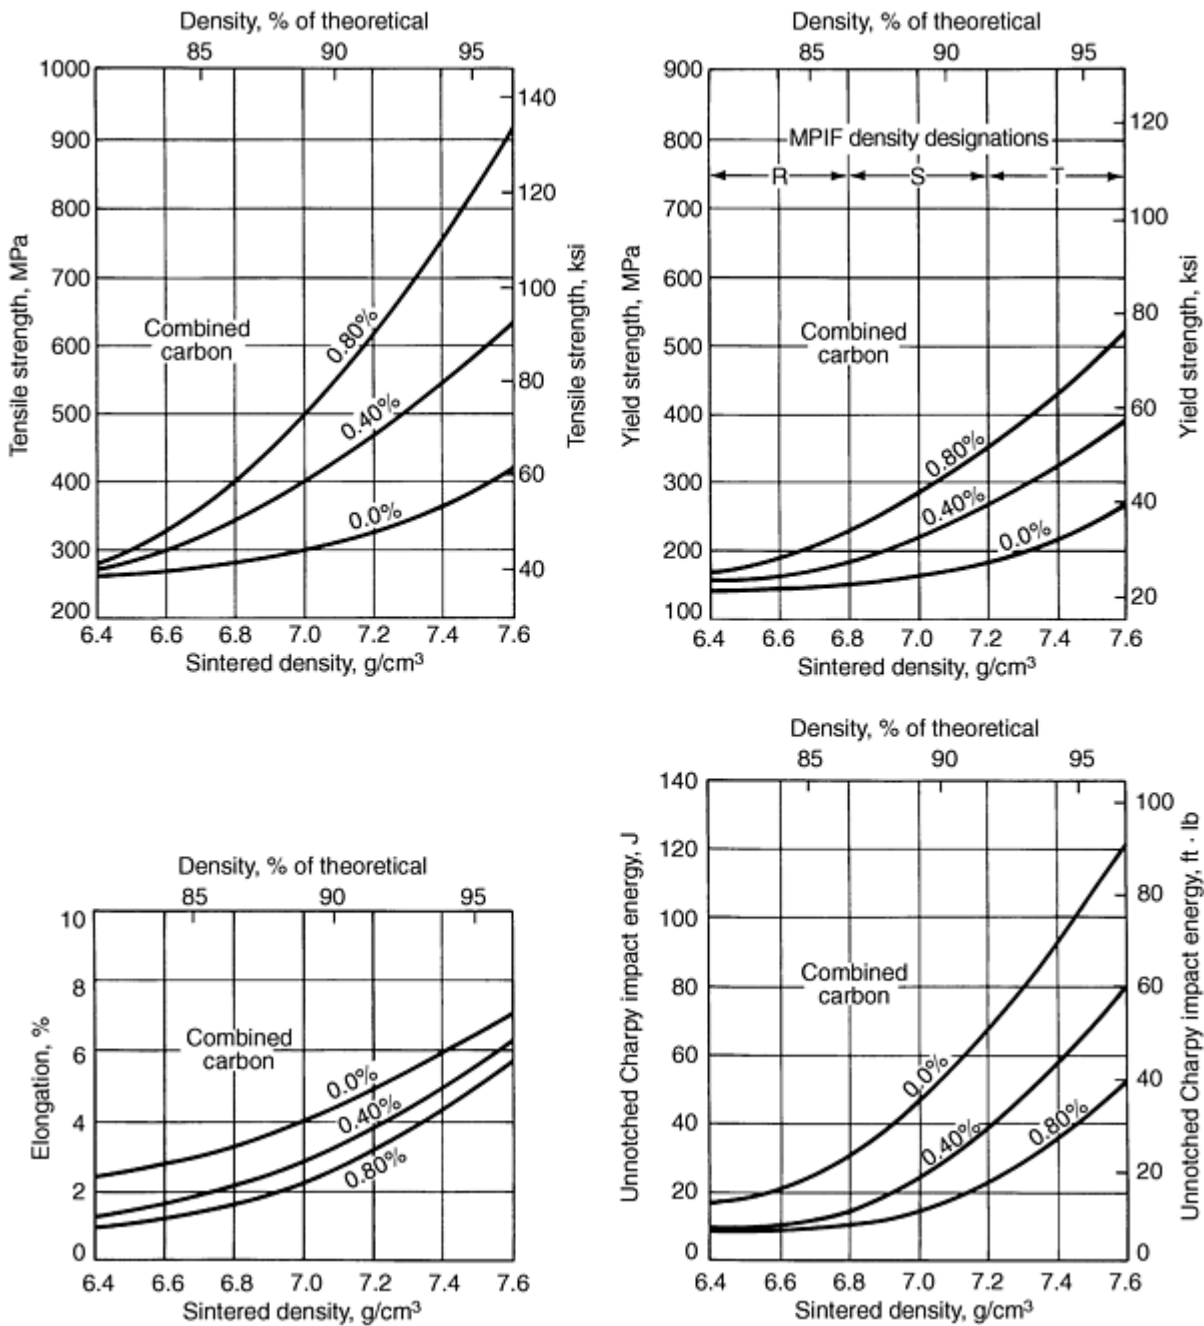

Fig. 8 Effects of density on mechanical properties of as-sintered 4% nickel steel (FN-04XX)

Transverse-Rupture Strength. Changes in mechanical properties of compacts that occur during sintering may be illustrated by comparing the properties of green compacts with those of sintered compacts. The strength of green compacts usually is determined by the transverse-rupture strength of rectangular compacts according to the American Society for Testing and Materials standard ASTM B 312 and the Metal Powder Industries Federation standard MIPF 15. The level of strength determined by this test is quite low, generally below 15 MPa (2000 psi). Strength must be adequate enough to allow handling of green compacts during transfer from the compacting press to the sintering furnace.

The transverse-rupture strength of sintered metal powder specimens may be determined by a test very similar to the green strength test. The test is only applicable to brittle P/M materials and is often mistakenly applied to ductile alloys, leading to high, but invalid values. It is described in ASTM B 528 and MIPF 35. Strength values obtained are much higher than those for green specimens. The values vary, depending on the type of material (lower for weak metals and alloys and higher for strong metals and alloys) and specimen density (ratio of sintered compact density to that of the solid material). The highest values will be achieved for the densest sintered compacts. The sintered strength values are usually at least 20

times the transverse-rupture strength of green compacts. For many sintered materials, transverse-rupture strength is 1.5 to 2.2 times the ultimate tensile strength.

Although transverse-rupture strength is not a design consideration, it is often used to measure the strength of specimens from a lot of metal powder and to compare its strength with a standard strength value. The transverse-rupture strength test of sintered metal powder specimens is applicable only to a relatively brittle material whose permanent deflection, as a result of testing, is less than 0.25 mm (0.010 in.). However, low-density, high-carbon P/M steels generally are relatively brittle. The transverse-rupture strength test is therefore applicable to such P/M steels.

Strength and Toughness. Materials with "near-full" density have strength properties comparable to those of wrought materials of the same composition. Strength decreases with decreasing density, but the rate of decrease is not nearly as rapid as the decrease in ductility (elongation and reduction in area) and particularly impact energy. These properties are generally much lower than properties of corresponding wrought materials. Only sintered materials with densities that closely approximate wrought materials (on the order of 99% or more of theoretical density) have ductility and impact energy properties that approach properties of corresponding wrought materials. However, the mechanical properties of many cast products are equaled or exceeded.

Hardness. The large difference in mechanical properties between green and sintered specimens does not apply to conventional indentation hardness testing, particularly Brinell hardness. Green compacts pressed at high pressures often exhibit high Brinell hardness values, which decrease when the compacts are sintered because the strain hardening introduced during compacting is relieved.

At still higher sintering temperatures, compacts shrink and hardness increases due to their higher density. Conversely, the hardness of compacts pressed at low pressures increases with increasing sintering temperature, because the effect of increase in compact density predominates. This is illustrated in Fig. 9, in which the hardness of compacts made of carbonyl iron powder pressed at three different pressures is plotted as a function of sintering temperature for a sintering time of 2 h.

Fig. 9 Brinell hardness of compacts from carbonyl iron powder. Pressed at 76, 138, and 386 MPa (11,000, 20,000, and 56,000 psi) and sintered for 2 h as a function of sintering temperature

Sintering of Single-Metal Compacts

As discussed above, important changes in the dimensions of compacts occur when green compacts are heated to the sintering temperature. In many sintering operations, green compacts shrink and may even reach the density of corresponding wrought materials. Even when compacts shrink only minimally or not at all, changes in interior geometry

occur. In pressed compacts, the approach of the surfaces of the individual powder particles toward each other to distances on the order of metal lattice dimensions is quite limited.

One of the important occurrences in the early stages of sintering is the increase in the contact strength between particles. This may occur without significant changes in the overall density of the compact. Another change within the green compact that does not necessarily involve large density change is the rounding and spheroidization of the pore structure, which is best observed by metallography. Changes in mechanical properties during sintering are, of course, a direct consequence of these geometrical changes.

During compacting, powder particles are subjected to strain hardening that increases with higher pressure. At low temperatures, sintering causes annealing, during which strain hardening is relieved, primarily through recrystallization. A small portion of the geometrical changes that occur in compacts during sintering results from recrystallization. However, the fact that a well-developed sintered microstructure is formed only at temperatures above the recrystallization temperature range indicates that the major driving force for sintering is the reduction in surface energy, not cold work.

The principal driving forces are capillary forces due to the surface and interfacial tensions, also called specific surface and specific interfacial free energies, of the free surfaces and the interfaces between grains (Ref 1). These forces cause stresses that are related to the curvature of the surfaces and interfaces. Stresses due to surface and interfacial tension forces tend to decrease the surface and the interfacial areas and are the principal driving forces in sintering.

In single-phase systems, the existing interfaces are the free surfaces between the solid and gas phase and the interfaces between grains with different orientations. The simplest case would be a single-phase, monocrystalline system, for which the relationship between surface tension (specific surface free energy) and stress is given by the Laplace equation:

$$\sigma = \gamma \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \quad (\text{Eq 1})$$

where σ is the stress, γ is the surface tension, and r_1 and r_2 are the radii of curvature of the surfaces. Under convex surfaces for which the curvature is negative, the surface stress is tensile ($\sigma < 0$). For concave surfaces with positive curvature, the surface stress is compressive. Experimental methods for readily determining the surface tension of metals and alloys at sintering temperatures are available (Ref 2). The stress defined by the Laplace equation causes a gradient in chemical potential between surfaces with different radii of curvature:

$$\Delta\mu = \sigma\Omega \quad (\text{Eq 2})$$

where Ω is the atomic volume.

Single-phase metal powders shrink rather than expand during sintering, except for soft metal powders compacted at high pressures. Gases entrapped in these compacts may expand when heated during sintering. Stress caused by gas pressure, which increases with increasing temperature, counteracts surface tension stresses that cause shrinkage.

In this discussion of the driving forces that cause sintering--or, more specifically, material transport during sintering--compacts are assumed to be sintered without the application of external pressure. If external pressure is applied, the capillary forces are of secondary importance compared to external forces, particularly in metallic systems.

Several possible mechanisms have been identified that cause material transport under the influence of a chemical potential gradient. In single-phase systems, the chemical potential gradient is due to the stress gradient between surfaces and interfaces.

One of the early mechanisms postulated is evaporation and condensation. Atoms evaporate from surfaces that have a higher vapor pressure and are transported through the gas phase to highly curved convex surfaces that have a lower vapor pressure, where they condense. Because most metals do not have high vapor pressures at temperatures near their melting points, evaporation and condensation contribute nominally to material transport in the most common metallic systems.

Diffusional flow is the most important mechanism of material transport (Ref 3). It is based on the concept that a certain concentration of vacancies exists in the crystal lattice of a metal. This concentration is a function of temperature and may reach values on the order of one vacancy for every 10,000 occupied lattice positions at temperatures near the melting point of the metal. Vacancy concentration also is a function of the chemical potential or stress to which the surface of the metal is subjected. Consequently, a gradient of vacancies exists between a highly curved convex surface, which has a higher vacancy concentration, and an adjacent flat surface, which has a lower vacancy concentration.

Studies of diffusional flow have concentrated on the first or initial stage of sintering, where the small necks between particles become larger. This causes rounding of the pores and some decrease in total pore volume. However, the original particles are distinguishable. The studies were based on theoretical analysis and on experiments on models, such as those in which a sphere is sintered to a flat surface (Ref 4) or in which two spheres are sintered together (Ref 5).

Figure 10(a) schematically illustrates a cross section of a two-sphere model. The radius, ρ , is formed at the end of the neck between the two particles in Fig. 10(a). Figure 10(b) shows the geometry near this radius in more detail. Assuming that the two particles are single crystals, with different orientations, a grain boundary is formed at the neck. The difference in curvature at the neck with ρ and the adjacent flat surface causes a difference in stress and chemical potential between the two points, which in turn produces a gradient in the concentration of vacancies between the highly curved neck surface, which has a high vacancy concentration, and the adjacent flat surface, which has a lower concentration.

Fig. 10 (a) Schematic cross section through two spheres sintering together. Radius, ρ , is at the end of the neck. (b) Types of material transport when two single crystal spheres with a grain boundary at the interface sinter together. Path *a*, volume diffusion from the flat surface to the neck. Path *b*, surface diffusion from the flat surface to the neck. Path *c*, grain-boundary diffusion from the grain boundary to the neck. Path *d*, volume diffusion from the grain boundary to the neck

The difference in vacancy concentration under surfaces with different radii of curvature can be expressed mathematically (Ref 3). This difference causes a flux of vacancies away from the highly curved surface to the flat surface, which is equivalent to a diffusional flow of atoms in the opposite direction.

There are two types of diffusional flow possible under the influence of vacancy concentration differences between flat and highly curved surfaces. They are volume diffusion, indicated schematically by path *a* in Fig. 10(b), and surface diffusion, indicated by path *b*. As shown in Fig. 10(b), these two types of diffusional flow cause rounding and spheroidization of irregular pores in a compact. However, they do not explain shrinkage, which would be represented by a decrease in the distance between the centers of the two spherical particles.

To explain shrinkage, flow of atoms from the grain boundary to the neck must be considered. This is indicated by path c , which represents grain-boundary diffusion, and path d , which represents volume diffusion from the interior of the grain boundary to the neck. When atoms flow from the grain boundary to the neck, vacancies flow in the opposite direction and are thus eliminated at the grain boundaries. This causes the centers of the two particles to approach each other, and shrinkage occurs. The rates of the diffusional mechanisms (volume diffusion, surface diffusion, and grain-boundary diffusion) vary significantly, and the geometries that govern transport also vary and are quite complex even for simple model systems, such as sintering a sphere to a sphere. Nevertheless, the calculated rates of pore rounding and shrinkage in model systems, based on known values of specific surface and interface free energy, and the various types of diffusivities closely approximate those observed experimentally (Ref 6).

Rates of material transport during the initial stage of sintering can be calculated for model systems such as the two-sphere model discussed above. The presence of neighboring particles has constraining effects on neck growth and shrinkage (Ref 7).

Mathematical models have been constructed not only for the initial stage of sintering, but also for the intermediate and final stages. During the intermediate stage of sintering, the original particles are less distinguishable, because the pore channels between particles are pinched off and become closed. Grain boundaries between the original particles migrate due to grain growth. The pores form a more or less connected continuous network throughout the compact. They become isolated in the third or final stages of sintering. Models for the intermediate and final stages of sintering are complex (Ref 8).

Homogenization During Sintering

Alloys may be produced by P/M techniques either by sintering compacts formed from homogeneous prealloyed powder particles or by first mixing different powders for shaping and sintering. Typically, powder mixtures exist as solute-rich particles (either elemental or master alloy) surrounded by a matrix of solvent particles (normally elemental particles of the base element of the alloy). The density to which the powder is pressed determines the degree of residual interparticle porosity.

Dispersion of the solute-rich particles facilitates rapid homogenization and can be optimized through use of proper mixing procedures and determination of the best particle size ratio (the finer the matrix particle size, the greater the dispersion of solute-rich particles). Overall alloy composition and composition of the solute-rich particles also can affect the dispersion, but sometimes are specified and cannot be considered independent variables. Density differences between two different types of particles often cause mixing difficulties. Such problems are minimized by varying the size ratio of the particles used.

Sintering causes solid-state diffusion (lattice diffusion) of the solute atoms into the solvent matrix and diffusion of solvent atoms into the solute-rich particles. Homogenization, as a function of time at temperature, may be described in terms of concentration/distance profiles. Over time, the local composition approaches the average compact composition as the concentration gradients are eliminated via interdiffusion. Generally, the compact behaves as a collection of many small diffusion couples that are allowed to undergo interdiffusion to the point where atomic fluxes become negligible and homogenization is achieved.

Variation in sintered density with sintering temperature and time during homogenization is frequently quite different compared to the variation that exists if compacts are composed of particles of identical composition. This is due to two phenomena, which have opposing effects on the densification of the compact. The matrix densifies due to pore shrinkage. Additionally, a net flow of vacancies from one particle to the other occurs if there is a difference in the fluxes of the atomic species to and away from a specific type of particle. These vacancies can accumulate in the form of pores, which is called Kirkendall porosity (Ref 9). The formation of Kirkendall porosity results in expansion of the compact.

The variation of sintered density with time for compacts made from a blend of nickel and copper powders is shown schematically in Fig. 11. Density of the compact first increases and then decreases until a minimum is reached, at which point the density appears to stabilize. In the initial stages of sintering (short sintering times), the densification mechanism dominates, and density increases sharply. However, a point is reached where density begins to decrease, indicating that the formation of Kirkendall porosity (expansion) has begun to dominate.

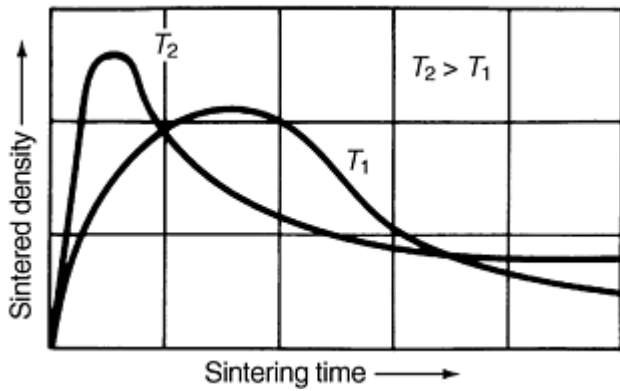

Fig. 11 Variation of sintered density during homogenization in nickel-copper compacts

With increased sintering time, density reaches a minimum, after which it remains almost stable (Ref 9). The time at which the density reaches a minimum indicates the point at which the two opposing mechanisms have balanced each other and that an advanced level of homogenization has been reached. The formation of Kirkendall porosity and its eventual stabilization are shown in Fig. 12(a) and 12(b), respectively. At higher sintering temperatures, the observed changes in density occur earlier.

Fig. 12 Formation and coarsening of Kirkendall porosity in compacts made from a blend of nickel (-325+400 mesh) and copper (-100+140 mesh) powders. Mean composition: 0.19 atom fraction copper. 100 \times . (a) $T = 850\text{ }^{\circ}\text{C}$ (1560 $^{\circ}\text{F}$); $t = 1.0\text{ h}$. (b) $T = 850\text{ }^{\circ}\text{C}$ (1560 $^{\circ}\text{F}$); $t = 24.0\text{ h}$

The formation of austenite during sintering of compacts from a mixture of iron and graphite powders is an example of complete homogenization. This is due to the high diffusivity of carbon in gamma iron at the sintering temperature. In this case, compacts generally exhibit only slight shrinkage during sintering. At the end of the sintering treatment at temperatures near 1100 $^{\circ}\text{C}$ (2010 $^{\circ}\text{F}$), compacts consist of homogeneous austenite. When cooled to room temperature at a moderate rate, the austenite transforms. The microstructure of a sintered steel of eutectoid composition (0.8% C content), which consists of the typical lamellae of ferrite and cementite (pearlite). Except for residual pores, this microstructure is similar to that of an annealed wrought eutectoid steel.

The following additional processing parameters can affect the rate and extent of densification or expansion during homogenization:

- Difference in the diffusivities of the particles in the compact
- Size of the particles in the compact
- Mean composition of the compact
- Compacting pressure
- Impurity content of the starting powders
- Entrapped gases within particles

Thus, the form of the density-time relationship for a specific homogenization treatment may vary, and it is frequently more complicated for multiphase systems.

Powder, Alloy System, and Homogenization Variables

Characteristics of the powder particles that compose the mixture exert a significant effect on homogenization kinetics (Ref 10). The sizes of the particles in the mixture establish the distance over which interdiffusion must occur to achieve homogeneity. In alloy mixtures where the elemental solvent particles form a continuous matrix around the dispersed solute-rich particles, particle size of the dispersed particles becomes the important parameter in establishing the interdiffusion distance (assuming that the proportion of the powders in the mixture is already established by the alloy composition desired). Very small powders, such as those produced by reduction of submicron mixtures of oxides or alternatively by mechanical alloying, result in diffusion distances that are small enough to preclude the consideration of homogenization.

The composition of the dispersed particles also can influence homogenization kinetics; for example, solvent alloyed into the solute-rich particles reduces the extent of inhomogeneity in the mixture and can shorten the interdiffusion distance. If the dispersed copper particles in a nickel matrix was 50% Cu, the amount of nickel needed in the mixture to achieve the same overall composition would be less, thus shortening interdiffusion distance.

Alloy systems with more than two components that contain more than a single phase are more difficult to analyze in terms of homogenization kinetics. Interdiffusion in single-phase ternary systems must be described by four diffusion coefficients to consider the diffusion of both solutes. Each is influenced by its own concentration gradient and that of the other solute.

Multiphase binary systems must be described by the solute solubilities and interdiffusion coefficients of each of the phases present (Ref 10, 11, 12). In such complexities, the parameters required to analyze the homogenization process are not available, and reasonable simplifications (assumption of binary and/or single-phase behavior) are made. Similarly, the presence of a transient liquid phase at the outset of the homogenization process also is difficult to analyze, and reasonable approximations are necessary.

The duration of sintering required to achieve a desired degree of homogeneity is critically dependent on temperature, because interdiffusion coefficients (\tilde{D}) (units of length squared time) are exponentially dependent on temperature:

$$\tilde{D} = D_0 e^{-Q/RT} \quad (\text{Eq 3})$$

where D_0 is the preexponential factor, Q is the activation energy, R is the universal gas constant, and T is the absolute temperature.

For example, the interdiffusion coefficient for most solid-solution elements in nickel doubles for every 50 K increase in temperature near the liquidus. The total duration (t) of elevated-temperature treatment to achieve essentially complete homogenization is inversely proportional to \tilde{D} :

$$t = k \ell^2 \tilde{D} \quad (\text{Eq 4})$$

where ℓ is the average diameter of the dispersed particles and k is a constant, depending on alloy system parameters, powder particle compositions, and overall alloy composition. For example, k is approximately 0.2 for a 4-to-1 mixture of elemental powders that exhibits complete solid solubility (Ref 10). Thus, it can be seen that both the homogenization temperature and the size of the dispersed particles are the most significant variables in controlling homogenization kinetics.

Mixing and mechanical working during powder fabrication of an alloy also can influence homogenization kinetics (Ref 10, 13). Ideal mixing is assumed in Eq 4 to predict homogenization time. Inadequate blending technique or incompatible powder particles (significantly different sizes and/or densities) result in poor mixing. The greatly enlarged interdiffusion distances dictate longer homogenization times. The serious problems of poor mixing stem from homogenization time being proportional to the square of the interdiffusion distance.

Effective interdiffusion distance may be reduced and homogenization kinetics increased by mechanical working (Ref 10). Such working has the same effect as a reduction in particle size of the dispersed particles. However, the effect of a given mechanical working reduction is less than that indicated by the same reduction in ℓ in Eq 4, because the spherical diffusion flux geometry in a compacted mixture of powders is changed to the less efficient unidirectional flux (by rolling) or cylindrical flux (by extrusion). Any enhancement of homogenization kinetics will result only if mechanical working reduces the thicknesses of the solute-rich regions, little, if any, increase in homogenization kinetics is exhibited during subsequent thermal processing.

Determination of the Degree of Homogeneity

Direct experimental techniques for the determination of the progress of homogenization or the evaluation of the state of homogeneity include microscopy (qualitative and quantitative), compositional analysis of the microstructure via electron microprobe analysis or scanning electron microscope instrumentation, magnetic, electrical, or x-ray compositional line broadening techniques (Ref 10, 11, 12, 14).

X-ray compositional line broadening is a technique for the rapid determination of the degree of homogeneity. It displays the spectrum of compositions existing in a given inhomogeneous phase from the shape of a diffraction peak broadened by a range of lattice parameters in the phase. This technique may be used for the analysis of single-phase or multiphase binary alloys. The experimental procedure involves obtaining x-ray diffractometer patterns of the specimen whose degree of homogeneity is to be determined.

The progress of homogenization is seen clearly, although qualitatively, in Fig. 13. The Ni (311) peak occurs at a diffraction angle $2\theta \approx 93^\circ$, and the Cu (311) peak occurs at $2\theta \approx 90^\circ$. Figure 13(b) indicates that the initial stages of homogenization (low temperatures and short times) proceed by forming the complete range of compositions from nickel to copper. This is the manifestation of the initial interdiffusion across the nickel-copper interparticle boundaries.

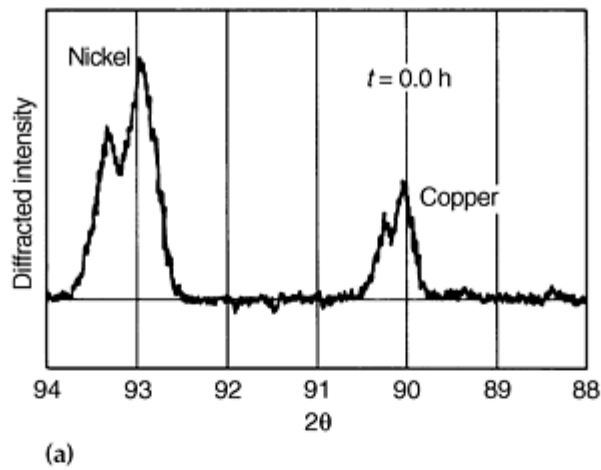

Fig. 13 X-ray diffraction peaks (311) for compacts of blended nickel and copper powders. Mean composition: 0.28 atom fraction copper. Nickel: -400 mesh. Copper: -200+270 mesh. (a) Initial condition. (b) and (c) Various partially homogenized conditions

As shown in Fig. 13(c), later stages of homogenization (high temperatures and long times) result in the formation of a single peak at a diffraction angle between those of pure nickel and pure copper. This corresponds to the approach to a single homogeneous phase having the mean composition of the system. The diffraction angle of the single peak is determined by this mean composition. Quantitative analysis of peak shapes can be used to obtain the spectrum of phase compositions within a specimen.

Microscopy is also useful to determine the degree of homogeneity, particularly for multiphase systems that are difficult to analyze using x-ray compositional line broadening techniques. Figure 14 shows the development of microstructures and the progress of homogenization in compacts made from a blend of nickel and tungsten powders. In a partially homogenized compact (Fig. 14), three distinct regions are apparent:

- Dispersed light gray particles (the undissolved tungsten-rich phase that originated as tungsten particles)
- Dark gray unetched regions surrounding the tungsten-rich particles (the nickel-rich phase that has tungsten concentrations ranging from approximately 0.05 atom fraction of tungsten at the interface between the etched and unetched regions up to 0.17 atom fraction of tungsten at the interface between the unetched region and the tungsten-rich particles)
- Etched matrix (the nickel-rich phase that has tungsten concentrations less than 0.05 atom fraction)

Fig. 14 Scanning electron micrographs showing the progress of homogenization in compacts made from a blend of nickel (-400 mesh) and tungsten (-325+400 mesh) powders. Mean composition: 0.05 atom fraction tungsten. 75 \times . (a) $t = 0.0$ h. (b) $T = 1150$ °C (2100 °F); $t = 10.0$ h. (c) $T = 1150$ °C (2100 °F); $t = 48.0$ h

Quantitative microscopy can be used to determine the extent of homogenization in multiphase systems. This technique is compatible with x-ray compositional line broadening (XCLB) in providing data on the presence of second phases and may be performed on the same test specimens used for XCLB measurements.

Activated and Liquid-Phase Sintering

In activated sintering, the rate of sintering is enhanced compared to that observed in compacts of a single metal powder or a homogeneous alloy powder. The process to which the term activated sintering is applied are the solid-state sintering processes. In contrast, liquid-phase sintering refers to processes in which a liquid phase is formed. Of the two types of liquid-phase sintering discussed in this article, the solution and reprecipitation process frequently is used to provide enhanced liquid-phase sintering. Transient liquid-phase sintering, however, may be used for applications where rapid densification is undesirable, or where alloy formation is desired.

Enhanced sintering, whether achieved by activated or liquid-phase sintering, is commonly used with refractory metals. This is due to the difficulties associated with the extremely high sintering temperatures of these metals. The problems in understanding conventional sintering are compounded in enhanced sintering by the presence of a second phase or supplemental treatment. Most enhanced sintering studies have been conducted with little or no theory to predict beneficial treatments. The eventual success of this approach cannot be denied. A theory to explain such behavior has evolved (Ref 15).

Sintering enhancement generally results from an increased driving force, through physical or chemical treatments. Many such processes are well known. While most attention has focused on tungsten, several other materials, including molybdenum, rhenium, iron, tantalum, uranium, tin, copper, aluminum, titanium, and several ceramic materials, have been investigated.

Enhancement of the sintering process generally is attributed to one or more changes in the fundamental material properties resulting from a special treatment. The strongest effects are those associated with changes in the interfacial properties (higher surface energy or lower grain-boundary energy). Alternatively, a less common means is to induce the operation of a normally dormant mass transport mechanism.

To the ceramist, many of these phenomena are commonplace. Impurities and stoichiometry departures can provide enhanced sintering of many ceramic materials. Likewise, the sintering atmosphere can have a profound influence on sintering rate, as well as the sintering mechanism. Any change in a material that induces an enhanced defect concentration or higher atomic mobility or that promotes the operation of new mass transport processes is considered enhanced sintering.

Typically, enhanced mass flow during the sintering cycle is beneficial. However, in the fabrication of filters, porous bearings, and flow restrictors, enhanced sintering can be detrimental. For most P/M materials fabricated for structural, magnetic, radiation, thermal, or electrical applications, improved service properties are associated with greater mass flow during sintering. Hence, any technique that delivers a greater degree of sintering is beneficial to these applications.

Usually, superior sintered properties are ensured by a higher sintered density. Pressing to high densities (above 90% of theoretical) before sintering is difficult. Consequently, specific techniques have evolved to enhance densification of powder compacts during sintering. Although the mathematics describing densification are somewhat formidable, they provide a concise description of the effects of the various process parameters. In a qualitative sense, there are some useful concepts worthy of review. For example, a smaller grain size (or smaller particle size) aids sintering densification and final properties. Higher sintering temperatures have a significant effect (because of an exponential term), thus increasing the rate of densification.

In a similar manner, a lower process activation energy has the same effect as an increase in sintering temperature. By contrast, a large pore size inhibits densification. Sintering time has a nominal effect on densification; generally, prolonged sintering is not advantageous, because grain size is increased. The grain size increase reduces the amount of grain-boundary area, thus reducing the beneficial effects of the enhanced diffusion rates at grain boundaries. Furthermore, time at temperature is expensive and usually is avoided for economic reasons.

Phase Changes. As previously discussed, compacts made from powders of body-centered cubic metals exhibit more rapid sintering than compacts made from face-centered cubic metals. This is directly related to the higher diffusivities in metals with a body-centered cubic lattice structure compared to metals with a face-centered cubic lattice structure.

In sintering compacts of iron-base compositions, it may be desirable to achieve maximum shrinkage rather than dimensional control. The body-centered cubic phase of iron (ferrite) is unstable at the usual sintering temperatures of 1000 to 1300 °C (1830 to 2370 °F). However, this phase may be stabilized in iron alloys with silicon or molybdenum. This is achieved by sintering compacts of mixtures of iron powder and ferrosilicon or molybdenum powders. Densification increases with the amount of ferrite stabilized at the sintering temperature. Increased densification is most likely due to the higher diffusivity and the fact that the phase boundary is a good vacancy sink. Additionally, the mixed phase microstructure resists grain growth during sintering.

Consolidation Principles and Process Modeling

Revised by Randall M. German, Pennsylvania State University

Activated Sintering

Activated sintering refers to any of several techniques that lower the activation energy for sintering. Several techniques have been developed to achieve this goal, including chemical additions to the powder and the use of special atmospheres. In this respect, the sintering treatments described previously in this article that achieve stabilization of the body-centered cubic crystal structure in iron are considered a form of activated sintering.

Many of the detailed investigations of activated sintering have been conducted on tungsten. Tungsten without special treatment exhibits a high level of porosity and is quite weak. Treatment with 0.4 wt% Pd promotes activated sintering. Diminished porosity produced with enhanced sintering increases strength significantly.

Fine tungsten powder coated with a uniform layer of certain transition metals undergoes rapid densification at unusually low temperatures. The amount of additive required to promote low-temperature sintering is equivalent to one atomic layer on the powder surface. Additive contents above this amount produce minimal further enhancement in sintering and tend to lessen the degree of activation. Densification occurs in two stages. The second, slower stage begins with the onset of grain growth. Thus, the importance of grain boundaries is well demonstrated in activated sintering studies.

The effect of palladium as an activator in the sintering of tungsten on the compressive strength of tungsten compacts is shown in Fig. 15. The strength of the compacts is plotted as a function of palladium content and sintering temperature. In addition to the amount of activator and sintering temperatures, particle size of the powder is an important parameter. In Fig. 16, the density of sintered compacts of two types of tungsten powder with 0.5 and 5 μm particle size doped with nickel are plotted as a function of nickel content.

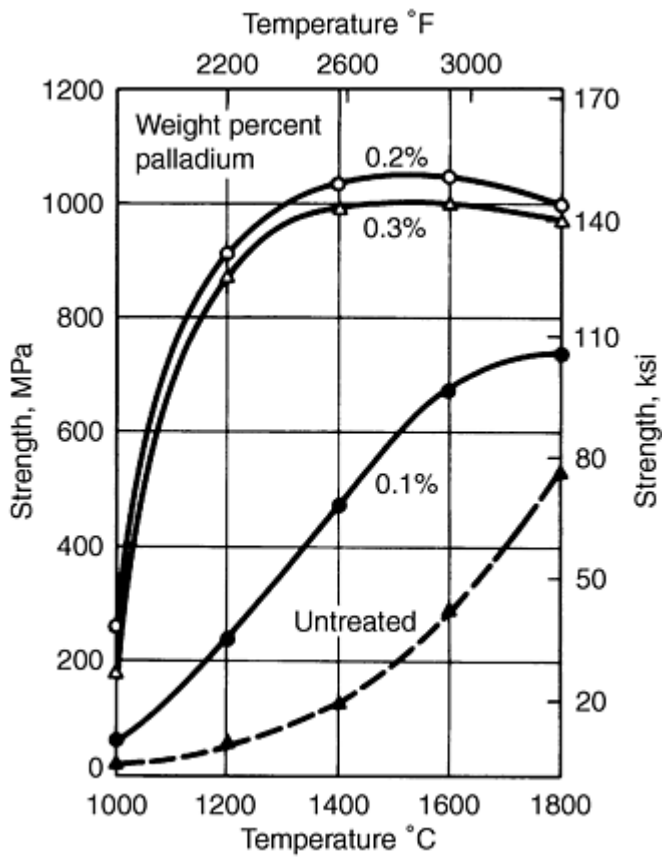

Fig. 15 Compressive strength of compacts from 0.8 μm tungsten powder. Treated with varying amounts of palladium as a function of sintering temperature

Fig. 16 Density of compacts of two tungsten powders treated with nickel with 0.5- and 5- μm particle size. Sintered 1 h at 1400 $^{\circ}\text{C}$ (2550 $^{\circ}\text{F}$) as a function of the amount of nickel

The type of additive that proves successful as an activator must meet several criteria. First, it must form a phase that has a lower melting temperature than the base metal being sintered. Second, the activator must have a high solubility for the base metal, while the base metal should have a low solubility for the activator. The function of the activator is to remain segregated to the interparticle interfaces during sintering. Such a segregated layer provides a high diffusivity path for rapid sintering. A lower melting temperature ensures a lower activation energy for diffusion, while the solubility ensures that the activator is not dissolved into the base metal during sintering. Typically, an activator that decreases the liquidus and solidus of the base metal remains segregated to the interface between particles. Figure 17 shows an ideal phase diagram for activated as well as liquid-phase sintering systems. Note that at temperatures slightly above the activated sintering range, a liquid forms. The formation of a liquid phase is another means of enhancing sintering.

Fig. 17 Idealized phase diagram showing favorable conditions for enhanced sintering by activated and liquid-phase sintering

The kinetics of activated sintering are dependent on the rate of diffusion of the base metal through the thin activator layer. It is necessary to form sufficiently thick layers to provide significant diffusion fluxes by sintering activation. Concentrations above this level frequently do not prove beneficial. The measured activation energies for shrinkage in activated systems closely approximate those for self-diffusion in the activator. Because the process has a low activation energy for diffusion, temperature is the most sensitive process control. The mechanism resembles grain-boundary diffusion-controlled sintering, thus shrinkage initially depends on the cube root of time. During the later stages of sintering, the rate of grain growth appears accelerated because of the low porosity and the high grain-boundary motion. Consequently, rapid grain growth during long-term sintering actually degrades the sintering rate and sintered properties.

Activated sintering also refers to sintering processes in which activation is produced through control of the sintering atmosphere. For example, the addition of a halide to the sintering atmosphere aids transport during sintering by the formation of high-vapor-pressure molecules. Consequently, major changes in pore shape are possible. In such cases, the sintered product has greater strength and significantly higher ductility.

Table 2 compares the strengths and the ductilities for iron compacts sintered in hydrogen. The addition of 1% hydrogen chloride to a hydrogen atmosphere results in improved properties. Metallographic examination indicates that the main effect of the hydrogen chloride is in promoting more rapid vapor phase transport by iron chloride molecules. Improvement in mechanical properties has been demonstrated in other systems. It is thus possible to achieve unique benefits from the sintering atmosphere in addition to control of oxide or carbon content.

Table 2 Effect of hydrogen chloride on iron sintered in hydrogen

Temperature °C	°F	Time, min	Atmosphere, % hydrogen chloride	Density, g/cm ³	Strength		Elongation, %
					MPa	ksi	
950	1740	30	0	6.20	131	19	6
		30	1	6.30	159	23	10
		120	0	6.30	138	20	6
		120	1	6.30	159	23	10
1375	2505	30	0	7.00	193	28	11
		30	1	7.20	234	34	20
		120	0	7.50	234	34	17

Chemical additions are the most successful means of effecting activated sintering. Other processes, such as radiation treatments, have been successful in promoting rapid sintering. However, there has been little interest in this process. Sintering activation treatments can be classified as means of altering either the kinetics or the driving force of sintering. In radiation bombardment, sintering kinetics are altered by the creation of a vacancy excess. This eliminates the vacancy formation energy from the activation energy for diffusion. Alternatively, treatments such as cyclic heating of a material such as iron through the polymorphic phase transformation represent a change in the driving force. In the latter case, cyclic heating generates an internal stress, which effectively raises the driving force. Such a treatment is analogous in some respects to external stresses with hot pressing.

Liquid-Phase Sintering

In systems involving mixed powders, liquid formation is possible because of the differing melting ranges of the components. Common systems involving liquid-phase formation during sintering include copper-cobalt, tungsten-copper, tungsten-nickel-iron, tungsten-silver, copper-tin, iron-copper, tungsten carbide/cobalt, and copper-phosphorus. Because of the faster sintering and superior properties, liquid phase sintering is applied to 70% of all P/M alloys and accounts for 90% of the value of all sintered products.

Heating of a mixed-phase system begins with a mixture of elemental powders. When the liquid forms, it flows and wets the solid particles and begins acting on the solid phase. Melt penetration between the solid particles can cause swelling of the compact, especially if the green density is high, and the particles are coarse.

However, along with melt penetration, there is possible rearrangement of the particles. The combination of wetting, liquid flow, and particle rearrangement contributes to a rapid change in the volume of the compact. With continued heating in the presence of a liquid phase, the solid phase begins to dissolve. Depending on the solubility limit, amount of liquid, phase diagram, and composition of the alloy, one of two actions occurs. If a solid has a high solubility in the liquid, the liquid composition may recross a solidus boundary of the phase diagram and solidify. This is termed transient liquid-phase sintering.

A commercial application of transient liquid-phase sintering is the production of self-lubricating bronze bearings by sintering compacts from a mixture of copper and tin powders. In these bearings, porosity must be controlled. The goal of this process is not to achieve rapid densification, but to control carefully the changes in density during sintering. This is achieved by proper selection of the initial particle size distribution of the powders, compacting pressure, sintering temperature, and rate of heating the compacts.

An alternative type of liquid-phase sintering is the solution and reprecipitation method, in which a limited solubility of the liquid phase in the solid is evident. In this type of sintering, the amount of liquid grows until saturation for the base phase is achieved. With continued time at temperature, the liquid phase becomes a carrier for the solid-phase atoms. Solution and reprecipitation does not change the amount of liquid and solid; however, it may lead to coarsening of the solid phase. Accordingly, the solid phase achieves a higher packing density through particle shape accommodation, with a flattening of faces.

An example of phase accommodation in liquid phase sintering is given in Fig. 18, which depicts a tungsten-nickel-iron alloy containing 95% tungsten. This material has achieved a high tungsten packing density (and full densification) by

shape accommodation of the tungsten grains. The grains are several times larger than the tungsten particles in the original powder mixture.

Fig. 18 Compact of 95 wt% W, 3.5 wt% Ni, 1.5 wt% Fe. Sintered 1 h at 1470 °C (2680 °F). Murakami's etch. 350×

Another example of liquid-phase sintering with solution and reprecipitation is shown in Fig. 19, which represents a cemented tungsten carbide with 10% cobalt. In this example, the solid-phase tungsten carbide grains are triangular and rectangular, rather than rounded. Their size is only slightly larger than that of the tungsten carbide powder particles in the powder mixture, indicating a slow rate of coarsening.

Fig. 19 Microstructure of tungsten carbide/cobalt alloy with 10 wt% Co. Murakami's etch. 1500×

The degree of dimensional change in the solution and reprecipitation type of liquid-phase sintering can be quite large. A schematic plot of density versus sintering time is given in Fig. 20. Initially, the liquid forms and contributes to rapid densification through rearrangement. Subsequently, the rate of sintering slows as the solution and reprecipitation stage begins. During sintering, the solid phase forms an interconnected network, which further reduces the densification rate. The use of small particles and large volume contents of liquid phase aids the achievement of high sintered densities in short times. With prolonged sintering, coarsening of the microstructure results, and shape accommodation is evident. Generally, coarsening should be avoided, because it degrades the mechanical properties, although it is often favored in magnetic components.

Fig. 20 Density versus sintering time for liquid-phase sintering

Liquid-phase sintering kinetics generally are more sensitive to temperature than to sintering time. For solution and reprecipitation shrinkage, the transport path is through the liquid phase. In the final stage, solid-state sintering is dominant, and the rate of densification is quite low. Hence, the major focus is on the solution and reprecipitation stage, where larger amounts of liquid and higher solubilities aid densification. Increasing the liquid content up to approximately 35 vol% aids initial densification. Beyond this amount, little benefit is gained, as full density has been achieved already. Such large amounts of liquid phase are not used, because most alloys lack sufficient rigidity during sintering to maintain dimensional or shape control.

Green density and initial particle size can have a profound effect on densification. Coarse particle size and high green density offset the favorable effects of the liquid. In many systems, swelling rather than densification results. The melt penetrates along the interparticle junctions and causes particle separation. Expansion occurs if there is not rapid dissolution of the solid phase.

Throughout liquid-phase sintering, material is transferred through the liquid phase. When the interfacial tension between the solid and the liquid phase is isotropic (liquid solidifies to same crystal as solid), a microstructure of smooth, rounded grains of the solid phase is produced in the matrix, as shown in Fig. 18 for a tungsten-nickel-iron alloy. When the interfacial tension between the solid and the liquid phase is highly anisotropic (the liquid precipitates at least one crystal type different from the solid), as in the tungsten carbide/cobalt system, a microstructure of rectangular or triangular particles is produced in the matrix, as shown in Fig. 19. The initial green compacts exhibit considerable porosity and irregular particle shape. After liquid-phase sintering, the microstructure shows essentially full density.

In many applications of the solution and reprecipitation type of liquid-phase sintering, the solid phase coarsens considerably with increasing sintering time, as shown in Fig. 18. In other cases, such as the tungsten carbide/cobalt system, change in the size of the solid-phase particles is minimal once characteristic shape has been established. In general, higher sintering temperatures cause increased microstructural coarsening.

The occurrence of swelling in liquid-phase sintering has been the subject of extensive study. In the iron-copper system, the onset of swelling is best explained by melt penetration along the grain boundaries within the iron particles. As a consequence, iron particles disintegrate and separate. If the amount of liquid is large, green density is high, and the particles are coarse, then swelling is more likely. Swelling can be controlled by selecting a finer particle size, lower compaction pressure, and slower heating rate. In the iron-copper system, the addition of carbon also offsets swelling. Carbon inhibits melt (copper) penetration of the iron grain boundaries.

The solution and reprecipitation types of liquid-phase sintering and activated sintering are similar in many respects. Both involve the use of a second phase at the sintering temperature to provide rapid mass transport by an effective short circuit path. As shown in Fig. 17, the phase diagram characteristics applicable to both enhanced sintering techniques are similar. Furthermore, the use of fine initial particle sizes and short sintering times produces the best sintered particles. Grain

coarsening via rapid diffusional processes is experienced with both forms of enhanced sintering. Closing of large pores is slow by either technique.

A major difference between liquid-phase and activated sintering is the amount of second phase sintering is the amount of second phase present at the sintering temperature. Liquid-phase sintering systems typically have several times more second phase than activated sintering systems. In many respects, this is beneficial, because the second phase is the continuous phase in the sintered product and is better able to sustain strain and deformation, leading to improved mechanical properties.

Consolidation Principles and Process Modeling

Revised by Randall M. German, Pennsylvania State University

Process Modeling

The modeling of powder processing is quickly advancing, especially as numerical simulation tools become widely available. Die compaction, hot isostatic compaction, mixing, sintering, injection molding, hot forging, and extrusion are now computer simulated on a routine basis in production operations. Unfortunately, most of these models are proprietary, and details are closely guarded. Two areas where there is much information on powder processing models is in sintering. The activities started in the 1960s, but computation speed was slow. Over the next several years, the sophistication of the models progressed, and the computer speeds advanced, making it possible to computer simulate real sintering cycles in seconds. Thus, experimentation is more rapid via simulation, as compared to experimentation. Many powder processing operations have embraced these new technologies as tools to improve production control and process specification. As a few examples, the basic concepts in modeling die compaction and solid-state sintering are considered. Further information can be found by referring to the Selected References .

Die Compaction

The major difficulty with die compaction traces to die wall friction. This friction inhibits ejection and, more importantly, causes density gradients in the green compact. Punch motion against the powder is similar to plowing snow. Close to the punch, the packing is dense, but far removed from the punch, the powder is unaffected. This pressure decay with distance is because the powder spreads load to the die wall in the form of friction.

Green density increases with compaction pressure. Consequently, density declines with distance from the punch. When the compact length is approximately six times the width, then the powder is poorly compressed. This is among the reasons why most die compacted parts are squat, to minimize density gradients. Also, density gradients are reduced when both the upper and the lower punch move toward the compact center. Double action pressing is a term used to describe the application of stress from both the top and bottom punches. In one variant, the die floats with respect to the lower punch, giving double action even though the lower punch remains stationary. Positive die motion ensures uniformity in green density. Inside the compact, the point where the lowest density occurs is the neutral pressure plane, and in most instances, the desire is for the neutral plane to be in the center of the compact.

As the compaction pressure and density increase, the die wall friction also increases. The die wall friction is proportional to the radial pressure when the powder is compressed uniaxially. By the end of the compaction stroke, wall pressures exceed 50% of the applied pressure. Thus, the higher the applied pressure is, the higher the radial pressure and concomitant die wall friction.

If pressure decays with depth in a compact due to wall friction and green density depends on local pressure, then die compaction results in green density gradients. Besides friction with the die wall, an additional factor is friction on the punches and core rods. Consequently, an objective of computer simulations is to calculate the green density contours in a multiple level compact pressed under a variety of press or tool options. If there are large density gradients, then the compact will exhibit nonuniform shrinkage or swelling in sintering, resulting in component distortion and loss of precision. Low density regions tend to change dimensions more in sintering as compared to high density regions.

Minimized density gradients are important to final dimension control. Accordingly, much study has been focused on reducing density gradients. Unfortunately, most cures possible by changing the powder or alloy are ineffective, but a few

concepts are important. However, computer simulation techniques show some important options. These include keeping the compact thin in the pressing direction (thickness), lubricating the die wall, and double action pressing. One alternative being studied is to move the top punch in a circular motion, which causes powder flow in a sideways motion to help eliminate low density regions. The need for minimum density gradients increases as the component becomes more complex. Since die wall friction is the culprit, the more die wall there is per unit volume, the greater the problem. This is one of the major barriers to the production of precise gears to P/M, since gear teeth have a large surface area leading to more die wall friction and larger density gradients.

Because of density gradients, problems occur with local weak spots, cracking on ejection, and subsequent component warpage in sintering. Thus, much effort is being applied to calculation of density gradients in pressing. Usually the friction between the powder, die, and punches is the main cause of density contours, but there is possibly a large effect from the die filling operation, especially if powder separation or nonuniform flow occurs. Most of the calculations are performed using a concept of finite element analysis. In this approach, the component is numerically subdivided into hundreds of tiny computation cells. The placement of these calculation cells is visible on the component as a fine mesh. Each cell compresses and deforms based on the forces from the neighboring cells using equations that relate pressure to density. Computer calculation of what happens in each cell then determines the flow of mass and stress through the compact, resulting in the plotted density contours. Soon, most tooling design and compaction setups will be guided by such computer simulations, with the goal being reduction of density gradients and weak spots in the compact. The aim is to make the tooling correct with minimal trial and error. Most tool design is assisted by computer-aided engineering packages. These packages allow accurate drawings and analysis of form, fit, and function. Also, finite element analysis is used to assess the stresses on the press and in the tool sets. Accordingly, the leading press manufacturers provide codes for analysis of press frame deflection. Of course, such efforts require knowledge on the part size and shape, and powder characteristics.

Most presses operate in an open-loop control mode. The position of the various tool members is adjusted at the beginning of a production run, but no monitor is provided for following operation conditions. Parts are selectively checked for weight and dimensions, but the preservation of the desired tool motions, pressures, fills, and other characteristics of compaction is not ensured.

A few advanced presses include pressure sensors, displacement transducers, strain gages, temperature sensors, position sensors, and other monitors needed to watch for consistent production. Rarely does this advance to in situ control where instantaneous corrections are made; although a few hybrid computer controlled presses are now installed. If sensors are used, they usually measure the die temperature and strain, upper and lower punch loads (via in-line transducers), and relative displacement of the tool components. Hydraulic and computer numerical controlled presses prove easier to instrument and control. For example, in-line load cells can be used to adjust pressure on the hydraulic cylinder via a servo-hydraulic valve. This results in one form of a hydraulic computer numerically controlled press, best suited to complex, multiple level part. The result is more consistent densities. Likewise, a few presses have multiple step feed shoes. The first step weighs the powder charge to ensure the proper amount is used in filling.

Computerization of die compaction has two objectives. One objective is to record the operating data, including set-up parameters and production data. This allows initialization at the same conditions each time the tooling is installed. In one variant, the tool setup is fully automated using computerized electric motors. The second variant is to monitor trends in parts. Part-to-part variations and differences between production lots are both concerns, which require monitoring systems and logic systems. Robots might be coupled to the press for component extraction, placement on sintering trays, or inspection. These too are coupled into the logic and control system. Pick and place robots are used on large volume production items, but much of the P/M industry relies on human intervention should there be a problem.

Monitoring is largely through load measurements in the pressing direction. Logic systems then decide what changes are appropriate when drifts in product quality are detected. Most important, these systems can stop production in cases where tool damage might occur. For example, if the powder fill changes, then excessive powder in the cavity might deform a punch. A load monitor during compaction would detect such a change and halt production. Generally only three monitors are used to detect product quality drift at the press: changes in weight, changes in compaction load, or changes in dimensions. The latter parameter might be manually input to the control computer via an operator.

Solid-State Sintering

The growth of the sinter bond from an initial loose powder contact is characterized as the initial stage of sintering. In this stage, the neck size is sufficiently small that neighboring necks grow independent of one another. The initial stage ends

when the necks begin to impinge. Various laws link the neck size ratio to other useful sintering parameters, including shrinkage, surface area, and density.

Computer analysis of initial stage sintering has been a popular theoretical topic. Early codes assumed sintering occurs between two equal spheres with conservation of volume by a single mass transport mechanism. Thus, any change in the neck size must have a corresponding functional relation to the volume of material deposited at the neck. There is a gradient in the curvature over the sintering geometry. The curvature gradient drives the mass flow, by any of the mechanisms presented, to smooth the surface and possibly densify the structure. At any point on the neck, there is a surface contour defined by the function $S(v)$, where v is a parameter describing the spacial relation between the x - y coordinate system and surface position. Consider surface transport controlled sintering where at any point on the surface curve the following exists:

$$\frac{dS}{dv} = \left[\left(\frac{dx}{dv} \right)^2 + \left(\frac{dy}{dv} \right)^2 \right]^{1/2} \quad (\text{Eq 5})$$

The instantaneous change in the neck profile depends on the normal motion at the surface, which can be described in the following manner:

$$\left(\frac{dS}{dv} \right)^{-1} \left(\frac{dx}{dv} \mathbf{Y} - \frac{dy}{dv} \mathbf{X} \right) \quad (\text{Eq 6})$$

where \mathbf{X} and \mathbf{Y} are the unit axis vectors. At point v on the neck profile, the principle radii of curvature are expressed according to the following:

$$R_1 = y \frac{dS/dv}{dx/dv} \quad (\text{Eq 7})$$

and

$$R_2 = \frac{dS/dy}{\left(\frac{d^2y}{dv^2} \right) \left(\frac{dx}{dv} \right) - \left(\frac{d^2x}{dv^2} \right) \left(\frac{dy}{dv} \right)} \quad (\text{Eq 8})$$

This allows determination of the local curvature κ :

$$\kappa = \frac{1}{R_1} + \frac{1}{R_2} \quad (\text{Eq 9})$$

It is the curvature gradient from point to point that drives the flux of atoms during initial stage sintering. Comparing the curvature at a position v and neighboring positions $v - 1$ and $v + 1$ gives a basis for calculation of the flux. According to Fick's first law, the flux depends on the curvature gradient at each point and the mobility of atoms, meaning the neck volume change depends on the arrival rate for mass at the sinter bond:

$$\frac{dV}{dt} = JA\Omega \quad (\text{Eq 10})$$

where J is the atomic flux, A is the bond area over which the new mass is distributed, and Ω is the volume of a single atom or molecule. The change in curvature with position gives a chemical gradient that directs mass flow into the sinter bond between the particles. The deposited or removed atoms change the neck size and shape. In turn the new shape and curvature gradient influence the flux. High temperatures promote faster mass transport and thereby contribute to faster

neck growth. Many concurrent deposition processes react simultaneously to the same driving force. Consequently, accurate calculations of sintering rates require numerical techniques.

Sintering models with simplified forms are available that provide an estimate of the relative rate of neck growth from any transport mechanism. These result in the following initial stage sintering model for the neck size ratio X/D as a function of sintering time t under isothermal conditions:

$$\left(\frac{X}{D}\right)^n = \frac{Bt}{D^m} \quad (\text{Eq 11})$$

where X is the neck diameter, D is the particle diameter, t is the isothermal sintering time, and B is a term that collects material and geometric constants that are specified in Table 3. The values of n , m , and B change with time and degree of sintering, but for many analyses, they have been assumed constant with the mechanism of mass transport. Many experiments have been analyzed using the exponent n to identify the sintering mechanism. However, in cases where the grain boundary energy is relatively high (dihedral angle is small), neck growth will be paced by grain growth ($X = G \sin \phi/2$) and will not follow Eq 11. In these cases, there will be a groove at the neck.

Table 3 Initial stage sintering equation for spheres

$$(X/D)^n = Bt/D^m$$

Mechanism	n	m	B
Viscous flow	2	1	$3\gamma/(2\eta)$
Plastic flow	2	1	$9\pi\gamma b D_v/(kT)$
Evaporation-condensation	3	2	$(3P\gamma/\rho^2)(\pi/2)^{1/2}(M/(kT))^{3/2}$
Volume diffusion	5	3	$80D_v\gamma\Omega/(kT)$
Grain boundary diffusion	6	4	$20\delta D_b\gamma\Omega/(kT)$
Surface diffusion	7	4	$56D_s\gamma\Omega^{4/3}(kT)$

Symbol	Definition
b	Burgers vector
D_b	Grain boundary diffusivity
D_s	Surface diffusivity
D_v	Volume diffusivity
k	Boltzmann's constant
M	Molecular weight
P	Vapor pressure
T	Absolute temperature
γ	Surface energy
δ	Grain boundary width
η	Viscosity
ρ	Theoretical density
Ω	Atomic volume

There are many different solutions to the initial stage sintering problem, so the forms given in Table 3 are only representative of the efforts. For example, depending on the assumptions, various models for surface diffusion controlled initial stage sintering give n values of 3, 5, 6, 7, and 7.5. The simplified model represented by Eq 11 gives a rough approximation up to a neck size ratio of 0.3. The diffusion coefficient is embedded in the parameter B and follows an Arrhenius temperature dependence. The required frequency factor and activation energy for several common materials are collected in Table 4 for surface, volume (lattice), and grain boundary diffusion. Equations such as those introduced here for initial stage solid-state sintering are typically in error by 10 to 20% over actual numerical solutions. Hence, little precision can be assigned to calculations based on these integral models.

- (d) SD, surface diffusion.

Although not very exact, Eq 11 does illustrate some key processing factors in sintering. A high sensitivity to the inverse particle size means smaller particles give more rapid sintering. Surface diffusion and grain boundary diffusion have the highest sensitivity to particle size changes; thus they are enhanced relative to the other processes by a smaller particle size. In all cases, temperature appears in an exponential term, which means small temperature changes can have a large effect. Finally, time has a relatively small effect in comparison to temperature and particle size.

Bulk transport processes decrease the interparticle spacing as neck growth processes, which results in compact shrinkage and the formation of additional, new necks. It is easier to measure the compact dimensional change instead of the neck size. Shrinkage is approximately related to the neck size by a simple model as follows:

$$\frac{\Delta L}{L_0} = \left(\frac{X}{2D} \right)^2 \quad (\text{Eq 12})$$

where the shrinkage $\Delta L/L_0$ is the compact length change divided by the initial length. Shrinkage is actually a negative value, but the sign is usually ignored. Actual measurements of both shrinkage and neck size reveal that the shrinkage is slightly larger than predicted by Eq 12. On this basis, shrinkage during initial stage sintering follows a kinetic law similar to Eq 11:

$$\left(\frac{\Delta L}{L_0} \right)^{n2} = \frac{Bt}{2^n D^n} \quad (\text{Eq 13})$$

The parameter B is exponentially dependent on temperature:

$$B = B_0 \exp \left(- \frac{Q}{kT} \right) \quad (\text{Eq 14})$$

where k is Boltzmann's constant, T is the absolute temperature, and B_0 consists of material parameters (such as surface energy, atomic size, atomic vibration frequency, and system geometry as defined in Table 3).

One of the benefits of such computer simulations is recognition that strength and other mechanical, thermal, or physical properties are dependent on the neck size. For example, strength data are directly related to the neck size ratio squared. A major complication arises due to multiple mechanisms contributing simultaneously to particle bonding. Accurate calculation of the sintering rate is necessary to build a basis for sintering predictions. Unfortunately, most of the models are only approximations to an underlying complexity that cannot be treated by simple geometric applications. Consequently, computer simulation is enlisted to address the sintering problem. This is an important direction to provide realistic modeling capabilities. Much of the early work focused on accurate predictions of the sintering geometry and mass flow kinetics by a single transport mechanism, for example grain boundary diffusion.

Only recently, have computer simulations embraced realistic conditions. A typical shortfall of the early models was a failure to incorporate a grain boundary dihedral angle in the sinter neck. Other problems are associated with the assumption of monosized spheres in ideal packing geometries with instantaneous heating. A serious deficiency in early simulations was a loss of mass or volume. For example, simulating the coalescence of spheres by surface diffusion resulted in nearly a 5% gain in volume. These problems limit the usefulness of the early simulations. In contrast, actual sintering experiments involve a wide range of particle sizes, packing inhomogeneities, and multiple sintering mechanisms during slow heating to the final temperature. A real difficulty is in using too few initial particles in the simulation. It is not uncommon in practice to see a final grain size that is ten times larger than the initial particle size. Thus, the initial simulation must start with over 1000 particles for every final grain in the sintered structure. This is a major computational burden. Furthermore, there are many situations where 10^9 particles are consumed to form one sintered grain, which is far beyond current simulation capabilities.

The variety of computer simulations for sintering processes is large. Approaches include numerical solution to the different equations, finite element analysis, finite difference solutions, and Monte Carlo simulations. A review of the field

is provided in the Selected References . Although there are over 200 sintering simulations in circulation, many focus on single mechanisms; even so they have provided important checks on the models and a basis for multiple mechanism simulations.

Multiple mechanism assessments of sintering are useful in determining dominant processes. For example, volume diffusion versus surface diffusion controlled sintering can be assessed by taking the ratio of neck growth rates. These assessments show that early sintering favors surface diffusion and grain boundary diffusion, while the latter stages tend to shift to volume diffusion control.

Most of the modern simulations recognize that sintering involves the delivery of mass to the interparticle bond by several simultaneous transport mechanisms. A typical assumption is that the instantaneous sintering mass flux is simply the sum of the contributions from each mechanism. At any instant, the rate of neck growth is the sum of the individual fluxes:

$$\left. \frac{dX}{dt} \right|_{\text{total}} = \sum \left. \frac{dX}{dt} \right|_i \quad (\text{Eq 15})$$

This assumes that each of the individual mechanisms, represented by the subscript i , provides an instantaneous contribution to the total neck growth. Accordingly, computer simulations are employed to continuously calculate the contributions from each transport mechanism at a given time. Once the rates of mass flow are determined, the sum is used to enlarge the neck by determining its new volume and shape for the next instant of time. With reposition of the transported mass, the geometry is recalculated. Time is advanced by a small step size, and the corresponding microstructure gradients are used to recalculate the fluxes and total mass flow. This process goes on with millions of small steps to eventually determine the geometry after a reasonable sintering time. Only in the past few years, has the speed of such calculations for just two particles exceeded the speed of actual sintering. (In the 1970s it would have taken 10 times longer to simulate the process than the actual experimental time; computer times of 600 min would be required for simulation of 60 min of sintering for two spheres.)

In calculating the rate of sintering, the evolution has been from simple geometric approximations to sophisticated multiple mechanism computer simulations. The usefulness of such simulations is evident in several of the proprietary codes, where the agreement with the experiment is excellent. Surface diffusion dominates sintering, while evaporation condensation is a minor contributor.

A consequence of these computer-based sintering calculations is the realization that the process is very involved and not easily treated using simple models. The logical extension has been the synthesis of sintering diagrams that provide guidelines on the interplay of the processing parameters with rigorous geometric models.

A sintering diagram proves useful in condensing and representing sintering behavior. These are based on computer simulations, wherein multiple mechanisms contribute to mass flow, and accurate geometric representations are used for the microstructure. Contributions are included from each of the mass transport mechanisms, and the geometric approximations are minimized to accurately reflect microstructure evolution during sintering. The more recent simulations include a change in grain size with time and recognize densification results in new particle contacts. A sintering diagram can have any of several forms, but typically shows the density or neck size versus temperature for isothermal sintering at various times. The underlying simulations rely on material data to combine mechanisms and determine the effects of the main process variables (time, temperature, green density, particle size, and grain size). Data needed for these calculations are collected in various books on sintering theory. The diagrams are sensitive to input material characteristics. The output might be density, neck size, dimensional change, or final compact shape (includes distortion from green density gradients) as a function of compaction conditions, sintering conditions, composition, or powder characteristics. The graphical output is most impressive, since the plots show the interactions between the key processing variables.

The effect of simultaneous transport mechanisms is to increase the overall rate of neck growth, but possibly with a decreased rate of shrinkage. One merit of computer simulated diagrams is that such combined effects are included in the calculations. When the sintering diagram is based on density, the surface transport contributions are less evident.

Today, the complexity of sintering is recognized, and realistic sintering calculations rely on sophisticated computer calculations. Early models failed to appreciate the multiple mechanisms and complex geometric changes associated with solid-state sintering. In modern industrial sintering situations, the systems are complex, and many proprietary codes exist

that include nonlinear heating, wide particle size distributions, liquid formations, atmosphere interactions, and the behavior of mixed powders. Sintering models have only recently embraced some of the practical realities.

Sintering Furnaces and Atmospheres

Introduction

DURING SINTERING, compacted metal powders are bonded or sintered by heating in a furnace to a temperature that is usually below the melting point of the major constituent. Sintering occurs in a series of overlapping but balanced phases, all of which depend on temperature, time, and atmospheric composition, flow, circulation, and direction.

Furnaces used for sintering typically are similar to protective atmosphere furnaces used in brazing and heat treating of steel. However, the significant differences between heat treating and sintering require careful selection of furnace atmospheres for sintering. Primarily, P/M compacts are porous; therefore, a much greater surface area is exposed to the furnace atmosphere than with solid parts. Sintering temperatures are considerably higher than heat treating temperatures (1120 °C, or 2050 °F, for iron and steel compared to 900 °C, or 1650 °F, for carburizing and neutral hardening of steel).

This combination of greater exposed surface area and higher temperatures enhances chemical reactivity between the surface and atmosphere during sintering. The trend toward higher sintering temperatures also places additional

requirements on furnace capability and tight atmosphere control. These factors are briefly discussed for both conventional and high-temperature sintering.

Sintering Furnaces and Atmospheres

Continuous Furnaces

Tim Raffeinner, Abbott Furnace Company

Continuous production sintering furnaces for powder metal compacts come in several designs including the mesh-belt conveyor furnace, the ceramic-belt conveyor furnace, the roller-hearth furnace, the pusher furnace, the walking-beam furnace, and the continuous vacuum furnace (Fig. 1). A typical continuous sintering furnace has four distinct areas: the preheat, delube, or burn-off area; the high heat or sintering area; the slow cool or transition area; and the final cooling area (Fig. 2).

Fig. 1 Schematic of various continuous furnaces

Fig. 2 Schematic of a muffled continuous mesh-belt sintering furnace

Sintering Furnaces and Atmospheres

Furnace Characteristics

Preheat Area. The function of the preheat area is to remove the compacting lubricants from the green powder metal part. Hence the preheat area is also called the delubing or burn-off zone.

Lubricants commonly used in compacting are zinc stearate, lithium stearate, Acrawax, and paraffin (Table 1). Because these lubricants have relatively low melting points up to ~ 220 °C (430 °F), it is assumed that the maximum operating temperature of the preheat would only need to be slightly above this. However, because the difficulty in removing lubricants increases as density and cross-sectional area increases, actual maximum operating temperature of the preheat area typically is ~ 1010 °C (1850 °F).

Table 1 Commonly used compacting lubricants

Lubricant	Chemical formula	Melting point	
		°C	°F
Zinc stearate	$Zn(C_{18}H_{35}O_2)_2$	130	266
Lithium stearate	$LiC_{18}H_{35}O_2$	221	430
Paraffin	$C_{22}H_{46}$ to $C_{27}H_{56}$	40-60	104-140

It is important for the green compact to have a controlled heating rate to avoid part blistering because the lubricant liquefies and progresses through the resulting porosity toward the surface of the part where it vaporizes. Length of the preheat is typically 50 to 100% of the high-heat section.

Most preheat areas contain a muffle that forms a narrow passageway for the vaporized lubricant to flow out of the front of the furnace. The muffle also prevents lubricant from condensing on other internal furnace components and reducing their life.

Preheat areas can be heated by either electric or gas. Wire elements are commonly used in place of silicon carbide elements due to the lower operating temperatures.

Nitrogen moisturizing systems, also known as bubblers, help to increase the dew point in the preheat area to aid in the delubing process. Nitrogen is fed into the bottom of a sealed, heated container filled with water, and then it is collected at the top of the container and injected into the preheat after it has picked up moisture.

Enhanced lubricant removal systems are specially designed for parts with large cross-sectional areas or heavy furnace loads. The length of the enhanced lubricant removal area varies depending on whether it is added as a separate unit previous to the preheat section or a combination thereof.

The enhanced delubing process works on the principle that the combustion products of a gas burner combined with the regular furnace atmosphere provide the proper combination for more efficient lubricant removal. On some units, once the gas burner is set, it fires at the same rate even as furnace loading changes. Wire-wound elements under the furnace hearth provide any extra heat needed as loading increases. Burner velocity does not increase, which means that internal furnace pressures remain unchanged. Consistent pressure yields a steady frontal flow, which results in consistent delubing results (Fig. 3).

Fig. 3 Schematic of an enhanced delubing system

High-Heat Area. The function of the high-heat area is to sinter the individual powder particles together, while at the same time increasing density due to shrinkage of the part.

The design of the high-heat area should be such that the P/M parts reach sintering temperature in the quickest time possible and then remain there until particles are adequately bonded and alloying elements fully diffused into the matrix. The maximum operating temperature of the high-heat area for conventional ferrous powders is usually 1177 °C (2150 °F) and 1300 °C (2400 °F) for high nickel/chrome alloys.

Length of the high heat is based on the average part cross section and belt loading. The high heat can be 100 to 200% of the length of the preheat area.

The high heat can be an open-chambered design or can contain a muffle. Open-chambered furnaces expose the brickwork and heating elements to reaction with the furnace atmosphere and do not offer as much carbon control as muffled furnaces. Muffles can be made of either an alloy or ceramic. Ceramic muffles can be silicon carbide or alumina, with silicon carbide offering better thermal conductivity, which in turn yields better thermal shock resistance. Ceramic muffles come in sections that are fitted together with a male/female joint structure (Fig. 4). Each ceramic muffle section can be a single piece design or can be a two-piece, base and lid, design. Because of the slight amount of porosity of ceramic muffles, each furnace section containing the ceramic muffle sections is sealed and purged with nitrogen gas to ensure that none of the P/M parts are subjected to outside air.

Fig. 4 Schematic of ceramic muffle sections

High-heat sections can be heated with gas or electricity. When heating with gas, a refractory alloy muffled design is preferable to keep burner off gases from entering the furnace atmosphere. Electric elements can be composed of silicon carbide or molybdenum, depending on the maximum operating temperature of the high-heat section.

Slow-Cooling Area. The function of the slow-cooling zone can be to aid in microstructure development or to act as a shock zone or transition zone, to lessen the thermal stress between the heated and cooled sections of the furnace. This section can be an open-chambered design, or it can contain an alloy or ceramic muffle.

Final Cooling Area. The function of the final cooling section is to cool the P/M parts below their oxidation point under atmosphere before they exit the furnace into the outside air.

Typically, the final cooling area consists of cool water, which surrounds a muffle-like design to keep the parts from being exposed directly to the water. This type of unit relies mostly on radiant cooling, with limited conduction through the product transfer mechanism. As the water collects heat, it is pumped to an area where it is cooled, then recirculated to the final cooling area to accept more heat. Length of the final cooling area is typically 150 to 250% that of the sintering section.

A water-jacketed cooler can be any one of several designs. It can be a simple inner and outer steel jacket with water flowing in between. The cooler can have an open top that eliminates pressure buildup. It can contain inserts welded into place between the inner and outer jacket to help direct the flow of water. The cooler can contain multiple injection locations that oppose each other to create a turbulent effect between the two jackets around the entire cooler. Uniform water temperature in the multiple injection port cooler eliminates thermal stress caused by uneven expansion associated with the other types of water-jacketed coolers (Fig. 5).

Fig. 5 Schematic of cooling chamber types

Another type of final cooling area now gaining rapid acceptance utilizes convection cooling to remove heat from the P/M product. This type of cooling system consists of an area that removes existing heated atmosphere from the furnace, a heat exchanger to cool that atmosphere, and another area where the cooled atmosphere is reintroduced into the furnace. These units contain features to increase atmosphere velocity and turnover, which in turn effect the British Thermal Unit (BTU) exchange rate.

Some systems offer a variable speed blower, the speed of which can be adjusted depending upon the cooling needs of each individual product line. It can also be completely water jacketed, allowing the convection portion to be shut off and the unit to be used as a conventional cooling chamber.

Uses of the convection cooling chamber can be to cool heavy loads or parts with large cross-sectional areas, to shorten the overall length of the furnace in areas with restricted floorspace, or to sinterharden certain materials, which eliminates subsequent heat treatment operations.

Sintering Furnaces and Atmospheres

Continuous Furnace Types

Mesh-belt Conveyor Furnaces. Mesh-belt conveyor furnaces used for sintering P/M compacts are the most common type of production sintering furnace. These furnaces provide a continuous, reproducible time-temperature-atmosphere profile.

The mesh-belt furnace consists of a load table, a preheat area, a high-heat area, a slow-cool area, a final cooling area, and an unload or discharge table. The belt is driven by a drum system located on the charge table, which frictionally drives the belt by pinching it between the drums.

The preheat and high-heat areas of the furnace can contain a muffle or can be of an open-chambered design. Muffled furnaces provide a narrower channel for better atmosphere flow, as well as protection for other furnace internals against reactions with the furnace atmosphere and lubricant byproducts.

The belt is made of mesh woven from alloy wire. Temperature limitations are typically $\sim 1177\text{ }^{\circ}\text{C}$ ($2150\text{ }^{\circ}\text{F}$).

Parts can be placed directly on the belt at the charge end of the furnace. Finer mesh screens or trays are used when parts will fall through the mesh size of the belt, or when certain part surface conditions must be met.

Mesh-belt conveyor furnaces have typical loading capabilities of 73 kg/m^2 (15 lb/ft^2). With heavier mesh belts and drive mechanisms, loading can be increased up to 122 kg/m^2 (25 lb/ft^2).

Ceramic-belt conveyor furnaces are used for sintering P/M compacts at a higher temperature than mesh-belt conveyor furnaces. Like their lower-temperature counterparts, they provide a continuous, reproducible time-temperature-atmosphere profile.

Ceramic-belt furnaces consist of a load table, a preheat area, a sintering area, a slow-cooling area, a final cooling area, and an unload table. The belt is driven by a sprocket located on the discharge table.

The high-heat area of the furnace contains a ceramic muffle instead of the conventional alloy design. Muffle material can be silicon carbide or alumina to eliminate the distortion at higher temperatures.

The belt can be made of silicon carbide or alumina. Silicon carbide offers better thermal conductivity and specific heat characteristics, which yield better thermal shock resistance. The belt consists of pressed links and spacers, held together by a crossrod. Parts are placed on ceramic trays to prevent contact and subsequent reaction with the belt.

The ceramic-belt conveyor furnace has production capabilities up to 136 kg/h (300 lb/h), with belt loading of 49 kg/m^2 (10 lb/ft^2). With a special roller belt design, which reduces friction inside the furnace, belt loading can be increased above the 49 kg/m^2 (10 lb/ft^2) rate.

Humpback furnaces are basically a mesh-belt sintering furnace adapted to using high-purity, low-density atmospheres such as dissociated ammonia or hydrogen. They are especially useful to conserve atmosphere when the need for a large charge opening exists.

Humpback furnaces consist of a load table, an upward inclined preheat area, a horizontal sintering area, a horizontal slow-cool area, a downward inclined, final cooling area, and an unload table (Fig. 6). The humpback furnace can be an open-chambered or muffled design. Muffled designs can contain a refractory alloy or ceramic muffle.

Fig. 6 Humpback sintering furnace. Source: Abbott Furnace Co.

The belt is made of alloy wire woven into a mesh design. Parts can be placed directly on the belt but can also be placed on trays to assist them on the inclined areas of the furnace.

The humpback furnace typically has belt loading capabilities of 73 kg/m^2 (15 lb/ft^2). With a special helper belt to assist the main belt up the incline, loading can be increased to $\sim 122\text{ kg/m}^2$ (25 lb/ft^2).

Pusher Furnaces. In a pusher furnace, parts are loaded on trays or ceramic plates that are pushed through the stationary hearth furnace. Generally, this type of furnace has a lower output than a belt furnace. Furnaces can have a manual, hydraulic, or mechanical pusher system. The pusher mechanism can operate intermittently or continuously. When it is continuous, a reproducible thermal profile of the work can be achieved. Pusher furnaces operate at temperatures up to $\sim 1650\text{ }^{\circ}\text{C}$ ($3000\text{ }^{\circ}\text{F}$).

Roller-Hearth Furnaces. In a roller-hearth furnace, parts are carried on trays through the furnace on driven rolls. Roller-hearth furnaces can be made to greater lengths and widths than most conveyor-belt furnaces, so they have large output potential. Generally, these furnaces are capable of heavier loading (pounds per square foot) on the hearth than mesh-belt furnaces. The roller-hearth design allows for fast entry and exit of the work, which minimizes open door time and reduces atmosphere consumption. This furnace also allows a continuous, reproducible thermal profile. The maximum achievable temperature is $\sim 1150\text{ }^{\circ}\text{C}$ ($2100\text{ }^{\circ}\text{F}$) because of the limitations imposed by available alloys for rolls.

Atmosphere quality in a roller-hearth furnace may be poor. The large cross-sectional area of this furnace gives the lowest forward velocity of atmosphere, which can allow lubricant burn-off residue to diffuse backward into the sintering area.

Walking-beam furnaces are particularly well suited for applications in which sintering temperatures are above the limitations of the mesh-belt conveyor and roller-hearth furnaces. These furnaces operate up to $1650\text{ }^{\circ}\text{C}$ ($3000\text{ }^{\circ}\text{F}$).

The work to be conveyed through the furnace is placed on ceramic carrier plates. In a walking-beam furnace, the middle section of the hearth is a movable beam system that extends the entire length of the furnace. This beam can be raised above the hearth level, lowered below the hearth level, and moved longitudinally. To convey the work through the furnace, the beam is raised, lifting the ceramic carrier plates off the stationary hearth section. The beam then moves forward a fixed distance, taking the carriers with it, and drops below the stationary hearth level, where it retracts to the initial position. With this rectilinear movement, the beam intermittently moves the carriers containing the work through the furnace and cooling zones.

Design of the walking-beam furnace permits all-ceramic construction of the furnace interior, the walking beam, and the carrier plates, thereby facilitating operation at high temperatures. In addition, walking-beam furnaces are capable of carrying extremely heavy loads at temperatures $\leq 1650\text{ }^{\circ}\text{C}$ ($3000\text{ }^{\circ}\text{F}$), which is unattainable in mesh-belt conveyor, roller-hearth, and pusher furnaces.

Sintering Furnaces and Atmospheres

Batch-Type Furnaces

Bell Furnace. The base of the bell furnace is permanently installed on the floor. Work to be processed is loaded onto the base and then covered with a heat-resistant alloy retort to contain the protective atmosphere. The furnace bell then is lifted and placed over the retort and base.

The elevator furnace has the furnace bell above the mill floor on a fixed structure. The base and work load are covered with a retort and rolled on tracks under the furnace. An elevator system then raises the base, work, and retort into the furnace.

Bell and elevator furnaces are commonly used for sintering friction materials. They can be equipped with work-pressing devices to apply heavy pressure to loads such as clutch and brake facings. They also are useful for sintering heavy loads or large pieces and for applications that require long programmed heating and cooling cycles. These furnaces can also be used when extremely pure atmosphere conditions are required.

Sintering Furnaces and Atmospheres

Vacuum Furnaces

Vacuum sintering can be conducted in either batch-type or continuous furnaces. Vacuum sintering does not differ from conventional atmosphere sintering, except for one modification: a vacuum furnace operates in the absence of an internal atmosphere.

Batch-type vacuum sintering furnaces were first developed for sintering compacts from refractory and reactive metals such as tantalum, niobium, titanium, zirconium, and their alloys (which react with any but the noble gases, such as argon or helium), for sintering cemented carbides containing titanium carbide and tantalum carbide and for sintering alnico magnets.

Generally, a batch-type vacuum furnace consists of an outer vacuum-tight cylindrical casing that contains a furnace with radiation shields or other types of insulation, work support, and heating elements. This casing is fitted with roughing and diffusion pumps to achieve the desired vacuum levels.

Vacuum furnaces are designed for use at a variety of temperatures. Units capable of reaching 2760 °C (5000 °F) are available. Because all heat transfer in a vacuum is accomplished by radiation, cooling cycles can be quite long. Therefore, in many cases, the furnace is designed for back filling with nitrogen or argon, which when combined with natural convection shortens cooling time.

Continuous vacuum sintering of iron and steel compacts and silicon-iron magnetic material is accomplished in automated furnaces. The furnace typically is comprised of an external loading table, followed by an atmosphere delubrication chamber, a transfer station, and an "atmosphere to vacuum" vestibule section, followed by a heating chamber, vacuum cooling chamber, a combination fan cooling and "vacuum-to-atmosphere" vestibule, and an unloading table. The advantages of a continuous vacuum sintering furnace are a more flexible temperature range and a choice of slow cooling or rapid cooling in a pressure quench. Most importantly, there is absolute carbon control and no need to continuously monitor an atmosphere for dew point or carbon concentration.

Sintering Furnaces and Atmospheres

Sintering Atmospheres

H.S. Nayar, BOC Gas Inc.

Atmospheres used for sintering must perform several functions (Ref 1, 2). During sintering, atmospheres must:

- Prevent air from entering the furnace
- Delube or dewax the parts
- Reduce surface oxides on the powder particles
- Control carbon on the surface and in the core of steel parts
- Remove carbon in special applications
- Provide controlled oxidation during cooling in special applications
- Convey or remove heat efficiently and uniformly

Because furnace atmospheres affect the sintering process and the material being treated, sintering is never performed in air or in an oxygen-rich atmosphere. A basic function of a sintering atmosphere is to protect metal parts from the effects of contact with air. Atmospheres must be maintained at a sufficient pressure and flow rate to prevent infiltration of air through furnace openings. In addition to protecting the part, atmospheres provide sufficient conduction convection for uniform heat transfer to ensure even heating or cooling within the various furnace zones (Fig. 7).

Sintering Furnaces and Atmospheres

Delube and Preheat Atmospheres

Delubing involves the burning and removal of hydrocarbon lubricants used to compact the powdered metal. Removal occurs early in the sintering process in the low-temperature delube zone of the furnace. Small amounts of oxidizing gases in the atmosphere cause effective lubricant burning without oxidizing parts or decarburizing steel parts. The most effective oxidants are controlled amounts of water and carbon dioxide.

Without such oxidizing gases, lubricants tend to decompose thermally into hydrogen and carbon >540 °C (1000 °F). Hydrogen is given off as a gas, but carbon remains as a sooty deposit. If a suitable oxidant is present, however, a chemical reaction (oxidation) rather than thermal decomposition occurs. The carbon in the lubricant combines with the oxidant and is removed as a gaseous mixture of carbon monoxide and carbon dioxide. For example, assuming C_xH_y is a waxlike lubricant and water is the oxidizing agent, the following reaction applies:

Delubing in a sintering atmosphere is performed most efficiently when a wet (high dew point) atmosphere is used. Atmosphere circulation should also be provided; atmosphere flow toward the furnace entrance is desirable. Ideally, the maximum temperature of the P/M compacts during delubing should range from 425 to 650 °C (800 to 1200 °F).

Sooting is primarily caused by improper delubing. The majority of sintering problems are caused by incomplete or improper delubrication. Sooting occurs when hydrocarbon vapors from the lubricants decompose thermally by the following reaction:

Sooting can also be explained by the following reaction:

Sooting problems can be classified into four types to help take corrective action as described in the following paragraphs (Ref 3).

Adherent soot appears as a black stain and is not easily rubbed off. It can occur on the top, bottom, and the sides of the P/M part. The lubricant oozes to the surface and does not fully vaporize or oxidize before the part enters the hot zone. The causes can be any one or more of the following:

- Dew point too low in the preheat
- The preheat length too short
- Part density too high
- Incorrect preheat temperature
- Belt loading too high
- Incorrect temperature profile

The short term solution is to increase the preheat dew point using a humidified nitrogen system. Reducing belt loading and belt speed can also help. Ideally, the preheat should be lengthened or a rapid burn off unit installed to accelerate the delubing process.

Granular soot looks like black snow and appears mostly on the top surface of the part. The flaky black soot can be easily blown off. It is caused when lubricant vapors thermally decompose into black soot and rains down onto the part. Granular soot is caused when the following conditions occur:

- The dew point is too low in the preheat
- Lubricant vapors migrate into the hot zone
- The forward velocity of atmosphere is too low
- The atmosphere profile shifts due to plant drafts
- Improper design of exhaust stacks

Solutions for granular sooting include increasing total atmosphere flows, redirecting the flow, and redistribution of flows into different inlets. It is also helpful to control up and down drafts in the exhaust stacks.

Soot deposits on belts are indicative of granular sooting. Correcting sooting problems in general will help get rid of soot on the belts. Even small amounts of sooting tend to accumulate along the belt edges over extended periods of time. Soot on belts can lead to carburization and embrittlement of the belts.

Shiny soot appears as a black uniform and shiny coating on all exposed surfaces of the part. It is caused by the catalytic cracking of natural gas on the P/M part surface in the hot zone. The obvious solution is to decrease the amount of natural gas addition. Changing the location of the natural gas addition can also help solve this problem.

Blistering/rippling can be seen on the P/M part and sometimes the part crumbles into powder at sharp edges. Blistering is an extreme case of sooting, which occurs within the P/M part. It is commonly seen in nickel-containing

grades and P/M parts with very high densities. Another cause is too rapid a heating rate in the preheat zone. Solutions include decreasing belt speed and belt loading rates. Increasing wet N₂ flows and adding a pre-preheater can be helpful.

Preheating Zone and Oxide Removal. As the sintering process progresses, the furnace performs another function in addition to delubrication. At ~650 °C (1200 °F), generally near the end of the delube zone and through the hot zone (~1120 °C, or 2050 °F for iron and steels), the atmosphere begins to strip surface oxides on the metal particles that comprise the part.

In the preheat zone, the atmosphere must reduce surface oxides on the metal particles to ensure a clean, metallic surface on the particles comprising the P/M compact. This permits admixed graphite to diffuse into the iron particles, thus creating a pearlitic microstructure during cooling. Graphite diffusion into the particles is essentially completed when parts reach ~1040 °C (1900 °F).

Clean particle surfaces further improve bonding of the particles at >1100 °C (2010 °F). Thus, the greater the oxide reducing effect of the atmosphere, the stronger the sintered bond. Furthermore, porosity between the particles becomes rounded, thus improving the structural integrity and toughness of the part.

Sintering Furnaces and Atmospheres

Oxidation

Under most operating conditions, metal oxides (*MO*) are reduced to metal (*M*) primarily by the hydrogen component of the atmosphere as shown by the following reaction:

The effectiveness of an oxide-reducing atmosphere can be determined by the ratio of hydrogen to water, as shown for iron in Fig. 8(a) and 8(b). In the P/M industry, water content is generally determined by measuring the dew point of the atmosphere. Figure 9 shows water content as a function of sintering atmosphere dew point. As the ratio of hydrogen to water increases, the reducing reaction is more effective. The ratio of hydrogen to water, not the absolute levels of these constituents, determines the reducing effectiveness of the atmosphere. Furthermore, for a given dew point, the hydrogen content of the atmosphere becomes more reducing to oxides as temperature increases.

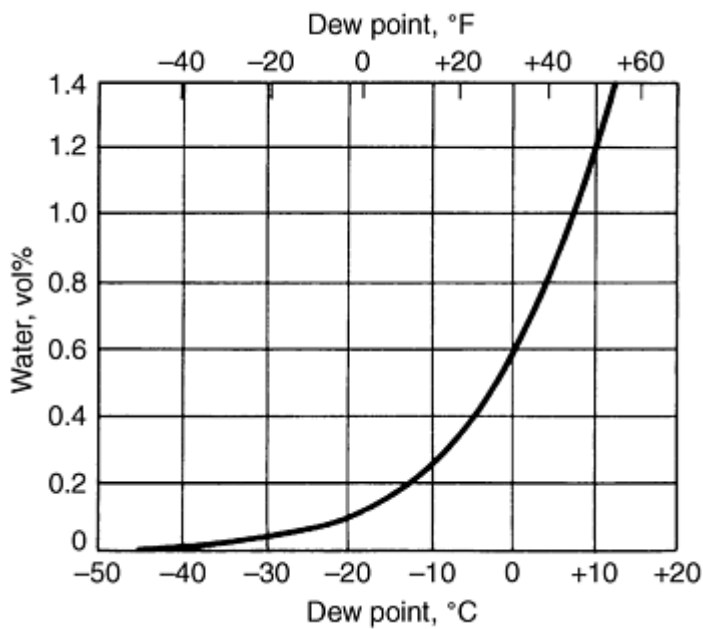

(a)

(b)

Fig. 8 (a) Metal-to-metal oxide equilibria for common elements used in powder metallurgy. Copper, lead, cobalt, nickel, and tin oxide are easier to reduce than iron oxide. (b) Iron-to-iron oxide equilibria

Dew point		Water, vol%
°C	°F	
-80	-112	0.00005
-60	-76	0.00106
-50	-58	0.00388
-40	-40	0.01270
-30	-22	0.03760
-20	-4	0.1020
-10	14	0.2570
0	32	0.6020
10	50	1.2120

Fig. 9 Water content as a function of dew point of the atmosphere

Oxidation of P/M parts can occur in many forms and to varying degrees. Oxidation of iron can be caused by air, moisture, or carbon dioxide.

Oxidation by air appears as a light gray to dull black color. It is generally a function of the oxygen partial pressure, temperature, and the metal. Oxygen contents >25 ppm in the cooling section will oxidize a steel part (Ref 3). Oxidation by moisture (H₂O) and carbon dioxide (CO₂) for a given temperature and material, is a function of the ratios H₂/H₂O and CO/CO₂.

The color of the oxidation is an indication of the degree of the problem. Given the color of oxidation and the temperature profile of the furnace, it is possible to approximate where the oxidation occurred. Table 2 gives colors for steel.

Table 2 Oxidation colors for steel

Temperature ^(a)		Color
°C	°F	
205	400	Faint straw
225	440	Straw
245	475	Deep straw

270	520	Bronze
280	540	Peacock
310	590	Full blue
340	640	Light blue
340-390	640-730	Gray to black

- (a) Higher temperature oxidation results in scaling or etching.

Surface oxidation occurs in the cooling zones and, in general, has only a surface effect with the other properties unaffected. Oxidation problems in sintering furnaces can be differentiated based on the source of oxidation.

Air Infiltration from the Exit End. The oxidation caused by air ingress from the exit end of the furnace will appear randomly and erratically. The oxidation color will change with part weight. It can occur preferentially along one edge of the belt and can show only on the leading edge of the part, or after a gap in the belt loading. Possible causes include:

- Insufficient atmosphere flow
- Atmosphere flow imbalance
- Pressure differential at the ends of the furnace
- Up and down drafts in exhaust stacks
- Improper design of exit door curtains

The solutions include increasing atmosphere flow rates, controlling the up and down drafts in the exhaust stacks, fixing or replacing exit door curtains, relocating fans at front and exit ends to avoid crosswinds, and keeping the exit door as low as possible with the front door kept 13 mm (0.5 in.) higher than the exit end door.

Air Leaks in Water-Cooled Sections. The oxidation in this case will be continuous and will get progressively worse. The oxidation will be on all surfaces, and belt marks may be seen on the bottom surface. Shielded surfaces may appear bright and clean. The causes include the following:

- Loose flanges due to creep of bolts
- Air leaks in the atmosphere piping
- Cracks in the joints between water-cooled sections

Solutions are to find and fix the leaks. An atmosphere profile will help pinpoint the leaks. The flanges should be checked for leaks. It is desirable to have the flanges welded. The incoming atmosphere should be checked to ensure that the O₂ content is <10 ppm.

Water Leaks in Cooling Section. This results in oxidation of a darker color, which is more adherent. The oxidation is continuous and gets worse with time. The causes are the following:

- Holes or cracks in the water-cooled section
- Incoming atmosphere too wet

Solutions to this problem involve differentiating between a water and an air leak. This can be done by performing the copper/steel test and by taking air and dew point readings.

A copper/steel test is performed to determine if the oxidation occurring in the cooling section is caused by an air leak or by a water leak. The test is performed as follows:

- Reduce the furnace temperature to 1040 °C (1900 °F)
- Place a piece of bright copper strip and a steel strip side by side on the belt and send them through the furnace

- Copper will be oxidized by oxygen but not by water
- Steel will be oxidized by both oxygen and moisture

Heavily oxidized parts occur when O₂ or moisture seeps into the hot zone from the front or the exit end or from leaks in the muffle. The part appears heavily oxidized (black) and has poor sintered strength. Adverse conditions in the preheat and water-cooled sections can compound the problem. Solutions include the following:

- Find and fix source of oxidant
- May require higher hydrogen percentage
- Incoming atmosphere may be too wet
- Incorrect pressure differential between the ends of the furnace

Frosted parts exiting the furnace will appear to have a dull matte finish on surfaces that normally have a shiny finish, such as the sides of the part. The part also tends to be decarburized and have lower hardness. This phenomenon occurs when oxidation occurs in the preheat zone followed by reduction in the hot zone. Causes include:

- Dew point too high in the preheat zone
- Air entering the preheat zone from the front end or hole in the muffle
- Down draft at front exhaust
- Shifts in atmosphere profile

Frosty parts can be avoided by reducing the front end oxidation, fixing imbalances in the exhaust system, and redirecting the atmosphere flows.

Belt Oxidation. Belts for sintering furnaces (314 stainless steel), contain chromium and will oxidize at lower oxidation potentials than regular steel parts. If the belt appears dark and parts look bright, then marginal air infiltration from the exit end is occurring. Increasing atmosphere flow at the exit end will dilute the O₂ contaminant. If the belt is clean and adherent scale is seen, then preheat oxidation followed by hot zone reduction is occurring. Solutions are the same as those for frosted parts.

Sintering Furnaces and Atmospheres

Carbon Control

Tight control of carbon levels in powder metal parts is one of the distinguishing attributes of the high-quality P/M producer. The carbon content affects many of the properties of the finished part such as dimensional tolerances and mechanical properties. The pick up of carbon also decreases the corrosion resistance of stainless steel.

Carbon control is achieved primarily through a fine tuning of the sintering atmosphere, as it relates to temperature, admixed carbon, carbon and oxygen content of the powder, and delubrication. The control of this atmosphere is greatly improved through the use of synthetic (N₂H₂) versus generated atmospheres.

The reactions relating to carbon control occur primarily in the hot zone and the slow-cool zone of the furnace (Fig. 7). If the atmosphere is very active--an endothermic atmosphere with 60% combustibles (hydrogen and carbon monoxide) at $\sim 5^\circ\text{C}$ (40°F) dew point, for example--a steel surface with $\sim 0.8\%$ combined carbon is decarburized to $\sim 0.2\%$ combined carbon (Fig. 10) in the hot zone (typically 1120°C , or 2050°F) to a depth of 0.5 to 2.5 mm (0.02 to 0.1 in.).

Fig. 10 Carbon equilibrium in endo gas at different dew points. Endo gas composition: 40% hydrogen, 20% carbon monoxide, and 40% nitrogen

The degree and depth of decarburization depend on the dew point of the active endothermic atmosphere, the processing time and temperature in the hot zone, and the porosity of the steel part. Higher values for these parameters lead to a greater degree of decarburization.

During slow cooling from ~ 1120 to 815°C (2050 to 1500°F) under an active endothermic atmosphere, carbon is more or less restored to the surface of the part. Decarburization in the hot zone followed by restoration of carbon in the slow-cooling zone also occurs in other active atmospheres, such as nitrogen-diluted endothermic or nitrogen-diluted dissociated methanol, with a combustible content of 20% or more hydrogen and carbon monoxide. The slow-cooling section of the furnace is designed to aid carbon restoration.

If the atmosphere is neutral to carbon (a low dew point synthetic nitrogen-base atmosphere with $<10\%$ combustibles such as hydrogen, for example), decarburization in the hot zone and subsequent carbon restoration in the slow-cooling zone do not occur at all or occur to a much less extent than they do under active endothermic atmospheres. Carbon potential for neutral atmospheres is unrelated to temperature. Consequently, neutral atmospheres, unlike endothermic atmospheres, are suitable for high-temperature sintering of steel P/M parts.

Furthermore, parts with different carbon levels can be sintered in the same tray or in random tray sequence under neutral atmosphere without the need for furnace conditioning. Carbon content in the steel part depends on the amount of admixed graphite in the powder and the dew point of the neutral atmosphere. With a lower dew point, less carbon is lost.

In some specialty sintering applications, such as those used for magnetic and stainless steels and high-ductility iron, carbon must be reduced to the lowest possible level during sintering. In such applications, atmospheres with carbon-containing gases such as carbon monoxide should be avoided. A relatively high dew point is required to decarburize the part without adversely affecting the sintered quality of the part.

In some applications, an atmosphere that is slightly oxidizing to sintered parts during cooling at $<540^\circ\text{C}$ (1000°F) is desired to provide controlled oxidation for improved corrosion resistance and increased service life.

Types of Atmospheres

Conventional atmospheres used in sintering are endothermic gas, exothermic gas, dissociated ammonia, hydrogen, and vacuum. According to the Metal Powder Industries Federation, the most common atmosphere, endothermic gas, was used by ~83% of the industry in 1976 for sintering carbon steels (Ref 4). Endothermic gas is generated directly from partial combustion of natural gas. Exothermic gas, also a product of incomplete combustion of natural gas, was used by 5% of the industry for sintering nonferrous materials, such as copper-base metal components (Ref 4).

Dissociated ammonia and hydrogen are indirectly derived from natural gas. These atmospheres are used for sintering stainless steels, magnetic alloys, and other specialty materials.

Among the more recently adopted innovations, synthetic nitrogen-base atmospheres were used by ~30% of the industry in 1983. Recent data show that nitrogen-base atmospheres, which are more versatile and relatively independent of natural gas, are becoming more economical and thus more widely used.

Tables 3 and 4 list typical physical properties of various gases and liquids used to produce sintering atmospheres. Table 5 summarizes the composition of conventional and synthetic nitrogen-base atmospheres. Various chemical requirements--burning of lubricant vapors, reduction of surface oxides, and carburization and decarburization, for example--are controlled by the ratios of various atmospheric constituents, as shown in Table 5.

Table 3 Typical physical properties of various gaseous feedstocks at 20 °C (68 °F) and 1 atm

Note: For nitrogen-base atmospheres, composition, dew point, and key ratios can be synthesized over a broad range, depending on which of the above generated atmospheres is blended with the high-purity nitrogen gas.

- (a) Control carburization or decarburization, oxidation or reduction, or combination of these.
- (b) Dew point is ~ 6 °C (10 °F) above temperature of cooling water; dew point may be reduced to 5 °C (40 °F) by refrigeration or to -45 °C (-50 °F) by absorbent tower dehydration. Hydrogen-to-water changes accordingly.

Endothermic Atmospheres (Ref 5, 6, 7)

Endothermic, or endo gas is generated by reacting relatively rich mixtures of hydrocarbon gas (usually natural gas, predominantly methane) and air over a clean catalyst such as nickel oxide in an externally heated chamber (Fig. 11). The volumetric reaction between natural gas and air is the following:

Fig. 11 Schematic of endothermic gas generator

The theoretical ratio of air to natural gas is 2.4 to 1; however, generator ratios are generally between 2.5 and 3 to 1. This reaction is endothermic. Consequently, the generator must be heated by an external source. Operating temperature in the catalyst must range from 980 to 1000 °C (1800 to 1830 °F); typically, the generator operates at ~1060 to 1100 °C (1960 to 2010 °F).

Air-to-gas ratios and the temperatures in the generator must be controlled to prevent sooting of the catalyst. Insufficient air or too low temperature can cause carbon monoxide to decompose to carbon dioxide and amorphous carbon (soot). Soot deposits destroy the efficiency of the catalyst and cause high levels of unreacted ethane, carbon dioxide, and water in the output atmosphere. When a methane-rich atmosphere is introduced to the furnace, the methane deposits soot on the parts.

A sooted catalyst also causes loss of control over the ability of the generator to maintain a definite carbon potential in the atmosphere. When higher concentrations of carbon monoxide are required, endo gas can be generated from propane instead of natural gas. Commercial propane containing >5% unsaturated hydrocarbons does not react properly and causes sooting.

After passing over the catalyst, the reaction is "frozen" by rapid chilling of the gases to below 315 °C (600 °F) in a water-jacketed zone surrounding the top of the retort. This prevents the reaction from reversing and forming carbon (soot) and carbon dioxide from carbon monoxide:

The reaction in the direction indicated previously predominates at 700 to 480 °C (1300 to 900 °F). The soot-free reacted gas can be further cooled for metering and distribution.

Changes in the air to natural gas ratio also change the composition of the output gas and hence the dew point and carbon potential. Sulfur (as H₂S) reacts with the catalyst to deactivate it. More than 0.65 g (10 grains) of sulfur per 2.83 m³ (100 ft³) of gas renders the catalyst less effective; consequently, carbon monoxide and hydrogen contents of the endo gas are lowered, and water, methane, and carbon dioxide contents are increased.

A higher concentration of hydrogen is found in endo gas generated by the hydrocarbon steam process. In this generator, natural gas and water are reacted to produce carbon monoxide and hydrogen:

The result is a higher proportion of hydrogen and an absence of nitrogen.

Regardless of the process or feedstock used to produce the endo gas, it is monitored by measuring dew point and carbon dioxide content upon exiting the generator. Oxygen probes are also used to monitor the composition of the endo gas.

Variations in composition and peak shaving of the natural gas feedstock make control difficult. Consequently, input ratios of air and methane or propane are adjusted to maintain the dew point and carbon dioxide at a constant level. Frequent monitoring and adjustment are required to maintain a consistent endo gas composition. Automatic ratio adjusters are available to ensure consistent composition of the endo gas (Ref 8). However, these controls require careful calibration and maintenance.

Endo gas is typically 40% nitrogen, 40% hydrogen, and 20% carbon monoxide, with small amounts of water, carbon dioxide, and methane (see Table 5). Typically 60% of the gaseous constituents are combustibles (carbon monoxide, hydrogen, and methane), which are oxide-reducing agents. Carbon monoxide and methane are carburizing; carbon dioxide and water decarburize, oxidize, and delube. The carbon dioxide and water content of endo gas generally burns off the lubricant vapors by chemical reaction in the delubing section of the furnace. Other atmospheres containing higher oxidant levels also are capable of achieving optimum results.

Typically, hydrogen-to-water ratio determines the reduction-oxidation function of an atmosphere (Fig. 8). Endo gas is reducing to iron at >260 °C (500 °F) because the typical 40% hydrogen and 0.8% water (dew point: 5 °C, or 40 °F) contents provide a hydrogen-to-water ratio of 50 to 1. Although this ratio achieves acceptable oxide reduction, other atmospheres--notably those based on hydrogen or dissociated ammonia or synthetic nitrogen-base atmospheres--can provide higher ratios.

The ability of typical endo gas to transfer carbon depends on the temperature and water or carbon dioxide content (Ref 9). Figure 10 shows carbon potential at various temperatures for three different dew points. Typically, a high-carbon part loses carbon at and near the surface as it approaches the peak hot zone temperature (1120 °C, or 2050 °F) in the heat-up cycle. At this peak temperature, the carbon potential corresponds to ~0.2% C, depending on the dew point of endo gas in the furnace. As the part slowly cools, the carbon potential increases, as shown in Fig. 10. The carbon thus tends to be restored.

The extent of decarburization and recarburization determines the finished carbon content at or near the surface of the P/M part. Because the sintering temperature profile is determined by the sintering process, carbon potential must be controlled by the dew point or the carbon dioxide content in the endo gas. Most sintering under endothermic atmosphere is done at dew points ranging from -5 to 15 °C (23 to 59 °F).

High-carbon steel parts are sintered at low dew points, and low-carbon parts are processed at high dew points. Endo generators tend to operate soot free at higher dew points; consequently, natural gas is sometimes added to the high dew point endo gas atmosphere to secure a lower dew point in the furnace for sintering high-carbon parts.

Exothermic Atmospheres (Ref 5, 6, 7)

Exothermic, or exo, atmospheres typically contain 67 to 87% nitrogen. The remainder is carbon monoxide, hydrogen, carbon dioxide, and water. Exothermic atmospheres are produced by the partial combustion of hydrocarbon fuels (generally natural gas) with air. A 6-to-1 ratio of air to natural gas produces rich exo gas, American Gas Association (AGA) class 102, which is high in carbon monoxide and hydrogen.

In contrast, lean exo gas (AGA class 101), produced from a 9-to-1 ratio of air to gas, contains low percentages of carbon monoxide and hydrogen, but correspondingly higher percentages of carbon dioxide and nitrogen (Table 5). Partial combustion in a gas generator equipped to control the ratio of air to fuel gas is capable of producing any desired composition between rich and lean exothermic gases.

The exothermic gas generator is a refractory-lined, water-jacketed combustion chamber that operates at 1100 to 1425 °C (2010 to 2600 °F). The internal temperature of the chamber depends on (a) the ratio of air to fuel gas, (b) the volume of gas being burned, and (c) the effectiveness of the heat transfer from the inside of the chamber to the water-jacketed exterior. Figure 12 shows a typical exo gas generator.

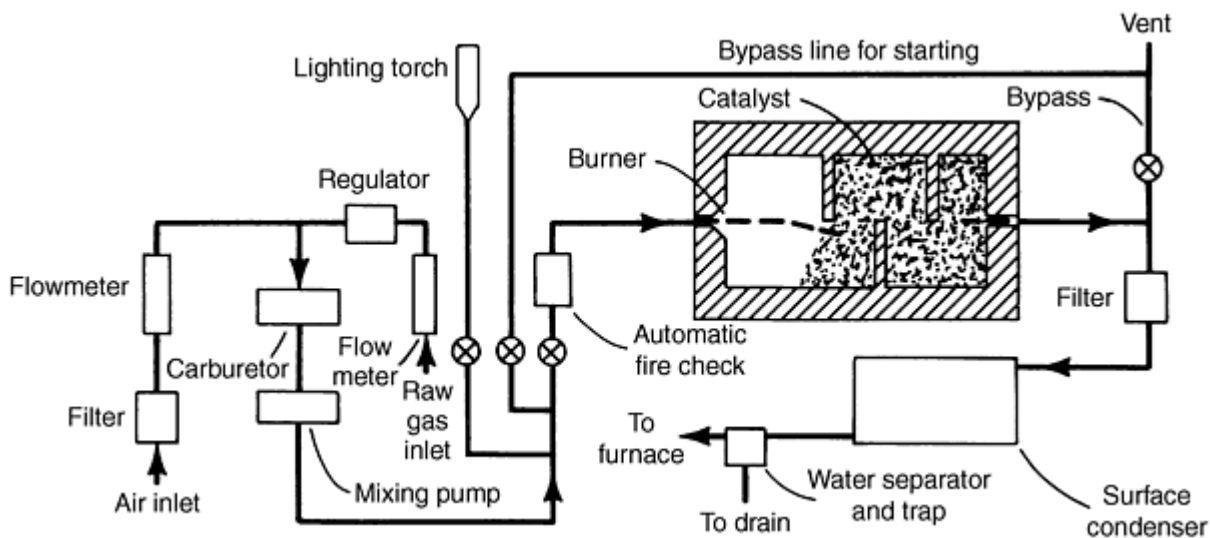

Fig. 12 Schematic of exothermic gas generator

The gas mixture enters the two-zoned converter, which is the main portion of the generator. In the first zone, where combustion occurs, most of the fuel and air react to produce hydrogen, carbon monoxide, and nitrogen. In the second zone, which is heated by the earlier combustion, the unburned hydrocarbon and combustion products are cracked over the catalyst into hydrogen and hydrogen byproducts. The turn-down volume (expressed as a percentage of the rated capacity) is limited by the minimum exo gas output that will maintain the chamber at 1030 °C (1890 °F) or above. Lean ratios permit lower turn-down volumes than rich ratios.

The hot gases are quenched in the hot gas cooler to separate water as condensate from the gas stream for removal through a condensate trap. The amount of moisture in the cooled gas varies according to the temperature of the incoming cooling water; the temperature of the exit gas should be within ~ 5 °C (10 °F) of the cooling water.

More moisture can be removed by refrigerating to a dew point of ~ 4 °C (40 °F) or by adsorbent tower dehydration to a dew point of -45 °C (-50 °F) when relatively high oxide reducing capability (hydrogen-to-water ratio) is desired.

Most exo gas (lean or rich ratio) has a typical dew point of 21 °C (70 °F), corresponding to 2.5% water. It contains 1.2 or 12.2% hydrogen, depending on whether it is a lean or rich exo gas. The hydrogen-to-water ratios for lean and rich exo gases are 0.5 and 4.9, respectively (Table 5). These atmospheres are significantly less oxide reducing than endo gas or synthetic nitrogen-base atmospheres.

Exo gas is highly decarburizing to steel above ~ 700 °C (1300 °F). Because of the high water and carbon dioxide content, it is a very effective delubing agent.

Exo gas generally is used to sinter bronze and some other copper-base parts. Copper and most copper-base alloys do not require high oxide-reducing power (Fig. 8). Exo gas requires much less natural gas than endo gas; consequently, it is one of the most economical atmospheres.

Dissociated Ammonia (Ref 5, 6, 7)

Heating metallurgical-grade anhydrous ammonia in the presence of a catalyst causes the ammonia to dissociate into a mixture of hydrogen and nitrogen molecular gases in a 3-to-1 ratio (75% hydrogen and 25% nitrogen):

Dissociated ammonia is pure, consistent, and dry; the dew point is typically less than $-51\text{ }^\circ\text{C}$ ($-60\text{ }^\circ\text{F}$). Residual undissociated ammonia is generally well below 250 ppm.

Although ammonia molecules begin dissociating at $315\text{ }^\circ\text{C}$ ($600\text{ }^\circ\text{F}$), $980\text{ }^\circ\text{C}$ ($1800\text{ }^\circ\text{F}$) provides a practical operating compromise between dissociated rate and equipment life. Higher temperatures must be used to ensure that virtually no undissociated ammonia molecules remain. Generally 1 kg of liquid ammonia yields $\sim 1.4\text{ m}^3$ of undissociated ammonia vapor or $\sim 2.8\text{ m}^3$ of dissociated ammonia (DA) (hydrogen and nitrogen in a 3-to-1 ratio). In English units, 1 lb of liquid ammonia yields 22.5 standard ft^3 of undissociated ammonia vapor or 45 standard ft^3 of DA.

A typical ammonia dissociator produces 2 to $140\text{ m}^3/\text{h}$ (70 to $4950\text{ ft}^3/\text{h}$) of dissociated ammonia at an outlet pressure of 35 to 100 kPa (5 to 15 psi). Liquid ammonia is fed from a storage tank into a vaporizer, which transforms it into ammonia vapor. A heater in the storage tank maintains gas operating pressure if the temperature of the liquid ammonia falls below the recommended level.

The vapor then passes through a pressure regulator, is preheated, and enters an externally heated retort (typically made from Inconel) that contains a nickel- and iron-bearing catalyst. The ammonia molecules dissociate into molecular hydrogen and nitrogen at 925 to $1040\text{ }^\circ\text{C}$ (1700 to $1900\text{ }^\circ\text{F}$). The resulting mixture leaves the retort and passes through a heat exchanger; heat is subsequently transferred to the incoming ammonia vapor. If necessary, the dissociated ammonia can be pressure regulated and piped to the furnace.

Output can be easily controlled between 0 and 100% of capacity by regulating flow at any point along the processing line. This control feature is unavailable on exo and endo gas generators, which typically operate between 70 and 100% of their rated capacity. Some recent designs of endo generators allow greater output reduction.

The most important component of the dissociator is the catalyst chamber or retort, which is generally fabricated from Inconel. This chamber is heated either electrically or by natural gas. If electrically heated, a dissociator requires 0.5 to 1.0 kW (depending on the size of dissociator) of electricity per cubic meter (14 to $28\text{ W}/\text{ft}^3$) of dissociated ammonia produced. Figure 13 shows a schematic of a typical ammonia dissociator. Ammonia dissociators are relatively maintenance free compared to endo and exo gas generators.

Fig. 13 Schematic of ammonia dissociator

Because dissociated ammonia is very dry (low dew point), it is highly reducing to surface oxides, as the high hydrogen-to-water ratio given in Table 3 indicates. Consequently, it is frequently used where the high reducing capability of stable

oxides is desirable, such as in sintering of stainless steel. Thermodynamically, the high hydrogen content in dissociated ammonia is decarburizing to carbon steel; kinetically, however, the decarburizing reaction is very slow when the dew point in the furnace remains low (below $-40\text{ }^{\circ}\text{C}$, or $-40\text{ }^{\circ}\text{F}$).

The decarburizing reaction can be further slowed by diluting dissociated ammonia with a lower dew point inert gas such as nitrogen when sintering carbon steel that cannot have any decarburization at the surface. Because dissociated ammonia is very dry, it does not provide optimum burning of the lubricant during delubing in the preheating zone. However, because dissociated ammonia is 75% hydrogen, it has a thermal conductivity higher than nitrogen-rich atmospheres.

Hydrogen (Ref 10)

Hydrogen, the lightest of all the gases listed in Table 3, is produced for the most part by steam reforming natural gas and light hydrocarbon liquids over a catalyst. Metallurgical hydrogen is refined from excess hydrogen-gas feedstocks from petrochemical steam-reforming plants. The gas supplier removes hydrocarbons and moisture from the raw gas stream and liquefies the partially refined gas at $-253\text{ }^{\circ}\text{C}$ ($-423\text{ }^{\circ}\text{F}$). Other impurities such as nitrogen and argon are removed during the liquefaction process.

Hydrogen is delivered either as compressed gas or liquid to volume and purity requirements. Commercial grades of compressed hydrogen gas, with typical pressure of 17 MPa (2500 psig), are delivered by trailer in cylinders with capacities between 1000 and 4000 m^3 (35,000 and 140,000 standard ft^3). Smaller quantities of compressed hydrogen usually are available in cylinders containing 7 m^3 (250 ft^3).

Most liquid hydrogen is delivered by trailer to liquid receivers or storage vessels with capacities between 5000 and 75,000 L (1500 and 20,000 gal). Liquid hydrogen usually is vaporized as required. One liter of liquid hydrogen yields 0.85 m^3 (113.4 ft^3) of hydrogen gas (or one gallon yields 133.4 ft^3 of hydrogen gas). Smaller quantities of liquid hydrogen are available in 1150 L (40 gal) cylinders.

Hydrogen specifications vary, depending on the grade. Typical hydrogen is 99.999% pure. Commercial-grade hydrogen meets the following specifications:

Hydrogen	99.995% min
Water	8 ppm max at $-68\text{ }^{\circ}\text{C}$ ($-90\text{ }^{\circ}\text{F}$)
Oxygen	1 ppm max

Because hydrogen is highly flammable, care must be taken to ground major stationary and mobile equipment to remove static electricity and the potential for spark ignition of the hydrogen. Electrical equipment must meet applicable national electric codes and fire prevention standards.

As indicated in Table 5, hydrogen is the most effective reducing atmosphere available because it has the largest hydrogen-to-water ratio. It is essentially nondecarburizing, like dissociated ammonia, to carbon steels as long as the dew point remains below approximately $-40\text{ }^{\circ}\text{C}$ ($-40\text{ }^{\circ}\text{F}$). It is similarly inefficient at burning lubricant vapors because of a low dew point. Of all atmospheres commonly used in the P/M industry, hydrogen is the most heat conductive.

Vacuum (Ref 11, 12)

Vacuum is essentially a lack of atmosphere. It is used mainly for sintering stainless steels, tool steels, carbides, magnetic alloys, and metals such as titanium, zirconium, uranium, tantalum, and other refractory metals and compounds that react with hydrogen-, nitrogen-, and carbon-monoxide-bearing atmospheres.

Vacuums are being used increasingly for high-temperature sintering of conventional ferrous P/M parts. Under vacuum, care must be taken not to lower the pressure in the furnace below the vapor pressure of the constituents of the alloy to be sintered so that depletion does not occur.

Vacuum cannot be used in the conveyor furnaces conventionally used by the sintering industry. Currently, almost all vacuum sintering furnaces are batch types. Some continuous (compartmentalized) conveyor vacuum furnaces are being introduced to the P/M industry.

Green compacts of carbides, refractory metals, and other materials are sometimes heated under a protective or reducing atmosphere in a separate furnace to drive off volatile lubricants before entering the vacuum furnace for sintering. This minimizes the contamination of heater elements and heater element supports that are frequently associated with vacuum furnaces.

Nitrogen-Base Atmospheres (Ref 13, 14, 15, 16, 17, 18, 19, 20, 21, 22)

The main constituent of the recently developed nitrogen-base systems is molecular nitrogen. Molecular nitrogen is obtained from air, which consists of $\sim 78\%$ nitrogen, 21% oxygen, 0.93% argon, 0.03% carbon dioxide, and small amounts of rare gases such as neon and helium.

Nitrogen is produced commercially by cryogenic and noncryogenic methods. Air is first filtered to remove particulates and is then compressed and passed through a heat exchanger for cooling to remove water and carbon dioxide. The air is then rapidly depressurized to an ultracold liquid that is distilled to separate out the high-purity molecular nitrogen gas. The gas is either piped directly to the sintering plant or liquefied for long-distance shipping. One cubic meter of liquid nitrogen equals 697 m^3 of nitrogen gas.

Nitrogen is also produced in noncryogenic generators located at the sintering plant. In noncryogenic production, a stream of compressed air is passed through a bed of special adsorbent, such as a carbon molecular sieve maintained at ambient temperature. Oxygen, water vapor, and carbon dioxide are preferentially retained on the adsorbent, but nitrogen (with a small amount of oxygen) flows through it. As the adsorbent bed becomes nearly saturated with oxygen, water, and carbon dioxide, the system automatically switches to a second bed without interrupting nitrogen delivery.

The system regenerates the first bed by reducing the bed pressure and releasing the adsorbed bases. The regenerated bed is then ready to repeat the cycle. All adsorption and desorption activities occur at ambient temperatures rather than at the low temperatures used in cryogenic plants. To reduce the oxygen content of the nitrogen, the product stream with added hydrogen is passed through a catalytic deoxidizer and a dryer to produce high-purity nitrogen. Powder metallurgy fabricators with a nitrogen consumption greater than $\sim 100 \text{ m}^3/\text{h}$ ($3500 \text{ ft}^3/\text{h}$) could use an on-site noncryogenic plant for economic reasons. These plants have been introduced into the market only recently.

Whether produced cryogenically or noncryogenically, nitrogen is readily available and economical. Additionally, it provides a consistent source of high technical quality, high-purity product--maximum oxygen content is 10 ppm (typically 2 ppm) and dew point is $-65 \text{ }^\circ\text{C}$ ($-85 \text{ }^\circ\text{F}$). Because nitrogen is molecular rather than atomic, it is essentially inert to steel and other compositions that are usually sintered in P/M plants.

Inert nitrogen has a density close to that of air (Table 3); consequently, it effectively prevents air from entering the furnace, thus protecting porous P/M parts from harmful contact with air during sintering. Assuming an adequately air-tight furnace, an atmosphere of 100% nitrogen is suitable for sintering aluminum and some less critical ferrous and nonferrous metal parts. Nitrogen alone, however, will not reduce particle surface oxides or effectively control surface carbon of steel parts.

With small, controlled additions of active gases, nitrogen atmospheres can perform all functions required of sintering atmospheres. Furthermore, the amount and type of active ingredients can be varied to change the level of reactivity of the atmosphere. The most important active ingredient required for sintering of commonly produced P/M parts is hydrogen.

Systems that use low dew point hydrogen sources and that maintain other oxidants at low levels require only small amounts of reducing gas (hydrogen) to create an effective and efficient nitrogen-base atmosphere. Such atmospheres are potentially highly reducing to metal oxides. Typically, nitrogen-base systems consist of essentially inert nitrogen and small amounts of one or more active gaseous ingredients.

Conventional atmosphere generators are not required in such systems; instead, feedstock gases (nitrogen and active gases) are piped through a flow panel into the furnace. The gases entering the panel regulation system exit as the atmosphere--the metering panel becomes, in effect, an atmosphere generator.

These systems exhibit great flexibility by enabling the ratio and types of active ingredients to be varied easily to suite the various sintering requirements within the plant. Nitrogen systems can also provide different atmospheres in different sections of a furnace, as shown in Fig. 14. The volume output reduction for nitrogen is 100%, considerably more than for endo and exo atmospheres. Nitrogen-base systems contain three basic types of active ingredients, as discussed below.

Fig. 14 Schematic of nitrogen-base zoned atmosphere system. Atmosphere and temperature profiles corresponding to the nitrogen-base atmosphere system are shown.

Oxide-Reducing Agents

Hydrogen is the most desirable ingredient for reduction of particle surface oxides, which thus improves bonding and provides maximum integrity to the sintered part. It is supplied by compressed hydrogen tube trailers or liquid hydrogen storage tanks, dissociated ammonia, endo gas, or dissociated alcohols such as methanol. Each supply source has advantages and disadvantages. Technically, hydrogen sources can be divided into the following two systems.

System 1. Hydrogen is supplied from endo gas or dissociated methanol. The total amount of combustibles (primarily hydrogen and carbon monoxide) in system 1 (nitrogen-endo or nitrogen/dissociated methanol) atmospheres varies between 15 and 30%, typically 24%.

Hydrogen is accompanied by carbon monoxide in a 2-to-1 ratio. The dew point is relatively high. Consequently, the hydrogen-to-water ratio is relatively low (40 to 50, as shown in Table 3). Although this ratio achieves acceptable oxide reduction in steel parts, other atmospheres--notably system 2, which uses dissociated ammonia in a nitrogen base--provide better ratios and consequently greater oxide reduction.

Methanol, as a source of hydrogen, is mixed with nitrogen before introduction into the furnace. Methanol molecules dissociate in the hot zone of the furnace as:

For this reaction to occur, furnace temperatures must be >800 °C (1470 °F), preferably >900 °C (1650 °F). The reaction is endothermic and requires ~5 kW of heat energy per gallon of methanol dissociated.

One liter of methanol produces ~1.7 m³ of hydrogen and carbon monoxide in a 2-to-1 ratio (1 gal produces 225 ft³). Typical water, carbon dioxide, and methane contents in dissociated methanol (without nitrogen additions) are 1.7, 0.4, and 0.2%, respectively. The carbon potential of dissociated methanol (without nitrogen additions) is 0.2 to 0.3% C at 925 °C (1700 °F). Composition control is generally improved when hydrogen is derived from methanol rather than from endo gas.

Because hydrogen produced from endo gas or dissociated methanol is always accompanied by carbon monoxide, use is limited to sintering P/M compositions that are not adversely affected by the presence of the gas. Endo gas or methanol is not recommended as a hydrogen source in P/M plants that use only one basic nitrogen system and have capabilities to sinter not only carbon steels but also bronze (at relatively low temperatures), magnetic steel, stainless steel, high-ductility iron parts, and high-carbon high-density parts that blister, or "ripple," during sintering.

System 2. Hydrogen is supplied from tube trailers, liquid storage tanks, or from dissociated ammonia. This atmosphere does not contain carbon monoxide and is pure and dry (very low dew point). The total amount of combustibles (primarily hydrogen) in system 2 (nitrogen-hydrogen or nitrogen/dissociated ammonia) atmospheres varies between 3 and 10%, typically 5%.

Hydrogen-to-water ratios are much higher than in endo gas or dissociated methanol atmospheres (Table 5). Tube trailers and storage tanks are the most flexible hydrogen supply sources, but are approximately two to three times as expensive as dissociated ammonia per unit of furnace atmosphere.

A system 2 using dissociated ammonia provides the optimum combination of oxide-reducing power, long-range economics, technical flexibility, operator safety, furnace life, and ease of operation. Because these atmospheres do not contain carbon monoxide, a broader range of P/M compositions can be sintered compared to system 1.

Carbon-Control Agents. Systems using hydrogen or dissociated ammonia (system 2) as the only active ingredient in nitrogen-base atmospheres do not experience surface decarburization of P/M steel parts if the dew point in the furnace is kept below approximately -30 °C (-20 °F). However, if the dew point in nitrogen-hydrogen (dissociated ammonia) atmosphere is slightly higher, small amounts of noticeable surface decarburization occur, and wear resistance of the finished part is lowered. In such situations, small amounts of hydrocarbon, preferably from natural gas, can be used with an oxide-reducing agent (hydrogen or dissociated ammonia) in system 2 to prevent decarburization or to add small amounts of carbon to the surface of the P/M part.

Generally, the amount of carbon monoxide present in system 1 is adequate to prevent decarburization of P/M steel parts. Small amounts of hydrocarbon derived from natural gas can be added to nitrogen-endo gas or nitrogen/dissociated methanol (system 1) atmospheres if additional carbon is desired in the part surface.

Oxidants. Oxidizing agents enhance burning of lubricants in P/M parts. Water and/or carbon dioxide can be added or generated within the furnace in controlled amounts for use in the delube section of the furnace to accomplish this purpose.

Oxygen from air is a relatively strong oxidant compared to water and carbon dioxide. Generally, adding oxygen or air to the atmosphere entering the delube section is not recommended for burning of lubricants.

Small amounts of oxidizing agents such as water can be added to the atmosphere entering the hot zone to achieve limited surface decarburization of parts requiring subsequent pressing and sizing. Small amounts of oxygen (air) or water can be added to nitrogen-base atmospheres with some circulation in the cooling section of the furnace to provide controlled but limited surface oxidation of the sintered parts. This procedure improves the appearance of the parts by imparting a straw,

blue, or gray finish, depending on the amount of air or water added and the temperature of the part in contact with the oxidant-containing atmosphere. This also improves corrosion resistance and service life of sintered parts.

Sintering Furnaces and Atmospheres

Furnace Zones Concept (Ref 23, 24, 25, 26, 27, 28)

Typical sintering furnaces can be thought of as having three or more interconnected zones (depending on the material being sintered), each with a separate function. The sintering process consists of several sequential phases, each requiring a unique combination of temperature, time, and atmosphere composition; flow; direction; and circulation. Each phase of the sintering process occurs in a specific zone of the furnace. Separating these zones and phases conceptually enhances design flexibility. A close match between the temperature and atmosphere of each zone and the function of each phase results in an optimum overall sintering process. In a single system, the base nitrogen can be modified with other gases or active ingredients to produce an appropriate and optimum atmosphere composition for each sintering phase before introduction into the proper furnace zone.

To understand the optimum combination of temperature, time, and atmosphere for each sintering phase, the processing sequence of a P/M part through the sintering furnace must be visualized. If the first sintering phase is completed effectively and efficiently in the first furnace zone, then the second phase in the second furnace zone, and each successive phase, is likely to be successful. The net result is improved productivity (production rate, quality, consistency, safety, versatility, and cost). Figure 7 shows a schematic of the processing sequence for sintering steel.

For example, if a P/M part composed of iron, 1% graphite, 2% copper, and 1% lubricant was processed in this furnace, at least five phases would be required to complete the sintering process. These would occur in five different zones of the furnace. The requirements for each sintering phase and furnace zone are outlined in Fig. 7 and are summarized in Table 6.

Table 6 Furnace zones, sintering phases, and atmosphere requirements to sinter an iron, 2% copper, 1% graphite, and 1% lubricant part

Furnace zone	Temperature		Time, min	Sintering phase	Sintering subphases	Atmosphere requirement	Atmosphere composition ^(a) , %			Flow	Circulation
	°C	°F					Hydrogen ^(b)	Methane	Water ^(c)		
1 delube	425-650	800-1200	10-30	Delubing	Lubricant vaporizing, vapor burning, flushing vapors to entrance	Fast, uniform heat transfer, slightly oxidizing	2-7	0-0.1	0.5-1.5	High toward entrance	Highly desirable
2 preheat	650-1070	1200-1960	5-15	Elimination of particle surface oxides	Oxide reducing, graphite diffusing, copper melting, and coating particle surfaces	Highly reducing to surface oxides, neutral to carbon fast, uniform heat transfer	5-15	0.1-0.3	0.01-0.03	High toward entrance	Desirable
3 high temperature	1070-1150	1960-2100	10-30	Particle bonding	Copper diffusing, neck (bond) growing, pore rounding	Neutral to carbon reducing	3-8	0.2-0.5	0.01-0.02	Medium toward entrance	Desirable
4 slow cool	1150-815	2100-1500	5-15	Carbon restoring	Carbon transferring, homogenizing	Uniform slow cooling, slightly carburizing	2-7	0.3-1.0	0.01-0.02	Medium toward entrance	Highly desirable
5 cool down	815-50	1500-120	30-90	Cooling down, optionally oxidizing	Pearlite forming, part cooling down, preventing oxidation or controlling light	Slightly reducing or neutral (optionally oxidizing) to iron,	0-2	0-0.1	0.01-0.02	Low to medium partially	Highly desirable

- (a) Balance is essentially nitrogen with or without small amounts of carbon monoxide and carbon dioxide.
- (b) Hydrogen can be derived from hydrogen storage vessel, dissociated ammonia, endothermic gas, or dissociated methanol.
- (c) If slightly oxidizing atmosphere is required, water is relatively higher or a small amount of air is introduced along with nitrogen in water-cooled section at a selected location.

Prime objectives in sintering this green part include the absence of sooting (internal or external). Admixed graphite should be effectively and uniformly diffused into iron particles as combined carbon. This results in an optimum pearlitic microstructure during cooling with minimum carbon loss. Admixed copper, after melting, should be uniformly distributed over all particle surfaces in the P/M part.

High structural integrity (maximum possible number of bonds or necks between particles, high average bond or neck area, and relatively rounded pores) is desirable. Surface carbon should be approximately equal to the carbon content in the core or interior. Emerging parts should be clean and bright or should have a controlled thin surface oxide to improve corrosion resistance. To meet these technical objectives economically, the total flow of atmosphere should be held to a minimum, with the least amount of added active gases.

For the purposes of the example, the atmosphere introduced into the furnace is nitrogen-base system 2 (carbon monoxide free), with 5% hydrogen and 0.5% methane. If the furnace is conventional, all of the atmosphere is introduced at one inlet--generally in the slow-cooling section between the hot zone and the water-cooled section. As a consequence, atmosphere composition (water, hydrogen, and methane content) is generally uniform throughout the different zones or sections as the atmosphere flows from the inlet toward both ends. This means that each active ingredient is at the same level whether or not the atmosphere is in a zone where a particular ingredient is needed. For the furnace to function, it is necessary to compromise between the atmosphere needed in one part of the furnace and that needed in another.

In the atmosphere system used in a zoned sintering furnace, however, different atmospheres (composition, flow, direction, and circulation) are introduced to different zones of the furnace (Fig. 14) to obtain optimum results. Wet nitrogen is introduced near the loading end of the furnace, hydrogen in the center, and dry nitrogen near the exit. Custom-designed injectors provide proper flow, circulation, and direction to these atmospheres. Injectors are also designed to act as gas barriers and reduce overall atmosphere flow. As a result of this zone, the constituents peak where they are needed (Fig. 14). In this example, water (dew point) is at the highest level near the entrance in the preheat zone, where delubing takes place. Hydrogen is introduced at a peak level at the mouth of the hot zone and in the hot zone, where it efficiently reduces surface oxides. Methane is added in sufficient amounts to reach maximum levels at the end of the hot zone and at the beginning of the slow-cooling zone, where it is needed for carbon control. Only nitrogen is added in the cooling zone, constituting nearly 100% of the atmosphere near the exit end of the furnace; furthermore, there is no need for a flame at the exit end. Therefore, exiting parts are cooler, and operators are safer and more comfortable.

In contrast to the conventional system, no compromise is needed to balance atmosphere makeup and furnace function; the zoned sintering atmosphere facilitates optimum sintering regardless of makeup or other part specifications. In zoned systems, atmosphere is introduced as needed with respect to composition, quantity, and location. Atmosphere zoning, combined with suitable temperature and time, allows each phase of the sintering process to be completed effectively, efficiently, and economically at the lowest possible atmosphere flow rates.

Nitrogen-base zoned atmosphere systems are compatible with existing furnaces, and the constituents can be varied to permit sintering of a wide variety of materials. A well-designed nitrogen-base system can meet the needs of a plant that sinters a wide range of ferrous and nonferrous parts. Technically, zoned atmospheres can achieve the same results as endo, dissociated ammonia, and exo atmospheres, while being more energy efficient, easier to operate, safer, and more flexible.

Nitrogen-base zoned atmosphere systems are capable of meeting the varying requirements imposed by furnace components. Atmospheres must be mild to furnace components. Conveyor belt alloys, for example, oxidize easily at sintering temperatures. However, under very dry and reducing atmospheres, the protective oxide layers are removed, and belt links tend to weld together. The belt "crackles" and gradually loses strength. Furthermore, belts, heating elements, and muffles become brittle and have short service lives under carburizing atmospheres. In addition, insulating brick oxides are reduced if the atmosphere is too reducing, which shortens service life.

Sintering Furnaces and Atmospheres

Safety Precautions (Ref 29, 30, 31, 32, 33, 34, 35)

Sintering atmospheres (endo, exo, dissociated ammonia, dissociated alcohols, and nitrogen-base) normally consist of a mixture of gases, which can be flammable, toxic, asphyxiant, or a combination of these. Explosion, fire, and poisoning are potential hazards. National Fire Protection Association standard 86C covers various safety considerations pertaining to continuous conveyor belt furnaces used in the P/M industry.

Four intrinsic dangers are associated with producing and using the common atmosphere gases. A mixture of atmosphere gas and air can accumulate in a confined area and explode. Relatively small quantities of atmosphere gas can unexpectedly burn or flash out of control. Personnel can be poisoned by carbon monoxide, ammonia, or methanol. "Simple" asphyxiation is possible when asphyxiants are present in high concentrations.

Table 7 describes the characteristics of the common sintering atmosphere constituent gases. Most of the major constituents are flammable; four are toxic and four are simple asphyxiants. Carbon monoxide, ammonia, and methanol are both flammable and toxic. The percentage by volume of the flammable ingredients ranges from 75% hydrogen in dissociated ammonia atmosphere to only a few percent in purified exothermic and nitrogen-base atmospheres.

Table 7 Potential hazards and functions of heat treating atmosphere constituent gases

Gas	Potential hazard			Atmosphere function
	Flammable	Toxic	Simple asphyxiant	
Nitrogen	Yes	Inert
Hydrogen	Yes	...	Yes	Strongly reducing
Carbon monoxide	Yes	Yes	...	Carburizing and mildly reducing
Carbon dioxide	...	Yes	Yes	Oxidizing and decarburizing
Natural gas	Yes	...	Yes	Strongly carburizing and deoxidizing
Ammonia	Yes	Yes	...	Strongly nitriding
Methanol	Yes	Yes	...	Carbon monoxide and hydrogen generating

Dangers are present even when heat treating with atmospheres that contain relatively small percentages of hazardous ingredients because these gases may accumulate or concentrate. Under typical operating conditions, however, the active ingredients in nitrogen systems are diluted below the level that is flammable, even if all the nitrogen is replaced by air. Explosion, burning, poisoning, and asphyxiation hazards are thus reduced, but not eliminated.

The explosive ranges of typical atmosphere constituents are the following:

Atmosphere constituents	Concentration in air, %
Hydrogen	4.0-74
Carbon monoxide	12.5-74
Methane	5.3-14
Ammonia	15.0-28
Methanol	6.7-36

Any mixture between the high and low limit of flammability will burn when ignited and, under certain conditions, detonate or explode. The destructive power of the pressure wave from an ignited flammable mixture depends on the amount of gas and the heat of combustion of the fuel gas, the combustion mode (deflagration or detonation), and the configuration of the confinement space. The energy released is either absorbed by the surroundings or destroys them.

The explosive potential of the large volumes of flammable gases used in sintering furnaces poses an important safety consideration. To ensure the safety of sintering and heat treating, the equipment and systems that handle gases must be designed, operated, and maintained to prevent accumulation of explosive mixtures. Dangerous accumulations that cannot be readily detected by personnel can occur. Properly designed safety systems, maintained and operated by well-trained and competent personnel, substantially reduce explosion hazards.

Generally, sufficient volumes of atmosphere gas flowing through the furnace leave the charge and discharge doors, mix with air, and burn uniformly and completely. However, several conditions can exist that prevent the atmosphere gas from burning off properly. Sometimes, a combustible mixture of air and gas can form in the furnace throats or vestibules. It can burn rapidly and forcefully exhaust, or flash, flames and hot gases through the furnace door. Unprotected personnel in the vicinity can be burned. Eyes are particularly sensitive to damage.

Although flashes of this type are more common than explosions, they are potentially less destructive. Nonetheless, personnel who approach these areas without safety glasses, protective face shields, gloves, and flameproof clothing risk serious flash burns. If safe methods are established and used for clearing jam ups, inspecting the furnace interior, and removing products from the furnace, this hazard can be substantially reduced.

Protective guards and shields used for routine operation are no substitute for the required protection of personnel working in the vicinity of the furnace doors. However, the possibility of flash back under nonflammable, nitrogen-rich atmospheres is remote.

Ammonia, carbon monoxide, and methanol, which are highly toxic, are used routinely in the sintering and heat treating industries. Liquid ammonia produces dissociated ammonia or ammonia vapor for nitriding, and carbon monoxide is a constituent of exothermic, endothermic, and dissociated methanol gases. Methanol is used to produce dissociated methanol, which consists of hydrogen and carbon monoxide. Concentrations of $< \frac{1}{2}$ % ammonia or carbon monoxide in the air are considered fatal in $< \frac{1}{2}$ h of exposure. Tables 8 and 9 give the physiological effects of various concentrations of these gases.

Table 8 Physiological effects of ammonia

Concentration, ppm	Physiological effects
20	First perceptible odor
40	Slight eye irritation in a few individuals
100	Noticeable irritation of eyes and nasal passages after a few minutes of exposure
400	Severe irritation of the throat, nasal passages, and upper respiratory tract
700	Severe eye irritation; no permanent effect if the exposure is limited to less than $\frac{1}{2}$ h
1700	Serious coughing, bronchial spasms; less than $\frac{1}{2}$ h of exposure may be fatal
5000	Serious edema, strangulation, asphyxia; almost immediately fatal

Table 9 Physiological effects of carbon monoxide

Concentration, ppm	Physiological effects
100	Allowable for an exposure of several hours
400	Can be inhaled for 1 h without appreciable effect
600	Causes a barely appreciable effect after 1 h of exposure
1000	Causes unpleasant symptoms, but not dangerous after 1 h
1500	Dangerous for exposure of 1 h
4000	Fatal for exposure of less than 1 h

Threshold limit values, published by the American Conference of Governmental and Industrial Hygienists, list carbon monoxide, carbon dioxide, ammonia, and methanol as commonly used toxic chemicals. Concentrations as small as 35 ppm of ammonia, 400 ppm of carbon monoxide, and 250 ppm of methanol are harmful; therefore, only short exposures are allowed.

Protection from poisoning by raw ammonia or methanol vapor or from contact with liquid ammonia or methanol is provided partly by the design of the storage and delivery system. Suppliers are excellent sources of detailed safety information on ammonia and methanol systems and ammonia dissociators.

Carbon monoxide is not quite as toxic as ammonia; however, because it is odorless, it poses a greater safety hazard. Lethal concentrations can collect in isolated areas and remain undiscovered until personnel are overcome by fumes. According to Ref 30, ". . . in concentrations far short of the asphyxiation level, carbon monoxide is still dangerous, especially if exposure is prolonged. Carbon monoxide (poisoning) can be a contributing factor to death that ultimately results from other causes, such as fatal accidents, and is a health as well as safety problem." Carbon monoxide interferes with the ability to breathe and, as a result, the body's ability to utilize oxygen. It is over 200 times more attractive than oxygen to the blood hemoglobin that delivers oxygen throughout the body. A relatively small amount of carbon monoxide, therefore, depletes the body of a large amount of oxygen.

To ensure personnel safety, piping between the generator and the furnace must be leaktight, and all gas that enters the furnace must be either burned off or properly vented. The highly toxic nature of carbon monoxide requires use under carefully controlled conditions. The safest and most convenient disposition of carbon monoxide is to ensure complete mixing of the furnace atmosphere effluent with air to combustible proportions and subsequent ignition of the mixture. Products of combustion are far less toxic, but should still be properly vented.

In some sintering applications, carbon monoxide cannot be burned directly because it has been diluted in inert gas to a level that is nonflammable when mixed with air. Special precautions must be taken to vent and dilute it to below toxic limits. To ensure the continued effectiveness of the venting, carbon monoxide levels near the furnace setup must be monitored continuously. Consequently, apparatus using or emitting gas containing carbon monoxide that will not burn when mixed with air should not be operated unless the user is willing to accept the added liability. Additionally, special gas monitoring and discharging equipment should be installed.

Personnel should also be familiar with the early symptoms of carbon monoxide poisoning and trained in appropriate first aid. Early symptoms include slight dizziness, weakness, or headache. In the later stages of poisoning, the victim's lips and skin turn a characteristic cherry red.

Finally, the danger of asphyxiation is not intrinsic to the gases used in the P/M industry, but it is a concern. Asphyxiation can be caused by a harmless gas (for example, a gas that has no significant physiological effect) if it is present in high concentrations in the air. Normal oxygen content in air is ~ 21 vol%. Minimum oxygen content should be 18 vol% under normal atmospheric pressure.

Production Sintering Practices

Introduction

SINTERING is a complex high-temperature process that consolidates and strengthens loose or compacted particles into a more dense coherent body. During sintering powder particles form coherent bonds and densify by pore shrinkage. There is no universally applicable theory of sintering, and much is not understood about the process; but sintering generally consists of six distinct, but not necessarily sequential, stages:

- Initial particle bonding
- Neck growth
- Pore channel closure
- Pore rounding
- Densification or pore shrinkage
- Pore coarsening

A comprehensive and systematic theory of sintering has not been established due to the multitude of variables that influence sintering. Nonetheless the major factors that influence sintering response can be classified in terms of transport mechanisms, reaction types, and sintering parameters. These major factors include the following variables:

Mechanism of material transport

- Viscous flow
- Surface diffusion
- Lattice or volume diffusion
- Grain boundary diffusion
- Evaporation and condensation

Types of sinter reactions

- Single-component sintering of metals, oxides, or hydrides
- Multiple component sintering of solid solutions, intermetallic, or mechanically bonded systems
- Activated sintering with additives

Sinter Conditions

- Rate of heating and cooling
- Sintering time
- Sintering atmosphere
- Sintering temperature

Sintering time and temperature are the most significant factors from a practical perspective, with temperature being the most important variable. Particle size, compact porosity, and powder type (mixed, prealloyed, and diffusion-alloyed) also influence sintering practices.

Table 1 lists typical sintering temperatures for various P/M materials and ceramics. Sintering is generally performed at temperatures around $\frac{2}{3}$ to $\frac{4}{5}$ of the absolute melting point or solidus of the material for a single-component system.

Multicomponent powder mixtures are generally sintered near the melting point of the constituent with the lowest melt temperature.

Table 1 Sintering temperatures for powder metal alloys and special ceramics

Sintered material	Sintering temperatures, °C
Aluminum alloys	590-620
Bronze	740-780
Brass, 890-910	
Iron, carbon steels, low-alloyed steels (Cu, Ni)	1120-1150
Low-alloyed steels (Cu, Ni, Mo; Distaloy)	1120-1200
High-alloyed ferritic and austenitic steels (Cr, Cr-Ni)	1200-1280
Hard magnets (Alnico)	1200-1350
Hard metals (cemented carbides) ^(a)	1350-1450
Molybdenum and molybdenum-alloys	1600-1700
Tungsten ^(b)	200-2300
Heavy metal (W alloy)	~1400
Ferrites (soft and hard)	1100-1300
Silicon nitride (with different additives) ^(c)	1750-2000
Silicon carbide (with different additives) ^{(d)(e)}	1750-2100
Alumina ^(e)	1400-1800
Zirconia (with different additives) ^(e)	1400-1750

Source: Ref 1

- (a) TiC-based hard metals (cermets) up to 1600 °C.
- (b) ~3000 °C, when direct sintering is used.
- (c) Highest temperature under pressured N₂ atmosphere or in powder bed.
- (d) Low temperatures for liquid phase sintering.
- (e) Low temperatures for highly active powders.

Sintering times are typically 20 to 60 min under a protective atmosphere. Widely used furnace atmospheres include endothermic gas, exothermic gas, dissociated ammonia (DA), hydrogen, hydrogen-nitrogen mixtures, and vacuum. The main function of the atmosphere is to protect a part from oxidation or nitridation, as might occur when heating in air. Frequently, however, critical aspects of a sintering atmosphere also include reducing and carburizing power and capability for efficient removal of the lubricant. Some sintering furnaces contain so-called rapid burn-off zones for rapid and efficient removal of the lubricant. This usually entails an atmosphere with a higher oxidation potential, that is, a higher concentration of gases such as steam and carbon dioxide.

Inadequate sinter generally is indicated by low strength, low hardness, and improper dimensions. Causes of inadequate sintering are often related to the atmosphere, but several factors may be involved, such as:

- Sintering temperature too low
- Insufficient reducing agent
- Dew point too high in the hot zone
- High O₂ content in hot zone
- Incorrect green density
- Incorrect belt speed or time at temperature

Corrective action includes:

- Measure and control dew point and O₂ content in the hot zone
- Measure and increase H₂ content
- Check and correct belt speed and/or powder compositions

Further information on atmosphere control for sintered steel is discussed in the preceding article "Sintering Furnaces and Atmospheres" in this Volume.

Production Sintering Practices

Sintering of Ferrous Materials

Pressed and sintered iron-base materials represent the largest segment of the P/M parts industry. Ferrous P/M parts are made from iron powders, alloy steel powders, or mixtures of (a) iron and graphite powders, (b) iron (or steel) and copper powders, or (c) iron, copper, and graphite powders (with or without powders of other metals). The overall sintering process consists of several stages and temperature regimes (Table 2). Excluding lubricant burnoff, the following reactions occur during sintering of ferrous powders:

- Metallurgical bonds develop from the mechanical interlocks between powders in the compact.
- Metal oxides are reduced by reaction with the carbon from the blended graphite powders.
- Carbon alloying of the iron powder is obtained by diffusion of carbon from graphite powder.
- Densification of P/M compacts is achieved by shrinkage and the reduction of porosity.

Table 2 General temperature regimes during steel sintering

Process stage ^(a)	Temperature range, °C
Lubricant removal, in the liquid state	150-200
Lubricant removal, by gaseous decomposition	300-600
Refining (reduction of iron oxide)	750-1000 ^(b)
Carbon diffusion	900-1050
Diffusion of alloy additions	1050-1300
Carbon pick-up by the atmosphere (in some cases)	1000-1300
Carbon restoration	1050-800
Microstructure formation	950-600
Final cooling, under reducing or "inert" conditions	Cool from 600 to 50

Source: Ref 2

- (a) Not all stages apply and some stages may overlap.
- (b) Reduction of metal oxides other than iron oxide may require higher temperatures depending on the element and furnace atmosphere.

Conventional sintering generally is conducted at 1120 °C (2050 °F) in mesh belt conveyor furnaces with conveyor mesh belts made from nickel-chromium alloy wire. Mesh belt furnaces can be used at temperatures up to 1150 °C (2100 °F) only, due to the temperature limitation of the belt material. For high-temperature sintering applications, walking beam furnaces have been successfully used for continuous operation at temperatures up to 1315 °C (2400 °F). Furnace temperatures rarely exceed 1350 °C (2460 °F) in ferrous P/M operations (Ref 3).

Sintering temperatures depend on the material and desired properties. Alloy steels typically require higher sintering temperatures (Table 3) and times to promote homogenization. Typical sintering practices for several ferrous materials, with an emphasis on the types of atmospheres used and the resulting as-sintered microstructures and properties, are described in this section. In practice, sintering parameters are usually determined empirically from a combination of technical requirements and economic factors (and furnace type).

Table 3 Sintering temperatures for various iron-base alloys

Material	Sintering temperature ^(a) , °C
Fe, Fe-Cu, Fe-Cu-Ni	1120-1280
Fe-C, Fe-Cu-C, Fe-Cu-Ni-C	1120-1150
Fe-Cu-Ni-Mo (Distaloy)-C	1120-1200
Fe-Mn, Fe-Mn-C	1120-1280
Fe-Cr, Fe-Cr-C	1150-1280
Fe-Mn-Cu	1120
Fe-Cr-Cu	1200-1280
Fe-Mo, Fe-Mo-C	1120-1280
Fe-Cr-carbide	>1280
Fe-V carbide	>1280
Fe-Ti-carbide	1200-1280
Fe-W-carbide	1200-1280
Fe-Mn-Cr-Mo-C, Fe-Mn-V-Mo-C	>1280
Fe-Cr-Ni	>1280

Production Sintering Practices

Sintering Atmospheres

Sintering atmospheres primarily control chemical reactions between the materials being processed and the furnace surroundings. Additionally, atmospheres may be the source of one or more chemical elements that alloy with the material being sintered. An example of this is the addition of carbon to iron in a carburizing furnace atmosphere. Sintering atmospheres may also prevent the loss of alloying elements existing in the material being processed. Atmospheres are routinely used to flush the decomposition products of the admixed lubricants from the furnace to prevent deposits on furnace interiors, where they rapidly degrade the performance of the equipment.

In common operating practice, the most important functions of select atmospheres are to aid in the reduction of oxides on the surfaces of the metal particles in the compact and to control carburization and decarburization of iron and iron-base compacts caused by oxygen, water vapor, and carbon dioxide when present in improper proportions with respect to the hydrogen and carbon monoxide contents of the sintering atmosphere. Iron oxides are reduced by hydrogen, carbon monoxide, and carbon. Carburization is caused by carbon monoxide and by hydrocarbons such as methane.

The most frequently used atmospheres in commercial sintering of P/M iron and steel materials are endothermic, exothermic, dissociated ammonia, pure hydrogen, and nitrogen-base atmospheres. Of these, endothermic gas is the most widely used, followed by dissociated ammonia.

Endothermic and Exothermic Atmospheres. Although other hydrocarbon gases may be used, methane and propane are the most commonly used bases for the production of endothermic gas and exothermic gas atmospheres. These furnace atmospheres consist of mixtures of nitrogen, water vapor, carbon monoxide, hydrogen, carbon dioxide, and methane. The degree of combustion that occurs is controlled by the amount of air admitted to the process. This air-to-gas ratio determines the properties of the resultant gas. With methane, endothermic gas is produced with air-to-gas ratios of ~

2.4, while exothermic gas ratios are usually above the 9.0+ value required for complete combustion (10-to-1 is the air-to-gas ratio for complete combustion).

For an endothermic-type gas produced from methane, the reaction can be approximated by:

This gas is strongly reducing to iron oxide. Control of carbon level, however, is difficult because the carbon potential of endothermic gas varies with temperature and dew point, as shown in Fig. 1. The carbon potential of the endothermic gas with -1 °C (30 °F) dew point varies from about 0.2% at 1120 °C (2050 °F) to 1.0% at about 850 °C (1560 °F). Dew point is a measure of the dryness of the atmosphere gas. The lower the dew point, the lower the water vapor content of the atmosphere. Generally, low dew point gases increase the reduction potential of the atmosphere. Figure 2 shows the relationship between dew point and water vapor content.

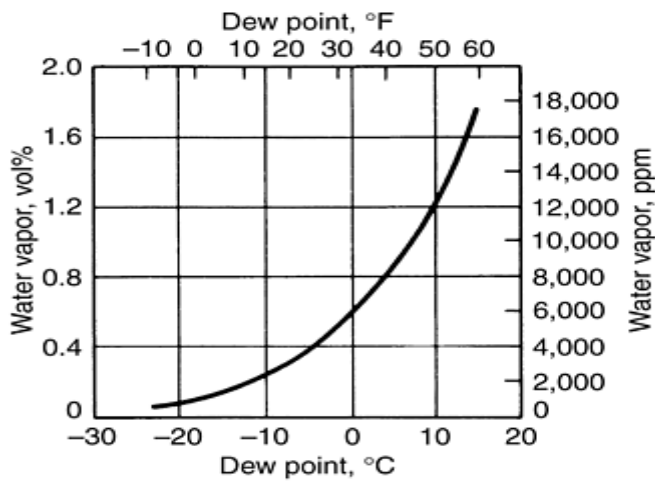

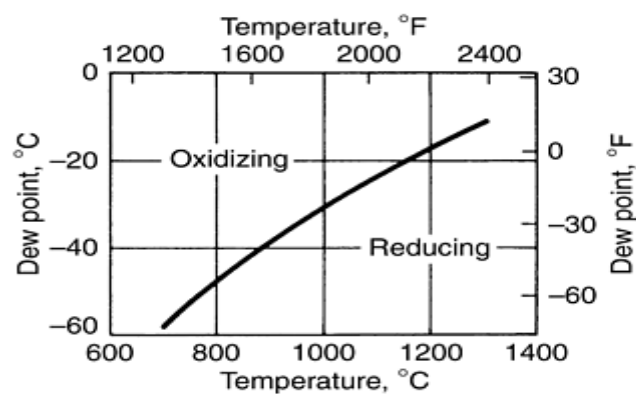

Fig. 1 Carbon potential of endothermic gas as a function of dew point and temperature

(b)

(c)

Fig. 2 Relationship between (a) dew point and water vapor content. (b) Equilibrium values of H_2/H_2O ratio and dew point of selected oxides. (c) Oxidation-reduction of chromium oxide for pure chromium in hydrogen.

When generating exothermic-type atmospheres, the reaction is self supporting and generates heat, which in the presence of a nickel catalyst promotes cracking of any of the hydrocarbons remaining unburned into hydrogen and carbon monoxide. The two reactions that occur are:

Exothermic atmospheres are not strongly reducing to iron and are decarburizing at normal sintering temperatures. Their use in sintering iron-base materials is limited to applications that do not require a residual carbon content. Removal of water and carbon dioxide can improve the properties of this protective atmosphere.

Nitrogen-Base Atmospheres. Protective atmospheres based on nitrogen obtained from the fractional distillation of liquid air are enjoying increased usage, not only in sintering, but in heat treating as well. This is primarily due to the increasing cost of hydrocarbon fuels.

Basically, nitrogen can be taken from a bulk storage facility or directly from the distillation tower and can be used as a replacement for all, or nearly all, of the carbon monoxide and/or hydrogen-containing gases previously used. Typical usage consists of utilizing nitrogen to extend either endothermic gas or dissociated ammonia through dilution. Hydrogen content can be reduced to a few percent of the total, versus a normal 40% presence in conventional endothermic gas.

Because there is less hydrogen available to reduce the oxide present on the surface of powder particles, greater demand is placed on the graphite present to take part in the reduction process. As a result, greater amounts of admixed graphite are required if the sintered carbon content is to remain the same.

Dissociated Ammonia Atmospheres. Dissociated ammonia, consisting of 75 vol% hydrogen and 25 vol% nitrogen, is produced from gasified ammonia by the reaction:

Dissociated ammonia directly from the dissociator is very dry, generally yielding dew points of -40°C (-40°F) or lower.

It is common practice to generate dissociated ammonia with higher nitrogen contents by reacting ammonia with air either catalytically or through partial burning. The water formed in such reactions is removed from the gas by absorption.

Hydrogen Atmospheres. Typical methods used to produce metallurgical-grade hydrogen include the electrolysis of aqueous solutions and the reaction of hydrocarbon gases with steam or oxygen to form mixtures of hydrogen and carbon monoxide. Carbon monoxide is subsequently converted to carbon dioxide and scrubbed from the mixture. Hydrogen is used primarily in the sintering of iron-base magnetic materials. Alnico permanent magnets, for example, are frequently sintered in an atmosphere of very dry hydrogen at 1300°C (2370°F).

Production Sintering Practices

Iron and Iron-Graphite Powder

Sintering of plain iron powder sequentially involves the establishment and growth of bonds between the particles of powder at their areas of contact, grain growth and migration of the grain boundaries formed at the bonds, spheroidization of the pores between the particles, and the elimination of small pores (and, possibly, the growth of large pores). The formation of bonds is opposed by residual material from the lubricant, by impurities and surface oxides, and by poor contact.

As the sintering temperature increases, porosity decreases and shrinkage increases. Bonds form between the particles during sintering, and the number of particle bonds increases as the temperature increases. In addition, some grain growth and spheroidization of pores occur as sintering temperatures increase.

Mixtures of iron and graphite powders are sintered by (a) establishment and growth of iron-to-iron bonds, (b) diffusion of carbon into and combination of carbon with iron, and (c) spheroidization of pores. The oxide content of iron is an important factor in determining the reactivity of iron with graphite.

During sintering, the major portion of the oxide must be reduced by the graphite and the sintering atmosphere before the iron and graphite can combine. To ensure high reactivity with the iron for rapid reduction of oxide and fast carburization, fine graphite powder--free of silicon carbide and having low ash content--usually is used.

Although iron powder of low oxide content is not required, determination of the oxide content (hydrogen loss value) is essential, because the graphite addition must be large enough to allow for reaction with the oxide and still provide a sufficient quantity to produce the desired iron-carbon alloy.

Effect of Combined Carbon. Aside from bonding, the main factor affecting the properties of a sintered steel part is the amount of combined carbon formed in the steel. Overall expansion during sintering is directly proportional to the amount of combined carbon. As with wrought steel, the strength of sintered steel increases rapidly with increasing combined carbon content. For wrought steel, strength increases rapidly up to 1.0% combined carbon, then gradually reaches a maximum at the highest carbon content of 1.6%, as shown in Fig. 3.

Fig. 3 Effect of combined carbon content on the tensile strength of wrought (rolled) steel. Source: Ref 4

Figure 4 shows a similar plot for sintered steel. Combined carbon was varied by adding increasing amounts of graphite. Test bars were pressed to a density of 6.3 g/cm^3 , then sintered 30 min at $1120 \text{ }^\circ\text{C}$ ($2050 \text{ }^\circ\text{F}$) in dissociated ammonia. Figure 4 shows transverse rupture strength as a function of combined carbon. As with solid steel, there is a rapid initial increase in strength with increasing combined carbon content, but a maximum is reached at about the eutectoid composition of 0.85% C. Between 0.90 and 1.00%, strength drops markedly.

Fig. 4 Effect of combined carbon content on the transverse rupture strength of sintered steel. Test bars were pressed to density of 6.3 g/cm^3 , then sintered for 30 min at $1120 \text{ }^\circ\text{C}$ ($2050 \text{ }^\circ\text{F}$) in dissociated ammonia. Source: Ref 4

As the amount of pearlite that contains the combined carbon increases, strength and hardness increase correspondingly until a combined carbon content of 0.8% is reached, at which point the structure consists entirely of fine pearlite. At 1.0% combined carbon, free cementite forms at the grain boundaries, which reduces the transverse rupture strength. At 1.2% combined carbon, the network of free cementite becomes continuous, further reducing the transverse rupture strength.

Thus, most sintered steel has a combined carbon content of 0.8 to 0.9%, and a graphite addition greater than 0.9%. Carbon loss is controlled by maintaining the carbon potential of the sintering atmosphere at 0.7 to 0.9%. The furnace atmosphere must be controlled at a high enough carbon potential to prevent excessive loss of carbon to the atmosphere, because decarburization results in correspondingly poor properties.

As the sintering temperature or time is increased, spheroidization of the pores causes the strength of a compact to continue to increase after carburization of the iron to an all-pearlite structure is complete. The resulting densification of the compact causes a reduction in overall growth of the part. The effect of sintering temperature on strength is shown in Fig. 5 for typical steel compact.

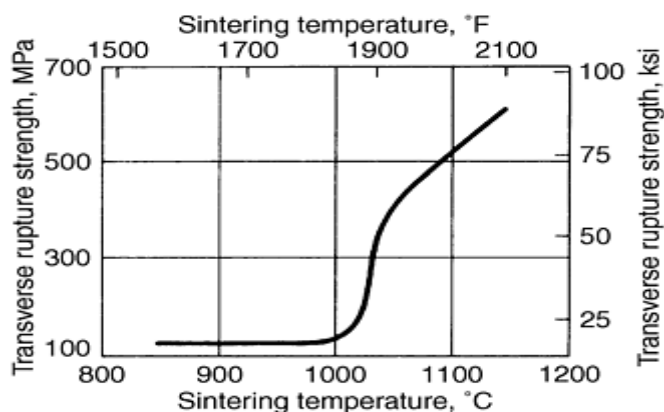

Fig. 5 Effect of sintering temperature on transverse rupture strength of iron plus 1.25% graphite test bars. Compacted to a density of 6.1 g/cm^3 and sintered for 30 min at temperature. Source: Ref 4

Effect of Atmosphere Composition. The tendency of parts to oxidize or reduce and to carburize or decarburize, as well as the rates at which these reactions occur during sintering, depends on the sintering temperature and the proportion of various gases contained in the sintering atmosphere. The sintering atmosphere has a strong effect on the amount of combined carbon formed during sintering. If the carbon potential is not controlled, excessive carbon may be lost to the atmosphere, or excessive carburization may occur.

The carbon potential is determined by the ratio of water vapor to hydrogen, carbon dioxide to carbon monoxide, and methane to hydrogen. The amount of graphite in the parts also contributes to the carbon potential in the furnace atmosphere. Figure 6 illustrates equilibrium ratios at various temperatures for oxidation-reduction and decarburization-carburization reactions. Typically, the carbon dioxide to carbon monoxide ratio can be fairly high at all temperatures without causing oxidation. However, it is necessary to keep the carbon dioxide content low to prevent decarburization.

Fig. 6 Equilibrium ratios at various temperatures for oxidation-reduction and decarburization-carburization reactions. Equilibrium reactions: R, reducing; C, carburizing; O, oxidizing; D, decarburizing. Source: Ref 4

Carbon dioxide content is kept low by maintaining a low enough dew point (water vapor content) to balance the otherwise continuously reversible "water-gas" reaction:

A dew point of -4 to -1 °C (25 to 30 °F) at the generator is usually low enough to maintain a 0.70 to 0.90% carbon potential during continuous sintering of iron-graphite mixes. If lower combined carbon is desired, then a smaller graphite addition can be made or a higher dew point can be used to raise the carbon dioxide content.

The ratio of methane to water vapor also determines the tendency of parts to gain or lose carbon. At normal sintering temperatures, even small amounts of methane in the furnace atmosphere increase carburizing tendency. Increased amounts of methane further increase this tendency.

Atmospheres having better than equilibrium ratios are required unless long sintering times or high sintering temperatures are permitted. Also, nitrogen content should be kept as low as possible. For example, purified exothermic gas (high-nitrogen content) can be used, but frequently larger graphite additions are required to obtain the desired combined carbon. Endothermic gas (low-nitrogen content), however, promotes rapid carbon pickup, and less graphite is required.

Effect of Temperature. Although sintering temperature has a profound effect on the amount of combined carbon formed for a given sintering time, graphite combines readily under normal sintering temperatures and times. Figure 5 illustrates the effect of sintering temperature on the transverse rupture strength of bars made of iron plus 1.25% graphite, pressed to a density of 6.1 g/cm³ and sintered for 30 min at temperature. No strengthening occurs as the sintering temperature is raised from 900 to 1010 °C (1650 to 1850 °F). Above this temperature, however, a substantial increase is noted.

Figure 7 illustrates the changes in microstructure. At low sintering temperatures, no carbon is combined, as evidenced by the complete absence of pearlite. At 1010 °C (1850 °F), some carbide has begun to form (Fig. 7a), while at 1040 °C (1900 °F), the maximum combined carbon content is achieved (Fig. 7b). Additional strengthening at higher temperatures is caused by increased sintering, as evidenced by the elimination of grain boundaries and spheroidization of pores--shown in Fig. 7(c) at 1120 °C (2050 °F) and Fig. 7(d) at 1175 °C (2150 °F).

Fig. 7 Effect of sintering temperature on the microstructure and transverse rupture strength of iron plus 1.25% graphite test bars. Etchant: 4% picral plus 0.5% nitric acid. 800 \times . (a) Sintering temperature: 1010 °C (1850 °F). Combined carbon: 0.1%. Strength: 138 MPa (20 ksi). (b) Sintering temperature: 1040 °C (1900 °F). Combined carbon: 0.75%. Strength: 352 MPa (51 ksi). (c) Sintering temperature: 1120 °C (2050 °F). Combined carbon: 0.75%. Strength: 552 MPa (80 ksi). (d) Sintering temperature: 1175 °C (2150 °F). Combined carbon: 0.75%. Strength: 655 MPa (95 ksi)

Effect of Sintering Time. Time of sintering also affects the amount of combined carbon formed. At the sintering times normally used, however, the maximum amount of combined carbon is usually formed. A noticeable effect on strength and dimensional change during sintering was apparent for a series of test bars sintered at several temperatures for times varying from 5 to 120 min. Figure 8(a) is a plot of sintering time versus transverse rupture strength. A rapid increase in strength occurs up to 30 min, followed by smaller increases at longer times.

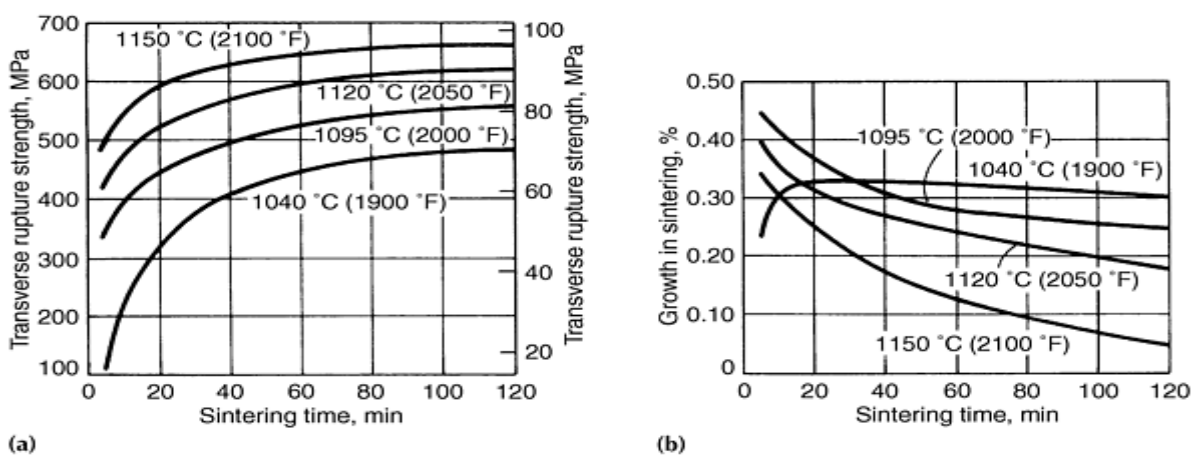

Fig. 8 Effect of sintering time on properties of iron-graphite test bars pressed to a density of 6.1 g/cm³. (a) Transverse rupture strength. (b) Dimensional change. Source: Ref 4

Figure 8(b) is a plot of sintering time versus dimensional change for several temperatures. These are typical size change curves showing a high growth at relatively short times, followed by lesser growth at longer times. Figure 9 illustrates how microstructure is influenced by sintering time at 1120 °C (2050 °F). Figure 9(a), a microstructure of an unsintered bar, shows the individual particles, grains within particles, and graphite located primarily at the pores formed between particles. Figure 9(b) shows almost complete formation of pearlite in 5 min; numerous grain boundaries are visible, and the porosity is quite angular. Figure 9(c) shows some disappearance of grain boundaries and slight spheroidization of pores after 30 min, while Fig. 9(d) shows an almost complete absence of grain boundaries and substantial spheroidization of pores after 120 min. Sintering for 10 min at 1200 °C (2200 °F) typically results in strength equal to that attained after 120 min at 1120 °C (2050 °F).

Fig. 9 Effect of sintering time on the microstructure and transverse rupture strength of iron-graphite test bars pressed to a density of 6.1 g/cm³. (a) As-pressed condition. Combined carbon: 0%. Strength: ~124 MPa (18 ksi). (b) Sintering time: 5 min at 1120 °C (2050 °F). Combined carbon: 0.7%. Strength: ~421 MPa (61 ksi). (c) Sintering time: 30 min at 1120 °C (2050 °F). Combined carbon: 0.7%. Strength: ~552 MPa (80 ksi). (d) Sintering time: 120 min at 1120 °C (2050 °F). Combined carbon: 0.7%. Strength: ~627 MPa (91 ksi)

Effect of Cooling Rate. The influence of cooling rate on strength in wrought steel is well known. Iron-graphite samples similar to those used in the study of effect of time and temperature were sintered for 30 min at 1120 °C (2050 °F), followed by cooling at different rates. Table 4 shows the three rates used and the resulting mechanical properties. Typically, faster cooling rates cause increased strength and hardness.

Table 4 Effect of of cooling rate on iron-graphite samples

Pressed to a density of 6.1 g/cm³ and sintered 30 min at 1120 °C (2050 °F)

Sample No.	Cooling rate		Transverse rupture strength		Hardness, HRB	Pearlite spacing
	°C/min	°F/min	MPa	ksi		
1	1.9	3.5	462	67	37	Very coarse
2	64	115	565	82	50	Medium
3	125	225	600	87	57	Very fine

Production Sintering Practices

Iron-Copper and Iron-Copper Graphite

The sintering of iron-copper mixtures involves (a) solid bonding of iron to iron, (b) solid bonding of copper to iron, (c) melting of copper, (d) solution and diffusion of copper in solid iron, and (e) solution and precipitation of iron in liquid copper.

At typical sintering temperatures of 1095 to 1120 °C (2000 to 2050 °F), 7.5 to 9.0% Cu is soluble in iron. However, with this copper content and typical sintering conditions, some of the molten copper remains undissolved, or free, and can dissolve ~3% Fe.

The solubility of copper in iron decreases with decreasing temperature and is less than 0.1% at room temperature. Therefore, copper dissolved in iron at the sintering temperature must precipitate as the compact is cooled, thus hardening it. Faster cooling rates lower the temperature at which the precipitate forms, which makes the precipitate finer and increases the hardening effect.

The solution of copper in iron causes growth of the compact; the solution of iron in the free copper causes shrinkage. These processes go on simultaneously, with solution of copper predominating only in the early stages of sintering. For example, the addition of 7.5 to 10% Cu causes significant amounts of growth, but a 20% addition increases the amount of free copper to the extent that growth is no greater than for a 7.5% copper addition.

The sintering of iron-copper-graphite mixtures involves the mechanisms associated with both the iron-graphite and iron-copper mixtures mentioned previously. Diffusion of carbon usually is complete before the melting point of copper is reached. Carbon has little effect on the solubility of copper in solid iron, but it decreases the rate of solution. Thus, there is usually more free copper remaining when carbon is present, which acts to reduce the amount of growth.

Figure 10 illustrates the combined effects of graphite and copper powder additions on iron compacts sintered in an endothermic atmosphere to a density of 6.8 g/cm³. Transverse rupture strength is plotted as a function of the amounts of graphite and copper powder added to the iron powder. The amount of combined carbon in these compacts is ~80% of the graphite added. The highest value of transverse rupture strength of 1240 MPa (180 ksi) is obtained with additions of 0.9% graphite and 5% copper.

Fig. 10 Transverse rupture strength of iron, copper, and graphite powder compacts. Sintered to a density of 6.8 g/cm³ in endothermic gas. Lines represent compositions having the same transverse rupture strength, given in MPa with ksi equivalent values in parentheses; combined carbon in alloys is ~80% of amount of graphite included in mixture.

A steel of this composition is quite brittle and is used in applications that do not require superior toughness. The high strength of iron-copper-carbon compacts in the as-sintered condition is essentially due to the combined effect of copper causing precipitation strengthening and increasing the hardenability of the steel.

Production Sintering Practices

Sintering of Alloy Steels

Sintered alloy steels are made from various powder types that may be elemental, prealloyed, diffusion alloyed, or a hybrid mix of these types. The most common alloying method is mixing and compaction of elemental powders, which then alloy during sintering by diffusion. Mixing of elemental powders is advantageous because elemental powders have high compressibility due to the absence of solid solution strengthening. However, in order to achieve adequate homogenization, uniform composition and good diffusion rates must be maintained during sintering. Ferrous master alloys are sometimes used for base powders in admixed systems. Powders manufactured from ferrous master alloys can also be advantageous when the alloy elements are strong oxidizers (like chromium or manganese).

In contrast, prealloyed steel powders are alloyed during atomization and do not require homogenization during sintering. This allows a higher level of chemical and structural homogeneity in sintered parts. Prealloyed powders are more expensive and have lower compressibility than elemental mixes, but they are used in high-performance parts that require structural integrity in demanding applications. Diffusion alloyed powders are an intermediate powder form where alloy elements are partially bonded onto base iron particles. Because the elements are not fully alloyed, the powders still have good compressibility, while the bonding improves the level of chemical homogeneity. Diffusion bonded powders typically involve iron alloying with nickel, molybdenum, and/or copper and can be sintered like elemental mixes. Prealloyed powders include a wider variety of possible compositions.

Sintering of Ferrous Alloys with Copper, Nickel, Molybdenum, and/or Phosphorus. A major constraint in conventional P/M alloy development is that typical production furnaces and atmospheres require elemental mixes and diffusion-alloyed powders based on elements with a low affinity for oxygen (copper, nickel, molybdenum, and phosphorus). Nickel, molybdenum, phosphorus, and copper have low affinity with oxygen (Table 5) which thus allows reduction of their oxides in typical mesh-belt furnaces (which cannot exceed 1150 °C and have typical atmosphere dew points around -10 to -40 °C). Under these typical production conditions, elements with high-oxygen affinity (chromium, manganese, and silicon) may not be adequately reduced during sintering. This limitation on alloying can be overcome to some extent by vacuum sintering, high-temperature sintering, or by using prealloyed powders.

Table 5 Alloying properties of selected elements in iron

Alloying element	Hardening Grossman factor ^(a)	Diffusion coefficient (D_x/D_{Fe}) ^(b)	Enthalpy of oxide formation, kJ/g · atom of oxygen
Copper	1.7	1	-150
Nickel	1.4	0.5	-250
Cobalt	2	0.5	-270
Tungsten	...	4.5	-270
Molybdenum	3.7	5	-310
Iron	-350
Chromium	3.1	5	-540
Manganese	4.5	2.5	-500
Vanadium	...	5	-620
Boron	-650
Silicon	1.7	10	-680

(a) Grossman factor for 1 wt% alloy.

(b) Diffusion coefficient of alloying element in γ -iron (D_x), self-diffusion coefficient of γ -iron (D_{Fe})

Nickel-Steel. Sintering of mixed iron-nickel powders is subject to inhomogeneous alloying due to the low diffusion rate of nickel into iron (Table 5). Fine (carbonyl) nickel powder should be used when mixing with iron powder, and the sintering temperature should be at least 1100 °C (2010 °F) or preferably up to 1200 °C (2190 °F).

Cu-Ni-Mo Steels. Copper-nickel steels are sintered at temperatures up to 1150 °C, and the temperature must be increased to at least 1200 °C when molybdenum is added (Ref 3).

Phosphorus Steel. Unlike wrought forms (where phosphorus causes grain boundary embrittlement), phosphorus is a common alloying element in P/M Steels. phosphorus P/M steels provide a unique combination of strength and ductility, which is attributed to the formation of a eutectic liquid phase in the initial stages of sintering (starting at 1050 °C) and the stabilization of ferrite even at normal sintering temperatures of 1120 °C (2050 °F).

Sintering of Ferrous Alloys with Chromium, Manganese, and Silicon. Chromium, manganese, and silicon have a higher affinity with oxygen (Table 5), which thus requires cleaner atmospheres and high enough temperatures for adequate oxide reduction (Fig. 2b) during sintering. A nitrogen atmosphere with a small amount of hydrogen and hydrocarbons can ensure oxide reduction (Ref 3). Another general approach is to tie up the reactive alloying elements in compound form by adding alloy powders from either ferroalloys (ferrochromium, ferromanganese, and ferrosilicon) or as

carbides. Addition of carbides (or carbon ferroalloys) has a low-alloying cost, but carbides increase tool wear and require sintering temperatures above 1200 °C (2190 °F) in typical production atmospheres (Ref 3). This practice is not prevalent.

Chromium Steel Sintering (Ref 3). Chromium steel parts are sintered from powder mixes, prealloyed powders, or from special master alloys based on carbides, sigma-phase compositions, and other complex alloying with carbides. To obtain a homogenous structure from sintering of powder mixes, the sintering temperature should be above 1250 °C (2280 °F) with the formation of a liquid phase in the presence of carbon. Effective carbon control is a decisive factor, but high strength chromium alloy steel can be achieved (Table 6).

Table 6 Properties of chromium alloyed steels prepared from elemental powders

Chromium powder size, μm	Sintering parameters ^(a)	Density, g/cm^3	Dimensional change, %, linear	Ultimate tensile strength MPa	Yield strength (0.2 offset), MPa	Elongation, %	Impact, toughness, J	HV30

(a) Compacted at 1200 MPa, sintered at 1 h at 1270 °C/H₂ or 2 h at 1270 °C/vacuum as listed. vac, vacuum

The problem of sintering chromium steels at high temperatures can also be solved by adding chromium to the iron powder in the form of low-melting master alloy. Higher hardness was achieved in a Fe-1.5Cr-0.25C sintered steel based on a low-melting master alloy (33%Cr5%C-8%Mn+Ni+Mo+P) as compared to chromium carbide or ferrochromium additions. With the low-melting master alloy, the material can be effectively sintered at 1120 °C (Ref 3).

Manganese Steels. Manganese is one of the least expensive alloying elements for iron, but is not widely used in P/M steels due to high reactivity with oxygen. It can be added to iron in elemental form or as ferromanganese alloys. It is also added with other elements as low-melting master alloys (Table 7).

Table 7 Chemical composition of master alloys for alloying powder steels with manganese for liquid-phase sintering

Chemical composition, wt%							T _l , °C	T _s , °C	ΔT , °C

Manganese steels can be sintered efficiently at 1120 °C in typical production atmospheres due to self getting of the atmosphere. Manganese sublimation occurs at sintering temperatures and manganese vapor reacts with oxygen in the furnace atmosphere, which in effect cleans oxygen from the furnace atmosphere (Ref 3). Table 8 presents mechanical properties of manganese steels prepared from atomized iron powder and electrolytic manganese sintered at different temperatures. The properties change only slightly if ferromanganese is used instead of electrolytic manganese. Dimensional stability was obtained at 2 to 3% Mn.

Table 8 Effect of sintering temperature and time on mechanical properties of Fe-Mn steels

Alloy	Sintering		Density, g/cm ³	Yield strength, %	Ultimate tensile strength, %	Elongation, %
	Temperature, °C	Time, min				
Fe-2Mn	1200	50	7.03	170	300	11.0
	1200	100	7.05	220	340	10.0
	1250	50	7.06	200	320	10.0

	1280	100	6.87	440	620	4.0

Manganese Silicon Steels. Iron silicon materials are not used in the fabrication of P/M parts due the excessive shrinkage of parts during sintering. However, the shrinkage is reduced by the addition of manganese in elemental form or by master alloys. To increase activity, additions for liquid phase sintering are also considered (Ref 3).

Production Sintering Practices

High-Temperature Sintering

Interest in high-temperature sintering of ferrous components continues to grow in the P/M industry (see the article "High-Temperature Sintering of Ferrous Powder Metallurgy Components" in this Volume). Improvements in both production rates and properties are possible as sintering temperatures increase above 1120 °C (2050 °F). Rounding of the porosity results in increased strengths, especially impact strength. Higher diffusion rates also increase the strength and hardenability of admixed powder compositions. The greater oxide reduction that occurs at higher temperatures proves valuable in powder forging and other applications.

To demonstrate the feasibility of high-temperature sintering of ferrous materials on a production basis, a study was conducted on three iron-base compositions sintered in a nitrogen-methanol atmosphere (Ref 5). Alloys tested had the following nominal compositions: Fe-0.9C, Fe-4Ni-0.7C, and Fe-2Cu-0.9C.

Transverse rupture bars were pressed to a density of 6.8 g/cm³. Methanol was blended with nitrogen to form the following compositions: 1% carbon monoxide and 2% hydrogen, remainder nitrogen; 3% carbon monoxide and 6% hydrogen, remainder nitrogen; and 5% carbon monoxide, 10% hydrogen, remainder nitrogen. Methane additions of 0, 0.25, and 0.5% were made to each of the atmospheres. Atmosphere composition in the hot zone of the furnace was monitored by infrared analysis, gas chromatography, and dew point analysis.

Lubricant was burned off in a mesh belt furnace at 760 °C (1400 °F) for 35 min. An atmosphere of 90% nitrogen and 10% hydrogen with a dew point of -12 °C (10 °F) was used for lubricant burn off. Sintering was performed in a pusher furnace with a ceramic muffle and wound molybdenum heating elements.

A temperature cycle was selected (Fig. 11) that held the parts above 1290 °C (2350 °F) for 7 min and above 1280 °C (2340 °F) for 10 min. The maximum temperature reached was 1301 °C (2374 °F). For comparison with conventional sintering, a set of test bars was sintered at 1123 °C (2053 °F) for 32 min (Fig. 11). A single nitrogen methanol atmosphere forming 5% carbon monoxide, 10% water vapor, 0.25% methane, and the remainder nitrogen was chosen for conventional temperature sintering.

Fig. 11 Temperature profile of sintering cycles. Profile A shows the high-temperature cycle used in study. Profile B shows the conventional sintering cycle used as a standard. Source: Ref 5

The sintered bars were tested for transverse rupture strength, apparent hardness, and dimensional change. Surface and core carbon contents were determined metallographically and by combustion and thermal conductivity analysis.

Effect of Sintering Temperature. The 10 min sinter at 1290 °C (2350 °F) exhibited equivalent or slightly better properties than the longer 30 min sinter at 1120 °C (2050 °F) in a comparable atmosphere. Transverse rupture strengths were very similar, with only a 1 to 1.5% variation in the Fe-Ni-C and Fe-Cu-C alloys and 5% for the Fe-C steel (Table 9).

Table 9 Effect of sintering temperature on transverse rupture strength of test bars pressed to 6.8 g/cm³

Alloy	Transverse rupture strength at 1120 °C (2050 °F)		Transverse rupture strength at 1290 °C (2350 °F)	
	MPa	ksi	MPa	ksi
Fe-0.9C	693	100.5	728	105.6
Fe-4Ni-0.7C	910	132.0	924	134.0
Fe-2Cu-0.9C	975	141.5	964	139.8

Transverse rupture strength of bars sintered for 32 min at 1120 °C (2050 °F). Average transverse rupture strength for all atmosphere tests of bars sintered for 10 min at 1290 °C (2350 °F). Source: Ref 5

Metallographic analysis revealed a slightly more spheroidized pore structure and increased sintering in the 1290 °C (2350 °F) specimen. Dimensional change (Table 10) was more negative by approximately 0.2% for the Fe-C and Fe-Ni-C samples sintered at 1290 °C (2350 °F). Consequently, increased particle diffusion may have occurred at the higher temperatures even though a shorter sintering time was used. No difference in dimensional change was evident for the Fe-Cu-C samples.

Table 10 Effect of sintering temperature on dimensional change of test bars pressed to 6.8 g/cm³

	Change at 1120 °C (2050 °F), %	Change at 1290 °C (2350 °F), %
Fe-0.9C	+0.25	+0.04
Fe-4Ni-0.7C	0.0	-0.2
Fe-2Cu-0.9C	+0.4	+0.4

Dimensional change of bars sintered for 32 min at 1120 °C (2050 °F) and average for all atmosphere tests of bars sintered for 10 min at 1290 °C (2350 °F). Source: Ref 5

Apparent hardness increased slightly for all three alloys at the higher sintering temperature (Table 11). Generally, the 10 min sinter at 1290 °C (2350 °F) was found to be an adequate substitute for a 30 min sinter at 1120 °C (2050 °F). This type of cycle can be used if an increased production rate that yields equivalent mechanical properties is desired.

Table 11 Effect of sintering temperature on the apparent hardness of test bars pressed to a density of 6.8 g/cm³

Alloy	Apparent hardness, 1120 °C (2050 °F)	HRB, 1290 °C (2350 °F)
Fe-0.9C	57.9	63.2
Fe-4Ni-0.7C	73.1	75.9
Fe-2Cu-0.9C	75.6	81.3

Apparent hardness of bars sintered for 32 min at 1120 °C (2050 °F) and 10 min at 1290 °C (2350 °F) in comparable atmospheres. Source: Ref 5

Effect of Atmosphere Composition. Variations in methanol (forming carbon monoxide and hydrogen) and methane additions to the nitrogen carrier gas did not result in any significant change in transverse rupture strength for any of the alloys. This is attributed to the consistent carbon content (0.6 to 0.7%) at the core of the samples for all atmospheres tested.

Dimensional change of the alloys was unaffected by the atmosphere composition. The Fe-Cu-C and Fe-Ni-C alloys were consistent for all atmospheres tested. Some variations were evident in the Fe-C compacts, although no trend was evident.

Atmosphere composition was found to significantly affect surface carbon content and apparent hardness. Methanol enrichment without methane additions resulted in the most decarburization. Increases in methanol alone did not significantly increase the surface carbon. The surface of an Fe-0.9C sample was decarburized to a combined carbon content of 0.45 to 0.55% when sintered for 10 min at 1290 °C (2350 °F) in 15% dissociated methanol. Methane additions were required to increase the surface carbon.

Although some decarburization was still evident, acceptable results were obtained with an atmosphere containing 15% dissociated methanol (5% carbon monoxide and 10% hydrogen) with 0.5% methane additions. The dissociation of methanol and the resulting carbon dioxide and water vapor levels were found to be affected by localized temperature, residence time, and availability of local catalytic surfaces. When introduced properly, the methanol dissociation was demonstrated to be very efficient at 1290 °C (2350 °F).

Concentrations of carbon dioxide and water vapor were low, and the formation of methane was too low to be detected by gas chromatography. The atmosphere formed with nitrogen-methanol compared favorably to an equivalent atmosphere formed by blending nitrogen and endothermic gas.

These results indicate that efficient dissociation of methanol was achieved and that methane additions should be used to further reduce carbon dioxide and water vapor levels. As a result, nitrogen-methanol-methane atmospheres can be considered as viable alternatives to nitrogen-hydrogen-carbon monoxide and nitrogen-hydrogen-methane atmospheres for high-temperature sintering of ferrous alloys.

Production Sintering Practices

Sintering of Stainless Steel

E. Klar and P.K. Samal, OMG AMERICAS

Sintering is the most critical step in processing stainless steel parts. It is also more complex than the sintering of most other materials. Correctly sintered stainless steel parts will approach the corrosion resistance of wrought stainless steel of the same composition. Incorrectly sintered parts will have inferior corrosion resistance, frequently inferior by one to two orders of magnitude.

The majority of the studies dealing with the corrosion resistance of sintered stainless steels are based on immersion and/or salt spray testing in 5% aqueous NaCl, using the length of time until the appearance of rust as a quantitative measure of corrosion resistance (Ref 6). Some are based on weight loss measurements in H₂SO₄, HNO₃, and HCl of various concentrations. Metallography (Ref 7) and potentiostatic anodic polarization tests (Ref 8) have been used to elucidate the various mechanisms of corrosion, as well as for troubleshooting.

Microstructure-corrosion resistance correlations of sintered stainless steels have shown that for maximum corrosion resistance, it is important to minimize or avoid the occurrence of precipitates of chromium carbides, chromium nitrides, and of silicon and chromium oxides in the structure (Ref 6). Surface depletion of chromium during vacuum sintering can also be a cause for low-corrosion resistance (Ref 9). Furthermore, certain sintered densities can cause severe crevice corrosion in a neutral salt environment (Ref 10).

Requirements for optimum sintering of stainless steels are described in this section for the most commonly used sintering atmospheres. The typical problems present during processing, particularly during sintering, are discussed together with measures necessary to avoid the previous problems. The precautions necessary to avoid the previous problems differ for the various sintering atmospheres. Moreover, to guarantee maximum corrosion resistance, quality control must begin powder production.

Production Sintering Practices

Powder Quality

Contamination-Free Stainless Steel Powder. Widely used commercial grades of stainless steel powders are summarized in Table 12. Those grades containing tin have superior corrosion resistance over their tin-free equivalents on account of an enrichment of tin on the surfaces of the sintered parts.

- (a) Oxygen content, 1000-2500 ppm; nitrogen content, 200-500 for all listed grades.
- (b) Maximum.
- (c) Typical.
- (d) With C < 0.03%, this grade is ferritic. Graphite addition to the low carbon grade powder renders it martensitic upon sintering.

When powder producers manufacture stainless steel powders in a facility or with equipment where cross contamination with iron or low-alloy steel powder is possible, the sintered parts are likely to have low-corrosion resistance because the electrochemically less noble contaminants will form so-called galvanic couples with the stainless steel particles in which the less-noble particles oxidize (corrode) (Ref 11). Austenitic stainless steel powders contaminated with ferritic stainless steel powders also form galvanic couples, that is, the corrosion resistance of a sintered austenitic stainless steel is significantly reduced if it is contaminated with ferritic stainless steel particles. The only exception to the above statement is when the contaminant particles dissolve during sintering, which is possible for fine particles (<38 μm) and high sintering temperatures (>1260 °C, or 2300 °F).

Contamination can also occur at the part producer's facility if stainless steel and carbon steel processing are done under one roof.

It is important to assure that a stainless steel powder is contamination free prior to pressing and sintering because after sintering, the identification of contamination as the cause for inadequate corrosion resistance can be rather difficult and time consuming. The authors have found that as little as 100 ppm of iron contamination in 316L can reduce corrosion resistance in aqueous NaCl by 50%. It is for this reason that stainless steel powders as well as green parts should be

subjected to the so-called copper sulfate or Ferroxy test prior to compacting and, additionally, prior to sintering if contamination in the part producer's facility is possible.

Copper Sulfate Ferroxy Tests. For the detection of contamination of a stainless steel powder with a less-noble metal powder, two tests are available.

The copper sulfate test (ASTM 380) is based on the plating out of elemental copper from a concentrated copper sulfate solution onto particles that are less noble than copper, in accordance with:

The plated-out copper can be seen within minutes with the naked eye or preferably with a low-power microscope. A serious shortcoming of the copper sulfate test is that lubricants prevent the copper sulfate solution from properly wetting the powder or green compact.

The Ferroxy test is based on the development usually within minutes, of a blue precipitate, Turnbull's blue, when elemental iron or ferrous ions react with hexacyanoferrate (III) in accordance with:

Ref 12 summarizes optimum solution strengths for performing this test. This test is also mentioned in ASTM Standard for Cleaning and Descaling Stainless Steel Parts (Ref 13).

Production Sintering Practices

Delubrication

The delubing of stainless steel compacts influences oxygen and carbon balance, which can affect corrosion resistance of the sintered part by precipitation of chromium carbides. Carbide precipitation (sensitization) depletes chromium from grain boundaries.

Sensitization. For a number of austenitic stainless steels, the maximum carbon content allowable to avoid sensitization is 0.03%. Higher carbon contents are tolerable only if the cooling rate after sintering is high enough to prevent sensitization and if the parts are not subjected to elevated temperatures again such as in welding. Critical cooling rates can be estimated from time-temperature-sensitization curves for wrought austenitic stainless steels. Carbide precipitates can be readily shown with optical microscopy. A properly sintered low-carbon austenitic structure (Fig. 12a) is free of carbide precipitates and has clean and thin grain boundaries with evidence of twinning. Higher carbon structures show necklace type (Fig. 12b) and continuous precipitates (Fig. 12c) of chromium-rich carbides in the grain boundaries.

Fig. 12 Microstructures of type 316L stainless steel sintered in hydrogen at 115 °C (1200 °F) (Glyceregia). (a) C is 0.015%, clean and thin grain boundaries. (b) C is 0.07%, necklace type chromium-rich carbide precipitates in grain boundaries. (c) C is 0.11%, continuous chromium-rich carbide precipitates in grain boundaries.

For ferritic stainless steels, the maximum amounts of C + N allowable to avoid sensitization are much lower, namely ~ 100 to 150 ppm (Ref 14). Because such low contents of interstitials are difficult to obtain in practice, niobium and/or titanium are often used as stabilizers in wrought ferritics. For P/M versions of ferritic stainless steels, niobium is the stabilizer of choice as niobium becomes less oxidized during water atomization than titanium. More information on sensitization conditions and corrosion is discussed in the article "Corrosion-Resistant Powder Metallurgy Alloys" in this Volume.

Atmospheres. In the early years of stainless steel parts production, much of the sintering was done in dissociated ammonia at 2050 to 2100 °F (1120 to 1150 °C). Under these conditions, lubricant removal in the preheat zone of the furnace occurs under partial decomposition such that residual carbon contents typically exceed 0.03%. As this residual carbon is not sufficiently removed during low temperature (<1205 °C, or 2200 °F) sintering, the sintered parts have low-

corrosion resistance due to the formation of chromium-rich carbides upon cooling. Delubing was, therefore, often done separately in air, which resulted in lower-carbon contents because of the more complete combustion of the lubricant. While air delubing reduced the carbon content to more acceptable levels, particularly for austenitic stainless steels, it also was at the expense of increased oxidation. Oxidation begins before complete lubricant removal (Fig. 13). It appears impossible to obtain maximum carbon removal without additional oxidation. The oxides formed during delubing are not always removed during sintering and can impair the corrosion resistance of the sintered parts.

Fig. 13 Effect of delubrication temperature on oxygen and carbon contents, and weight loss of 316LSC transverse rupture strength compacts of two densities--6.0 g/cm³, dashed lines, and 6.6 g/cm³, solid lines--lubricated with Acrawax and delubed for 30 min in (a) air and (b) dissociated ammonia

With higher sintering temperature (>1205 °C, or 2200 °F), the reaction between residual oxygen and carbon is more complete, and delubing is, therefore, preferably completed in a reducing atmosphere. As Fig. 14(a) shows for several stainless steels, lubricated with 1% Acrawax and pressed to green densities of 6.5 to 6.7 g/cm³, delubing in dissociated ammonia prevents any significant oxidation up 510 to 538 °C (900 to 1000 °F). Although carbon removal under these conditions is not yet at its maximum, and still >0.03% (Fig. 14b), a higher sintering temperature effectively lowers the carbon content to below 0.03%. It is partly because of these relationships that stainless steel parts sintered at high temperatures often exhibit better corrosion resistance than those sintered at lower temperatures.

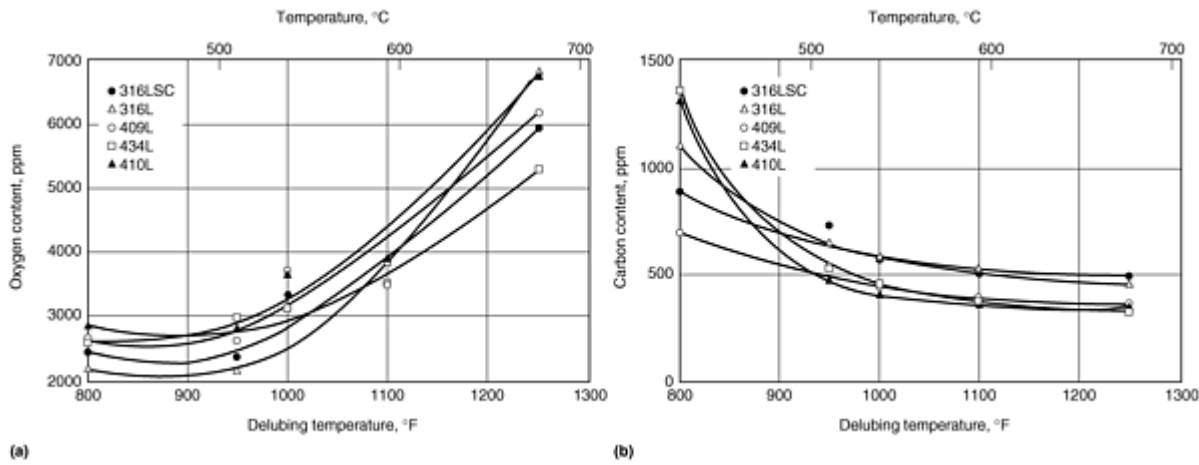

Fig. 14 Effect of delubing temperature on (a) oxygen content and (b) carbon content of stainless steel transverse rupture strength bars (6.5 to 6.7 g/cm³) lubricated with 1% Acrawax and delubed for 30 min in dissociated NH₃

For high-temperature vacuum sintering, the reaction between residual carbon and oxygen is even greater so that carbon can even be added, in the form of graphite, to some stainless steels to achieve lower-oxygen contents at acceptable carbon contents (Ref 9, 15, 16). Lower-oxygen contents are beneficial to both corrosion resistance (Ref 7, 9) and dynamic mechanical properties.

Production Sintering Practices

Sintering

Most commercial sintering of stainless steel parts is completed in belt, pusher, walking beam, and vacuum furnaces. A wide range of processing parameters is common. Typical sintering atmospheres include hydrogen, dissociated ammonia, H₂-N₂ mixtures, and all of "low" dew point, as well as vacuum. Sintering temperatures range from 1120 to 1344 °C (2050 to 2450 °F), and sintering times range from 20 to 60 minutes. Insufficient sintering, either too short a time or at too low a temperature, will result in sintered parts showing insufficient bonding, original particle boundaries, and sharp, angular pores as shown in Fig. 15 for a 316L stainless steel part sintered for 30 min at 1093 °C (2000 °F) in H₂. Such sintering

produces parts with a high concentration of interstitials (carbon and oxygen), low-corrosion resistance, and inferior mechanical properties.

Fig. 15 Insufficiently sintered 316L showing original particle boundaries and sharp, angular pores. As-polished cross section

The significance of the various sintering parameters is discussed in the following paragraphs.

Sintering in Hydrogen. In spite of higher cost, the use of hydrogen for the commercial sintering of stainless steel parts has been increasing at the expense of dissociated ammonia. The main reasons for this change are that with present sintering furnaces, it is very difficult to obtain good corrosion resistance in dissociated ammonia, and the increasing use of ferritic stainless steels in magnetic applications also requires the absence of nitrogen in the sintered part. Nevertheless, sintering in hydrogen also requires careful control to obtain maximum corrosion resistance.

Figure 16 shows the redox curves for chromium and silicon in 316L in H_2 of various dew points at atmospheric pressure (Ref 17). Chromium and silicon are the two constituents in 316L with the highest oxygen affinities. Sintering with dew-point sintering temperature combinations to the left of the two curves of Fig. 16 will result in selective oxidation of chromium and silicon, respectively, and produce parts of inferior corrosion resistance. Thus, for the lowest sintering temperatures employed in commercial sintering of stainless steels (1120 °C, or 2050 °F), the hydrogen should have a dew point not higher than approximately -40 °C (-40 °F) to ensure reduction of chromium oxides in 316L stainless steel (Fig. 16). A similar relation is shown in Fig. 2(c) for pure chromium.

Fig. 16 Redox curves for chromium and silicon in 316L in H₂ at atmospheric pressure. Source: Ref 17

What happens after sintering, that is, during cooling, is even more important. Figure 16 shows two scenarios. For both scenarios, the sintering temperature is 1200 °C (2192 °F). In the first scenario, the dew point of the sintering atmosphere is -40 °C (-40 °F); in the second scenario, it is -60 °C (-76 °F). In the first scenario, the stainless steel part crosses the SiO₂/Si relox curve (Fig. 16) upon cooling at ~1070 °C (1960 °F). At this temperature, the rate of oxidation of silicon is quite rapid and, therefore, rapid cooling is necessary to prevent or minimize, the formation of silicon oxides on the surface of the stainless steel part. Figure 17 shows a scanning electron microscopy (SEM) of such oxide precipitates for 316L. These precipitates do not cause the part to discolor, and they are visible only under a microscope. When tested in aqueous FeCl₃, in accordance with ASTM G 46 (20 °C), such parts exhibit inferior corrosion resistance due to pitting. Higher-alloyed stainless steel powder such as SS-100 (20Cr-17Ni-0.8Si-5Mo) appear to be more immune to this type of corrosion (Ref 10).

Fig. 17 Spheroidal silicon oxide particles formed on 316L part on cooling

With the second scenario in Fig. 16, the lower dew point of $-60\text{ }^{\circ}\text{C}$ ($-76\text{ }^{\circ}\text{F}$) causes the parts to cross the SiO_2/Si redox curve in the cooling zone of the furnace at the much lower temperature of $\sim 890\text{ }^{\circ}\text{C}$ ($1632\text{ }^{\circ}\text{F}$). At that temperature, the rate of silicon oxidation either is very slow, or any oxides formed at that temperature have little effect on the corrosion resistance of the part. Figure 18 shows tentative critical cooling rate-dew point combinations as a function of dew point for three hydrogen sintered austenitic stainless steels. Upper critical cooling temperatures, that is, the lowest high temperatures where rapid cooling is to commence, are shown in Fig. 19.

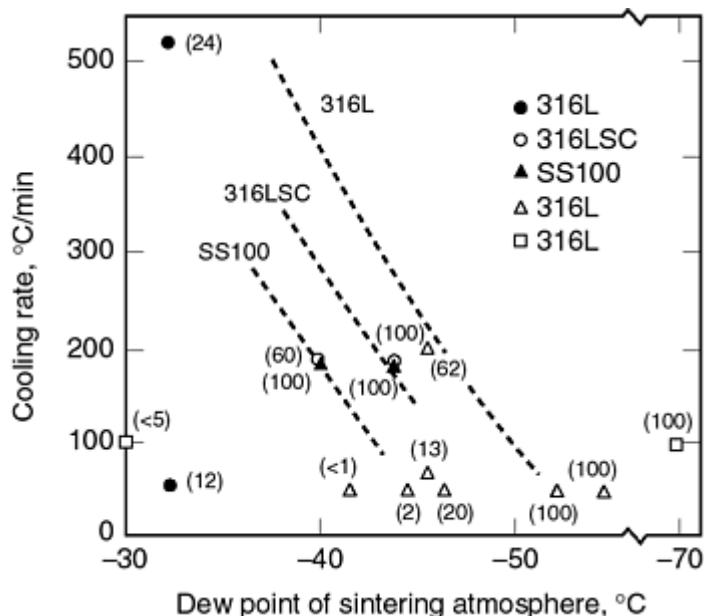

Fig. 18 Effect of cooling rate and dew point upon corrosion resistance (5% aqueous NaCl) of hydrogen sintered stainless steels. Dashed curves representing maximum corrosion resistance are tentative. Corrosion resistances shown in parentheses are percentages of maximum corrosion resistance for given grade and density.

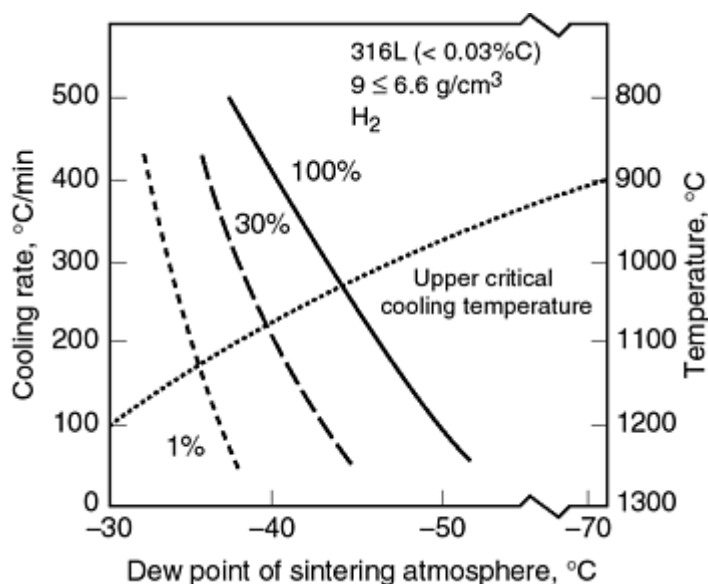

Fig. 19 Upper critical cooling temperature and iso-corrosion resistance curves (5% aqueous NaCl) for H_2 sintered 316L (schematic)

Processing to the right of the cooling rate-dew point curves produces maximum corrosion resistance. Processing to the left results in rapid deterioration of corrosion resistance as shown schematically in Fig. 19 for 316L. It is clear from these relationships that for maximum corrosion resistance, sintering in hydrogen requires very low dew points and/or rapid

cooling after sintering. Mechanical properties of hydrogen sintered stainless steels are given in the article "Powder Metallurgy Stainless Steels" in this Volume.

Sintering in Vacuum. In the early years of commercial sintering of stainless steel parts, vacuum furnaces were said to be good alternatives to other types of sintering because of their low consumption of gas. After years of experience, parts producers learned that in addition to high initial capital cost, vacuum furnaces also were costly to maintain. Nevertheless, it is clear from the previous section on sintering in hydrogen that with the typical furnaces (belt, pusher, and walking beam) used presently in the industry, the number one property of stainless steel, superior corrosion resistance, is for most presently used P/M stainless steels not attainable to a sufficient degree. Therefore, future P/M opportunities that require excellent corrosion resistance cannot be realized until furnace manufacturers construct furnaces that are capable of lower dew points and parts producers equip their furnaces with (already available) rapid cooling devices. This is where vacuum furnaces are used. With a state of the art vacuum furnace, it is much easier to maintain a low dew point and to obtain rapid cooling than it is with a typical atmosphere furnace. Nevertheless, certain precautions are necessary.

For maximum corrosion resistance of vacuum sintered stainless steel, surface depletion of chromium due to high-vapor pressure and the presence of original surface oxides must be minimized. Sintering under a partial pressure of nitrogen or argon of $\sim 1500 \mu\text{m}$ of mercury effectively reduces chromium losses. Reference 9 shows that after high temperature sintering ($>1205^\circ\text{C}$, or 2200°F), where chromium losses are more severe, holding the parts prior to cooling for a short time at a lower temperature, or by increasing the partial pressure of argon to 1 at the lower temperature, significantly improves corrosion resistance. Both measures allow the parts to replenish (from the interior) surface chromium that was lost at the high-sintering temperature.

In spite of the high-oxygen contents of water atomized stainless steel powders, vacuum sintered stainless steel parts usually are bright. This is because some of the surface oxides, during sintering, diffuse into the interior.

In the absence of an external-reducing gas atmosphere, vacuum-sintered stainless steel parts have relatively low carbon and oxygen contents due to the reaction between carbon and oxygen (or oxides) particularly at high-sintering temperatures, to form carbon monoxide (Fig. 20) (Ref 18 and 19). There is evidence, however, that the typical amounts of carbon present in a stainless steel part after delubrication are insufficient for removing most of the original oxide particles present on the outer surfaces of a part. These unreduced original oxide particles give rise to pitting corrosion. Admixing small amounts of graphite to the stainless steel powder, overall oxide reduction, particularly at the higher-sintering temperatures, is greatly enhanced and is also sufficient to reduce surface oxides. Alternatively, a small partial pressure of H_2 should accomplish the same.

Fig. 20 Oxygen versus carbon contents of vacuum and atmosphere sintered P/M austenitic stainless steels of varying compositions

When making graphite additions to a stainless steel powder, it should be kept in mind that the carbon content of the sintered part will increase. Thus, the optimum graphite addition is the maximum addition that produces no chromium carbide precipitates in the cooling zone of the sintering furnace. It depends, among other factors, on the composition of the stainless steel, the oxygen content of powder, the sintering temperature, and the cooling rate employed.

Vacuum-sintered stainless steels should be rapidly cooled in a non-oxidizing gas to prevent the formation of deleterious surface oxides. Cooling in nitrogen will result in the formation and precipitation of chromium nitrides on the surfaces of the parts. The attendant chromium depletion will cause the parts to have very low-corrosion resistance. Mechanical properties of vacuum sintered stainless steels are shown in the article "Powder Metallurgy Stainless Steels" in this Volume.

Sintering in H₂-N₂ Gas Mixtures. Sintering at 1120 °C (2050 °F) in dissociated ammonia was the most widely used method for sintering stainless steels in the 1960s and 1970s. Dissociated NH₃ was not only less expensive than H₂, but it also increased the strength of the sintered parts, although at some reduction in ductility, to levels comparable to wrought stainless steels of the same composition, at densities of ~85 to 90% of theoretical. The strengthening is the result of nitrogen absorption during sintering. The amount of nitrogen absorbed follows known phase equilibria in accordance with Sievert's law, that is, nitrogen absorption is proportional to the square root of the partial pressure of nitrogen in the sintering atmosphere. (See the article "Corrosion-Resistant Powder Metallurgy Alloys.") The relationships for 304L are shown in Fig. 21 (Ref 20), showing both the amount of nitrogen absorbed as a function of sintering temperature and sintering atmosphere (dissociated ammonia and nitrogen) and the strength increase due to nitrogen absorption.

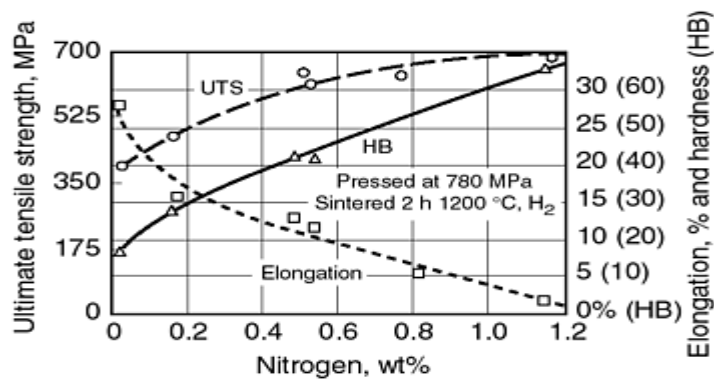

Fig. 21 (a) Effect of nitrogen content on ultimate tensile strength and elongation of 304L stainless steel. (b) Effect of sintering temperature on amount of absorbed nitrogen for 304L. Source: Ref 20

The problems with nitrogen absorption and chromium nitride (Cr_2N) precipitation during cooling (after sintering), and sensitization and loss of corrosion resistance, when sintering is done in dissociated ammonia, are described in Ref 21. They were not appreciated for many years, in part because corrosion resistance demands were modest and/or corrosion resistance was not assessed. Later, with increasing demands for improved corrosion resistance, and as more quantitative information on the effect of sintering in dissociated ammonia became available, recommendations were made to limit nitrogen absorption to some 3000 ppm in austenitic stainless steels. While this limitation seemed to satisfy some corrosion resistance requirements in an acidic environment, it was unsatisfactory for parts tested in aqueous NaCl. Even with small amounts of Cr_2N precipitates, rust spots would form in a short time. Figure 22 shows examples of Cr_2N precipitates in sintered austenitic stainless steels.

Fig. 22 Chromium nitride precipitates in 316L (a) sintered at 1150 °C (2100 °F) in dissociated NH_3 ; 4500 ppm N_2 ; Cr_2N precipitates along grain boundaries (1), and within grains (2). (b) sintered at 1120 °C (2050 °F) in dissociated NH_3 and slowly cooled; 6500 ppm N_2 ; Cr_2N in lamellar form near surface (1) and as grain boundary precipitates in the interior (2).

In an early study, Sands et al. (Ref 22) pointed out that 316L sintered in dissociated NH_3 required a cooling rate of 200 °C/min for preventing nitrogen absorption and precipitation of Cr_2N . More recently, Frisk et al. (Ref 23) determined in a laboratory study that sintering of 316L in dissociated NH_3 at 1250 °C (2280 °F) required cooling rates of >450 °C/min (Fig. 23). The higher critical cooling rate of Frisk et al. can probably be ascribed to their much lower dew point (-100 °C versus -40 to -60 °C for Sands), which allows for more rapid nitrogen absorption during cooling as illustrated in Fig. 24 (Ref 24) for the bright annealing of stainless steel strip. The deleterious reactions of increasing nitrogen absorption with decreasing dew point, and of increasing oxidation with increasing dew point, leave a relatively narrow dew point window for sintering in dissociated ammonia.

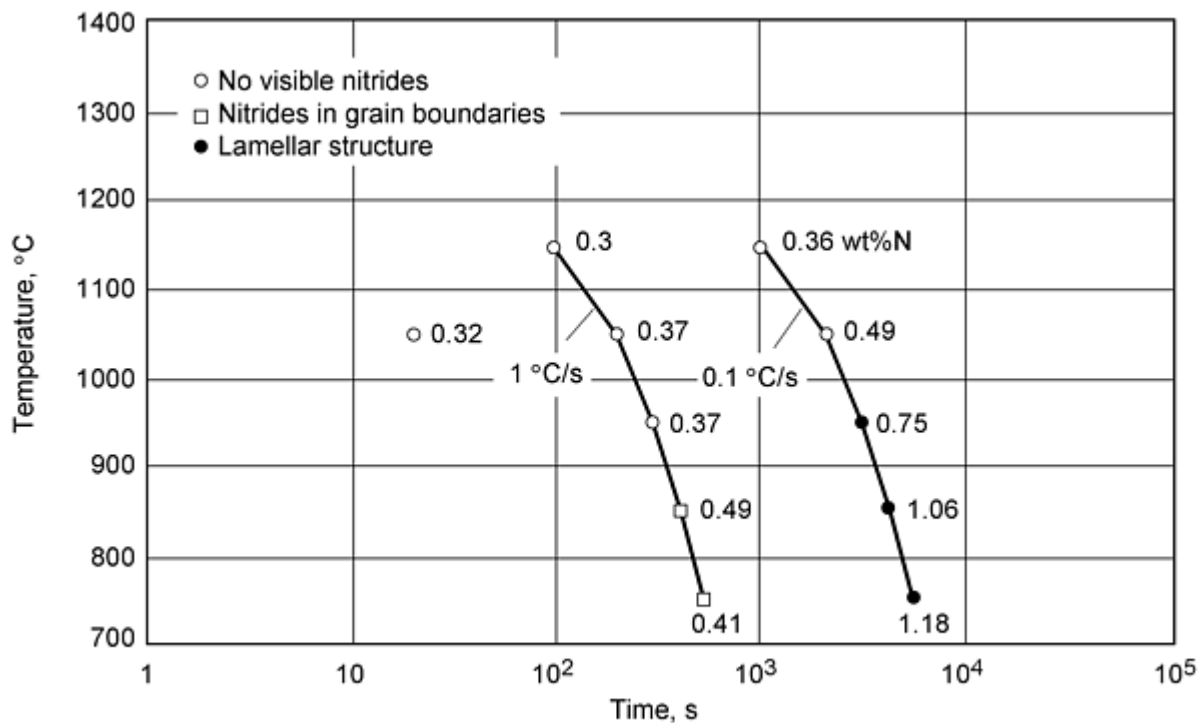

Fig. 23 Effect of cooling rate on presence of chromium nitrides in microstructure of 316L parts sintered at 1250 °C in dissociated NH₃. Source: Ref 23

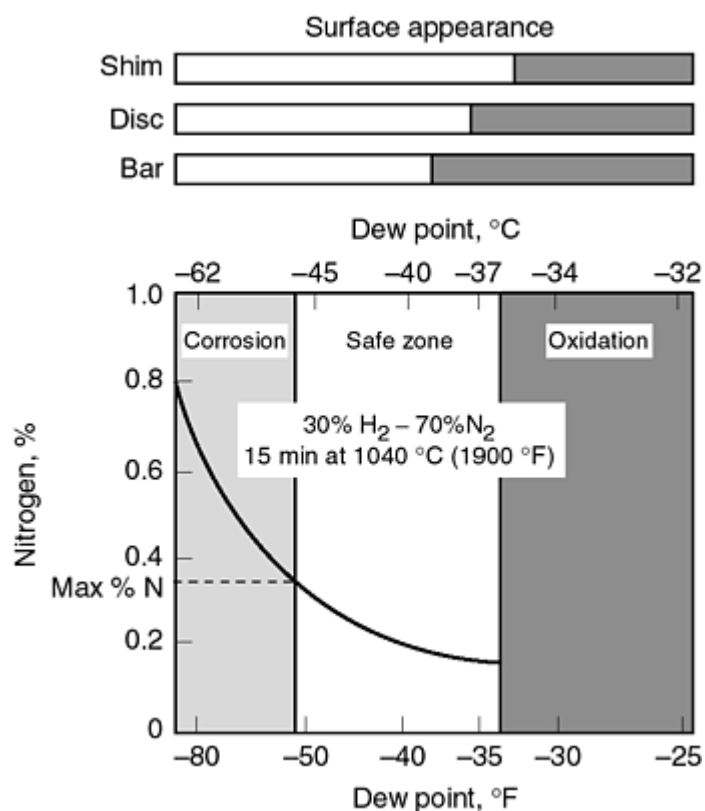

Fig. 24 Effect of dew point on nitrogen absorption and oxidation of 316L shim, disk, and bar stock annealed for 15 min at 1038 °C (1900 °F) in 30%H₂-70%N₂. It took 2.3; 2.8; and 4.7 min respectively to cool the three materials from 1038 °C (1900 °F) to 538 °C (1000 °F). Source: Ref 24

These cooling rate requirements are even higher than those for sintering in hydrogen to prevent oxidation during cooling, and the cooling-rate dew point relationship appears to be reversed. It is, therefore, not surprising that stainless steel parts producers are increasingly shifting towards hydrogen sintering at the expense of sintering in dissociated NH_3 .

Sintering in an atmosphere of 10% N_2 -90% H_2 may be a more practicable compromise that greatly reduces the high-cooling rate requirements of dissociated NH_3 to more manageable levels, while still benefiting substantially from the solid solution strengthening obtainable with the lower nitrogen concentration. Good corrosion resistance for such conditions were reported by Larsen (Ref 25) and Mathiesen (Ref 26).

The positive effect of nitrogen on corrosion resistance, as documented for wrought stainless steels, is expected to apply equally to sintered stainless steels. However, this beneficial effect has not yet been well documented for sintered stainless steels, probably because of the overshadowing negative effect of excessive nitrogen absorption on the surface of parts from the sintering atmosphere during cooling. Mechanical and other properties for 316L and 434L sintered in dissociated NH_3 are given in the article "Powder Metallurgy Stainless Steels" in this Volume.

Production Sintering Practices

Sintered Density

For many years, inferior corrosion resistance of sintered stainless steel parts has been and continues to be mistakenly attributed to the presence of pores in accordance with the mechanism of crevice corrosion. That this hypothesis is untenable follows from widely available evidence (Ref 7) that sintered stainless steel parts of identical composition and similar pore volumes, pore sizes, and pore shapes, but sintered under varying conditions, may have corrosion resistances (in 5% aqueous NaCl) that can vary by two orders of magnitude. Furthermore, a comparison of wrought and sintered (85% of theoretical density) type 316L for susceptibility to crevice corrosion in 10% FeCl₃, in accordance with ASTM G 48, showed that the wrought part was actually more severely attacked than the porous part (Ref 7, 27). More recent studies have shown that most cases of inferior corrosion resistance of sintered stainless steels are due to incorrect sintering, as previously described.

Also, for many years, there existed controversy as to the effect of sintered density upon corrosion resistance. Corrosion testing in an acidic environment, such as dilute H₂SO₄, HCl, and HNO₃, always showed that corrosion resistance improved with increasing density. Testing in a neutral salt solution, however, showed the corrosion resistance to decrease with increasing density (Ref 17, 28, 29, 30, 31), when corrosion testing was done in long-term immersion or salt spray tests, whereas higher density was found to be beneficial in short-term potentiodynamic polarization tests (Ref 32). Maahn and Mathiesen (Ref 8) attributed the failure to observe this important relationship between corrosion resistance and density in short-term, potentiostatic anodic polarization tests to the lack of time for the time-consuming build up of localized attack within the pores, in analogy to the mechanism of crevice corrosion. By using slow stepwise polarization, the expected relationship, that is, a decrease of the stepwise initiation potential with increasing density (equivalent to deteriorating corrosion resistance), was observed (Ref 33).

Recent studies, with austenitic stainless steels (Ref 10, 17, 31) showed that the corrosion resistance in 5% aqueous NaCl (by immersion) can be reduced by up to two orders of magnitude due to the presence of porosity. The negative effect appears at sintered densities of ~ 6.7 g/cm³, reaches a minimum corrosion resistance between ~ 6.9 and 7.2 g/cm³, depending on pore morphology, and thereafter disappears at densities of ~ 7.4 g/cm³ (Fig. 25). To the left of the minimum, corrosion resistance decreases with decreasing pore size due to increasing oxygen depletion and failure to maintain the passive layer. To the right of the minimum, corrosion resistance improves as pores become closed off and inaccessible to the surface. This type of corrosion can be reduced by impregnating the pores with a resin, by metallurgical modification of the pore surfaces, or by the use of higher-alloyed stainless steels, particularly those containing higher concentrations of molybdenum.

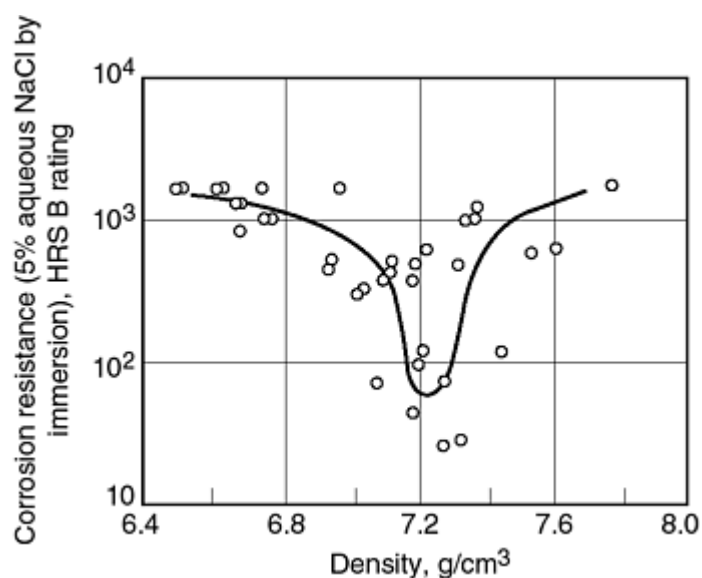

Fig. 25 Effect of density on corrosion resistance (B rating) of pressed, sintered, repressed, and annealed 317L parts

Another approach to avoiding the problem of long-term corrosion in a neutral salt solution due to the presence of certain size pores is to make use of the various forms of liquid-phase sintering (transient, persistent, and supersolidus) and to achieve sintered densities >7.4 g/cm³. For austenitic stainless steels, silicon additions of several percent (Ref 34, 35) or smaller amounts of boron (Ref 17), have been used. For ferritic stainless steels phosphorus additions (Ref 35) have been

used. The large shrinkage occurring during liquid-phase sintering is often accompanied by increasing loss of dimensional stability. Sizing is usually employed to establish dimensional accuracy. Also, depending on the composition of the liquid-phase sintering additive, secondary phases may be present after sintering, which can have a negative effect on corrosion resistance (Ref 17).

Production Sintering Practices

Sintering of High-Speed Steels and Tool Steels

Powder metallurgy processing offers several advantages to costly and highly alloyed tool steel materials. These advantages include uniform and finer microstructure, improved grindability, improved cutting performance, and capabilities of high-speed steels and tool steel alloys that cannot be made by conventional ingot metallurgy.

The use of conventional press-and-sinter technology offers the additional advantage of net shape or near-net shape capability. Cutting tools, bearings, and wear parts are being produced commercially by fully dense sintering. Wear parts also are produced by conventional P/M techniques to densities of 80 to 90%.

Current commercial fully dense sintering uses high green strength and compressible water-atomized tool steel powders that are compacted in rigid dies using uniaxial pressing or in flexible rubber molds using cold isostatic pressing to make green tools and parts. These parts are then sintered in a microprocessor-controlled vacuum furnace near the solidus temperature of the alloy to virtually full density (at least 98% and frequently 99+% of theoretical).

The flexibility of this process allows production of pressed and sintered tool and die parts in various forms. Generally, parts are pressed to 70 to 85% of theoretical density before sintering to full density. Pressing to lower green densities tends to require longer times at temperature to obtain full density and results in coarser microstructures. Pressing at higher pressures, which is required for increased green densities, results in increased tool wear and breakage. Parts with high green density also may require extra care in sintering. The surface can sinter rapidly to high density and entrap gases from the center of the part.

Production Sintering Practices

Sintering Mechanisms

Important contributions to sintering arise from diffusion and viscous flow. Diffusion rates increase with increasing temperature because of the increased number of vacancies that promote diffusion of substantial alloying elements. Sintering temperature must be held very close to the solidus temperature to attain full density in a reasonable time. A sintering temperature 5.5 to 11 °C (10 to 20 °F) above the solidus reportedly forms a small amount of liquid, which allows high-diffusion rates for enhanced sintering. These results are based on relatively rapid densification at high temperatures. However, metallographically, there is no resemblance between a successfully sintered high-speed steel and a typical liquid-phase sintered material, such as tungsten carbide or tungsten heavy metal. Additional research is required to fully understand high-temperature sintering.

Factors Affecting Sintering. Sintering is a series of complex processes, of which densification is only one phase. As green parts are heated to the sintering temperature, gases can be adsorbed (nitrogen, hydrogen, or oxygen) or evolved (nitrogen, hydrogen, or carbon monoxide). Admixed carbon dissolves and homogenizes, while carbides dissolve and grow. Grain growth also occurs as pores shrink and virtually disappear.

Sintering Time and Temperature. Increasing the sintering temperature decreases the amount of time required to achieve full density. Higher temperatures also reduce the time between reaching full density and oversintering. These relationships are shown schematically in Fig. 26. A sintering curve for M2 high-speed steel is shown in Fig. 27. Table 13 provides typical properties of M2 tool steel for various sintering temperatures.

Table 13 Sintering data for M2 tool steel

Testing was conducted on five lots. All compacts were pressed at 827 MPa (60 tsi) and sintered for 60 min.

Fig. 26 Relationship among sintered density, sintering time, and sintering temperature

Fig. 27 Sintering curves for compacted M2 high-speed steel. Sintering time for all materials is 1 h.

Effect of Carbon Content. Carbon content has a significant effect on sintering temperature. Increasing carbon content reduces the sintering temperature by lowering the solidus temperature.

Carbon can be controlled closely by blending graphite or lampblack into the powder before pressing. Carbon dissolves rapidly, and its high diffusivity enables rapid homogenization above 980 °C (1800 °F). However, blending of more than 0.15 to 0.2% C can cause several detrimental effects, such as nonuniform distribution of carbon, variable response to sintering, variable part-to-part density, and part distortion.

More than 0.15% C can be admixed with 0.05 to 0.30% blending oil, such as mineral oil. However, blending oils may create powder flow difficulties and can lead to excessive outgassing during vacuum sintering.

Figure 28 shows the effect of carbon content on microstructure for M2 high-speed tool steel. The amount of mixed carbon critically affects the microstructure. For a given sintering cycle, insufficient carbon produces incomplete sintering, and excessive carbon produces oversintering. Table 13 gives the effect of carbon additions for five heats of M2 tool steel and three sintering temperatures.

Fig. 28 Effect of increasing carbon content on the sintered microstructure of M2. All samples were sintered in the same run. Carbon was increased by blending in graphite. Note the microstructure changes from being undersintered (round pores) for 0.0 and 0.1% C to being oversintered (sharp angular pores, eutectic) for 0.2 and 0.3% C. 250×

Effect of Oxygen Content. Oxygen affects the sintering of tool steels by reducing carbon content during sintering. Oxygen from the annealed powder reacts with carbon during sintering to form carbon monoxide. Approximately 0.01% C is lost in the atmosphere for every 0.01% of oxygen present in the annealed powder. This reaction reduces the oxygen to less than 200 ppm during vacuum sintering.

Effect of Silicon Content. Silicon aids sintering by suppressing the melting point of tool steels. A carbon equivalent (CE) for estimating sintering temperature can be calculated as:

$$CE = \%C (\text{powder}) + \%C (\text{graphite}) + \frac{\%Si}{30}$$

Admixed silicon does not homogenize rapidly because of low diffusivity; consequently, it usually causes incipient melting.

Effect of Boron Content. Boron forms a low-melting-point eutectic with steels. Only small amounts can be added without changing carbide morphology. Boron can be added to powder as an alcoholic solution of boron oxide, followed by drying at ~95 °C (200 °F). This results in an even coating of the particle with boron oxide. The treated powder thus sinters uniformly.

Effect of Carbide Formers. The amount of carbon required for sintering and heat treating increases with the concentration of tungsten, molybdenum, and vanadium. Tungsten, molybdenum, and vanadium combine with carbon to form carbides that deplete the matrix of carbon. Vanadium is especially potent, because the vanadium-rich MC carbide is very stable and resists dissolution at high-sintering temperatures.

The stability of the vanadium carbide effectively retards grain growth. Generally, increasing vanadium content (when properly balanced with carbon) facilitates sintering. High-speed steels containing 3% or more vanadium (M3 type 2 and T15) can be sintered to full density with microstructures finer than wrought.

In high-speed steels, chromium content does not affect sintering of alloys due to the diminished stability of chromium carbide compared to molybdenum, tungsten, and/or vanadium carbides. Chromium carbide is formed only in annealed material. Chromium content affects the sintering of alloys that contain only minor amounts of vanadium, molybdenum, or tungsten, such as the high-chromium die steels.

Production Sintering Practices

Vacuum Sintering to Full Density

The prime object of vacuum sintering to full density is to uniformly expose all parts to sufficient temperature and time. This is typically done to produce the minimum required density and to prevent overheating and/or excessive carbide growth.

Sintering Cycles. Figure 29 shows typical sintering cycles. These sintering cycles consist of a lower temperature hold, followed by one or more high-temperature holds to densify compacts.

Fig. 29 Sintering cycles for fully dense sintering of high-speed steels. (a) British Patent 1,562,788. (b) U.S. Patent 4,063,940

Deoxidation. Heating rates to the deoxidation temperatures are not critical. Parts should be heated at the maximum practical heating rate to minimize furnace time, provided the temperature of the load does not greatly surpass the deoxidation soak temperature. Batch-type vacuum furnaces can be backfilled with inert gas or hydrogen to >46 kPa (350 torr) to improve the heating rate and temperature uniformity of the load.

The primary function of the deoxidation step is to react oxygen with carbon to form carbon monoxide, which is removed by the vacuum pumps. Oxygen, nitrogen, and other gases that may be present in the powder compact must be removed before sintering closes the interconnected porosity to the surface. Once the porosity is no longer interconnected, gas evolution results in blistering.

The deoxidation soak or hold also provides an opportunity for load temperature to become uniform. Temperature in any part of the load should not vary more than ± 9 °C (± 16 °F) before heating to the sintering soak. The load may be soaked at 1040 °C (1900 °F) for several hours to improve temperature uniformity without seriously affecting the microstructure.

Heating to sintering temperature is slow and closely controlled to ensure temperature uniformity. Typical ramp rates are 0.5 to 5.5 °C/min (1 to 10 °F/min).

Sintering Soak. Sintering treatments may consist of an isothermal soak or a very slow ramp (typically 3 to 33 °C/h, or 5 to 60 °F/h). Temperature uniformity is essential for successful sintering. Temperature range should not vary by more than 8 °C (15 °F) at any location within the load. Table 14 gives typical sintering temperatures for two-soak sintering cycles for several alloys.

Table 14 Typical sintering temperatures and compositions for several high-speed steels

(a) Approximate sintering temperature for powders annealed at atmospheric pressure and pressed at 830 MPa (60 tsi).

(b) 1 represents the easiest, 5 is the most difficult.

Cooling. Generally, cooling from the sintering temperature is performed as rapidly as possible by backfilling the furnace with inert gas and using forced convection cooling (also known as fan cooling or gas quenching) to minimize furnace time. Typically, the hardnesses of gas-quenched fully dense tool and high-speed steels are 50 to 60 HRC. These hardnesses are substantially lower than the austenitized and quenched hardnesses of 55 to 65 HRC because of excessive dissolution of carbides, which results in excessive retained austenite.

Nitriding. Tool steels and high-speed steels can be alloyed with nitrogen by maintaining a nitrogen partial pressure after deoxidation, but before sintering. Significant alloying does occur with partial pressure at >133 Pa (1 torr). Increasing the partial pressure increases the nitrogen content. Depending on the alloy, nitrogen contents from 4000 ppm (M2) to over 8000 ppm (T15) can be produced by backfilling to atmospheric pressure.

Nitrided cases can be produced by introducing a suitable nitrogen partial pressure after sintering has closed off the interconnected porosity. Use of nitrogen as the quenching gas during forced convection cooling does not result in any significant nitriding.

Production Sintering Practices

Heat Treatment

Heat treatment of sintered high-speed steels is similar to the heat treatment of wrought counterparts. In both cases, heat treatment consists of hardening an annealed structure, followed by tempering to achieve desired properties. The finer microstructure of P/M high-speed steels may require slightly lower temperatures than wrought components to optimize performance.

Annealing. Sintered parts should be annealed before austenitizing. This treatment provides grain refinement and transforms large amounts of retained austenite. Sintering temperatures and times are higher and longer than optimum austenitizing heat treatment times. Consequently, parts quenched from the sintering temperature contain large amounts of retained austenite, which lower material properties. A suitable annealing cycle for sintered parts is heating to 900 °C (1650 °F) for 4 h and cooling at a rate of 50 °C/h (90 °F/h) to 500 °C (930 °F), followed by rapid cooling to ambient temperature.

Austenitizing. The austenitizing temperature of high-speed steels is influenced by the exact composition of the alloy (particularly carbon), as well as the carbide size. Fine carbides dissolve more rapidly than coarse carbides; consequently, parts with fine carbides should be heat treated at a lower austenitizing temperature. Table 15 gives hardness values, hardening and tempering temperatures, and the average Snyder-Graaf intercept grain size for several high-speed steels.

Table 15 Recommended conditions for salt bath hardening of sintered high-speed steels

(a) All samples were hardened for 150 s soak time.

(b) All samples were triple tempered ($\times 3 \times 1$ h)

The Snyder-Graaf method for determining intercept grain size is based on an actual count of the grains. In the as-quenched condition, the grain boundaries of high-alloy tool steels are clearly revealed by deep etching in nital. The test method is conducted on a metallograph, with the structure shown on a ground-glass screen at a magnification of 1000 \times . A 127 mm (5 in.) line drawn on the ground glass represents a length of 127 μ m (0.005 in.) on the sample. The number of grains crossed or touched by this 127 mm (5 in.) line is counted; the average of ten readings at random points on the sample gives the intercept grain size.

Tempering temperatures of P/M parts are similar to those used for wrought materials. Depending on property requirements, temperatures range from 540 to 595 °C (1000 to 1100 °F). Figure 30 shows tempering curves for M2 and T15. Heat treated properties of sintered M2, M35, and T15 are given in Table 16.

Table 16 Typical mechanical properties of commercially sintered M2, M35, and T15 high-speed steels

Production Sintering Practices

Sintered Microstructures

Fully dense sintered tool steel and high-speed steel metallurgy and microstructures are similar in most respects to wrought counterparts. Lower significant differences in carbide size and uniformity of carbide distribution may have significant consequences. Sintered T15 is capable of finer carbides and grain size than the wrought alloy. Sintered M2 exhibits carbide and grain sizes that generally are not as fine as sintered T15 and are frequently coarser than wrought M2. T15 contains a large amount of vanadium-rich carbides (MC) that are very stable and do not coarsen readily. These carbides also inhibit grain growth during sintering.

Sintered D2 microstructure exhibits somewhat finer carbides than wrought D2. Wrought D2, like wrought T15, frequently has a segregated or "banded" structure in which large carbides group together. Improved properties of P/M tool steels are attributed to their finer and more uniform microstructure.

As-sintered microstructures consist of untempered martensite within prior austenite grain boundaries and large amounts of retained austenite. Etching in nital reveals the presence of prior austenitic grain boundaries during sintering. Etching also can reveal gray or white areas in the matrix. Gray areas are reported to be caused by the very fine carbide dispersions that result from marginal or insufficient vacuum quenching. White areas indicate locations in which precipitation has not occurred.

Figure 31 shows undersintered, correctly sintered, and oversintered microstructures. Undersintered microstructures (Fig. 31a) have fine or very fine carbides and grains in addition to porosity. Porosity is rounded (without sharp ends) and can be irregular in shape when sintered density is low. Correctly sintered microstructures have little or no porosity, no eutectic structure or evidence of melting, uniformly dispersed carbides, and uniform grain size, as shown in Fig. 31(b).

Fig. 31 Photomicrographs of as-sintered T15 high-speed steel. (a) Undersintered structure. 190×. (b) Correctly sintered structure. 190×. (c) Oversintered structure. 190×

The oversintered microstructure has large carbides and grains. Porosity with sharp ends, usually at grain triple points, is evident. A eutectic structure from localized melting and a continuous carbide network around grains may also be present in oversintered microstructures (Fig. 31c). Oversintered parts have slightly lower sintered densities (~ 0.2 to 0.5 g/cm^3) than correctly sintered parts because of the formation of porosity at the grain triple points.

Contamination. Metallic contamination can be readily detected in sintered tool steel microstructures. Contamination appears as carbide-free areas with porosity and/or carbide networks. Such defects occur when lower melting alloy particles or alloy particles that react with carbon from the tool steel powder to form low-melting alloys are present in higher melting tool steel alloys. Iron, stainless steel, and low-alloy steel powders form such defects in M2, T15, and other high-speed steels. These defects also occur when particles of T15 are present in M2 high-speed steel.

Tool steel powder producers have significantly reduced typical levels of contamination by using powder cleaning, compaction, and sintering equipment only for tool steel powders and by keeping powder-producing environments meticulously clean. Tool steel powder users must also clean powder hoppers and blenders to maintain high-quality P/M part production.

Production Sintering Practices

Atmospheric Pressure Sintering

Although vacuum is the preferred mode of sintering, wear parts made of tool steels and high-speed steels can be sintered to conventional P/M densities or to full density at atmospheric pressure and in atmospheres with dew points below $-40 \text{ }^\circ\text{C}$ ($-40 \text{ }^\circ\text{F}$). Atmosphere-sintered parts have higher oxygen and nitrogen levels than vacuum-sintered parts.

Nitrogen-based, dissociated ammonia, and hydrogen atmospheres are viable alternatives to vacuum. Atmosphere composition has little effect, however, on sintered density. Parts sintered in pure nitrogen or nitrogen-base atmospheres are nitrided. Increasing the nitrogen content decreases the sintered transverse rupture strength. Consequently, as-sintered transverse rupture strength is lowest for parts sintered in nitrogen and highest for parts sintered in hydrogen. Sintered high-speed steels and tool steels should be double tempered to maximize transverse rupture strength.

Sintering of Copper-Base Alloys

Alain Marcotte, United States Bronze Powders, Inc.

Copper-base P/M materials rank second only to iron-base parts in terms of commercial applicability. As with other P/M materials, the final properties and related performance of copper-base parts depend on successful sintering techniques. This section reviews sintering practices for Cu-Sn, Cu-Zn-Pb, and Cu-Ni-Zn alloys.

Production Sintering Practices

Sintering of Bronze

Sintered bronze can be produced either from mixtures of copper powder and tin powder or from a prealloyed tin bronze powder. The nominal composition of 90Cu-10Sn can be complemented with other constituents such as dry organic lubricants, graphite, lead, and iron, depending on the specified grade.

Premix/Diffusion Alloyed Bronzes

Premix or partially diffused bronzes are used extensively in the manufacture of porous, self-lubricating bushings and bearings and for more complex structures requiring superior bearing and mechanical strength. Self-lubricating bushings and bearings are produced at nominal densities (oil impregnated) of 5.8 to 7.2 g/cm³, with oil contents ranging from 24 to 11 vol%, respectively. Corresponding radial crush values (*K* strength constant) are approximately 69 MPa (10 ksi) of the lower density, increasing to 228 MPa (33 ksi) at the highest nominal density.

The basic manufacturing procedure consists of compacting the powder shapes to the appropriate green density and sintering to achieve a homogeneous metallurgical alpha bronze structure, followed by oil impregnation. A sizing operation completes the process to ensure dimensional precision and general surface integrity.

Dimensional Change. Several methods are used in the industry to produce bearings and structural parts from sintered 90Cu-10Sn bronze. For practical purposes, either pure copper and pure tin or prealloyed bronze and tin powder can be mixed. There are advantages and disadvantages to both methods. Mixed powders possess relatively good pressing properties, but there is always a risk of segregation. Premix powder containing prealloyed bronze (e.g., 94Cu/6Sn + 4Sn) have less liquid phase during sintering, which accounts for a comparatively lower sintered strength at similar green density. However, "partially prealloyed" bronze minimizes the risk of segregation and still maintains acceptable sintered strength.

Partially diffused bronze is possible when premix bronze is presintered at a temperature range from 400 to 750 °C (750 to 1380 °F), such that a metallurgical bond between tin and copper powder is created. The sintered cake is then crushed, ground, and screened. This treatment minimizes segregation and gives similar sintered properties to premix bronzes.

To include all dimensional patterns with related absolute dimensional change values for each commercially available premix system is prohibitive. A variety of premixed powders are available with specific sintered dimensional patterns to satisfy customer design and tooling needs. Despite the dimensional magnitude of the particular premix being sintered, compositions of this type exhibit a common sintered dimensional pattern. Absolute sintered dimensional characteristics typically are unique to a specific source of copper and tin powders. For example, sintered dimensional consistency can be obtained by blending two or more copper-base powders that exhibit different growth characteristics and/or by use of tin powders that also exhibit different growth characteristics.

Generally, copper-tin blends composed of relatively coarse powder sinter to higher growth values than a blend composed of finer powders. After powder blends have been tested and adjusted to provide an approximation of target dimensions, final adjustments are made during production sintering to obtain dimensional precision. For discussion purposes, Fig. 32

shows the relationship between dimensional change, sintering time, and green density of a premix bronze and a partially diffused bronze, using the same source of powders and a similar particle size distribution (see Ref 36).

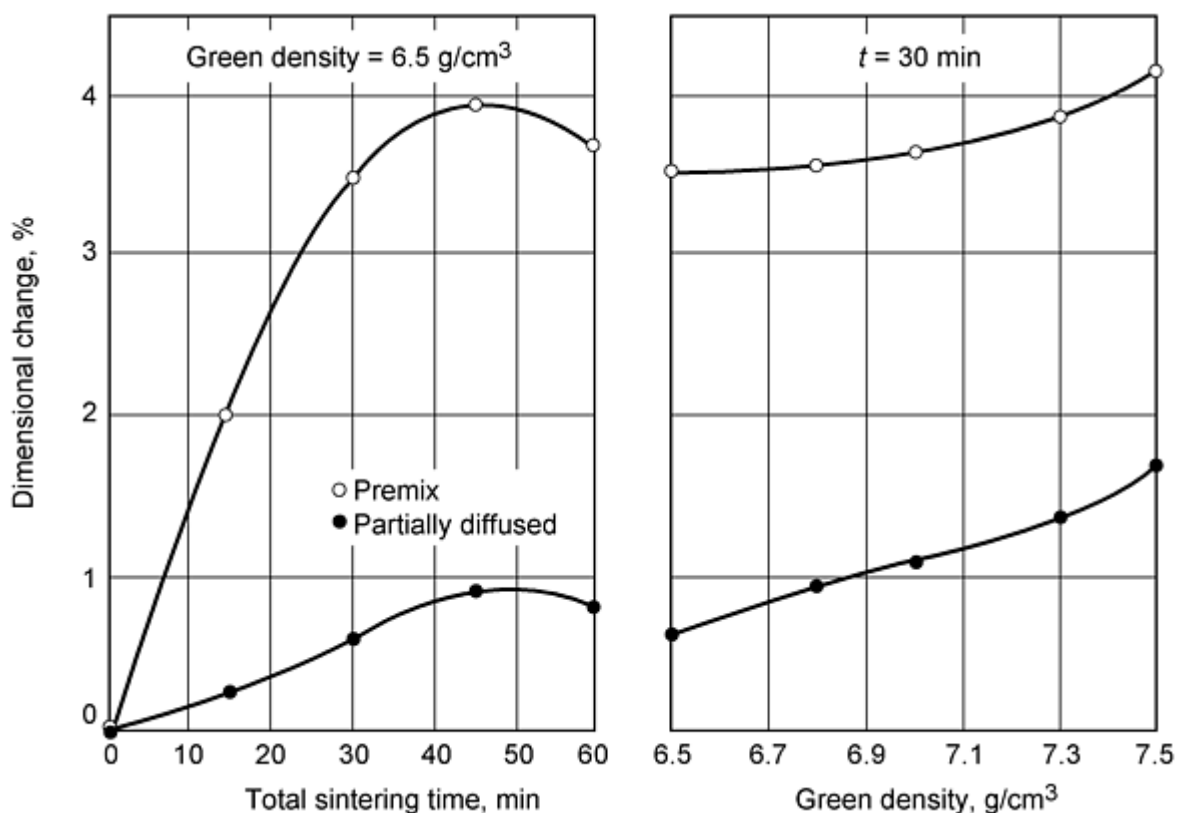

Fig. 32 Effect of properties on dimensional change of bronze. Sintered at 820 °C (1500 °F), under dissociated ammonia atmosphere.

Factors affecting the ultimate, or peak, dimensional values include physical characteristics of the constituents and compacted density. Control of sintered dimensions in premix systems is achieved by manipulating sintering time and/or temperature.

Sintering Time and Temperature. Typical sintering furnace temperatures for bronze range from 815 to 860 °C (1500 to 1580 °F); total sintering time within the hot zone ranges, from 15 to 30 min, depending on the furnace temperature selected, required dimensional change, and most importantly, the presence of an optimum alpha grain structure. Figure 33 shows the typical microstructure of a premix bronze part.

Fig. 33 Typical microstructure of sintered premix bronze. 90-10 bronze, etched in K₂Cr₂O₇ solution. 175×

Sintering atmospheres should be protective and reducing to facilitate sintering. Reduction of the copper oxides that may surround each copper powder particle and reduction of tin oxide formation allow for increased diffusion rates. Consequently, faster sintering rates and more homogeneous structures can be obtained.

Prealloyed Bronzes

Sintered bronze alloys are rather uncommon in powdered metal usage. This is primarily due to their relatively high cost compared to low-alloy steels. However, sintered bronze properties can be advantageous for non-magnetic applications that require very good corrosion resistance, good mechanical strength, and excellent ductility.

Prealloyed 80Cu-9Sn-2Zn bronze powders with a select lubricant are intended for the fabrication of high-density P/M structural components. Unlike many elemental copper-tin premixes, the sintering of prealloyed bronze results in the attainment of high sintered densities (85 to 90% of theoretical), that provide correspondingly high strengths and hardnesses.

Sintering properties. Prealloyed bronze powders are relatively easy to work due to the excellent ductility obtained on sintering. For example, an 89Cu-9Sn-2Zn bronze pressed at 414 MPa (30 tsi) to 85% of theoretical density, exhibits >30% elongation thus allowing for a substantial degree of cold working. Compared with sintered brass, bronze powders reach higher yield strength and hardness levels when compacted under similar conditions. For example, pressing at 550 MPa (40 tsi) results in hardness of 45 HRB for an 89Cu-9Sn-2Zn-2Fe bronze and of 90 HR for a 70Cu-30Zn brass, respectively (after 30 min sintering at 840 °C (1550 °F) under dissociated ammonia).

The addition of 2% of a select grade iron in the composition improves the sintered structure, which has a more uniform grain size and results in comparatively higher yield strength and hardness. Figure 34 shows the microstructure of a prealloyed bronze. Sintering temperature and atmospheres of prealloyed bronzes are similar to those of bronze premix. Figure 35 shows the dimensional change and transverse rupture strength of prealloyed bronzes as a function of green density.

Production Sintering Practices

Sintering of Brass and Nickel Silvers

Powders of brasses and nickel silvers are prealloyed, single-phase (alpha) powders that, on sintering, yield moderate mechanical strength, excellent ductility, and good corrosion resistance. Parts can be subsequently burnished to improve surface finish. The various alloy compositions produced also provide suitable color, or shade, selection for applications that require a high degree of surface finish and appearance.

During alloy preparation, lead can be added to improve machinability of the sintered forms. Typical machining operations include drilling, tapping, turning, threading, and grinding. Excellent sintered ductility also facilitates secondary operations, such as sizing, cold densification, swaging, and staking. By using multiple pressing and sintering operations, the yield strength and hardness of the P/M structure may approach those of its wrought alloy counterpart (Ref 37).

Standard prealloyed brass and nickel silver powder compositions are controlled to conform to existing materials standards. This conformance precludes the additions of foreign metallic constituents, such as tin and iron, that affect sintered mechanical and dimensional characteristics. In spite of the various compositions comprising these standard alloy powders, most exhibit similar characteristics. After blending with lubricant, powders densify approximately 10% more than their as-atomized apparent density. For example, an as-atomized powder with an apparent density of 3.0 g/cm³ usually blends to a density of 3.3 g/cm³ minimum with the addition of dry lubricant. Compressibilities are excellent, as lubricated powders compact to 85% of wrought counterpart densities at 414 MPa (60 ksi). Compression ratios of lubricated powders range from 2.0-to-1 to 2.2-to-1.

Effect of Lubricant. Blending of powders with dry organic lubricants is normally accomplished in a double cone-type blending unit. To minimize the inclusion of large lubricant agglomerates and other undesirable particles, the material is passed through a 40 mesh sieve, or screening is recommended prior to blending. The primary lubricant employed with brasses and nickel silvers is lithium stearate.

Lithium stearate provides an apparent scavenging or cleansing effect that enhances the sinterability of these powders. It may also result in spotty or speckled superficial stains on sintered surfaces. These phenomena affect the appearance of the components, but are not detrimental to mechanical properties. To minimize staining, lithium stearate additions of less than 0.5 wt% are recommended, and zinc stearate can be added to provide the additional required lubricity.

Different types of lubricant have a marked effect on the physical and mechanical properties of nonferrous prealloyed powder (Ref 37). To illustrate the effects on mechanical properties, Fig. 36 shows data for three frequently used lubricants in the P/M industry--lithium stearate, zinc stearate, and stearic acid. The beneficial effect of 1 wt% lithium stearate and the deleterious effect of 1 wt% stearic acid on mechanical properties are shown.

Fig. 36 Effects of lubricants and sintering time at temperature on tensile properties, sintered density, and dimensional change of brass compacts

Compacting of lubricated powders is performed with standard types of compacting presses employing steel or carbide dies and punches. Excellent compressibility and good green strength permit compacting to 75% of theoretical density at pressures as low as 207 MPa (30 ksi).

Although powders are normally free of gangue and other inclusive, abrasive material that may cause tool wear, their relative softness does cause tooling difficulties. If powders are not adequately lubricated, fines within tool clearances gall the die wall and adjacent punch areas, thereby requiring tool removal and cleaning. The amount of lubricant added to the powder should be proportional to the total surface area of the die assembly requiring lubrication during forming and ejection. Low-profile, minimum die wall contact parts may only require 0.5 wt% added lubricant, whereas a high die wall contact part having core rods for holes or internal cavities may require 1.0 wt% lubricant.

Generally, there are no restrictions on the compacted configuration of these powders. In tool design, particularly with regard to die fill, consideration must be given to the relatively higher apparent densities of lubricated brass and nickel silver powder. Typical apparent densities for lubricated powders range from 3.3 to 3.6 g/cm³.

Sintering of brasses and nickel silvers typically is not difficult; however, basic sintering practices do differ from those employed with other common alloy systems, such as elemental copper-tin blends and iron powder blends. These differences include sintering temperature, time at sintering temperature, and atmosphere protection.

Sintering temperatures for standard brasses range from 760 to 925 °C (1400 to 1700 °F). Temperature selection depends on the brass alloy being sintered and the mechanical properties desired after sintering. Lower brasses with higher zinc contents and lower melting points are sintered at the lower temperature. Generally, a starting temperature of 100 °C (180 °F) below the solidus temperature (as determined from any copper-zinc binary alloy constitutional diagram) is suitable.

Nickel silver can be sintered at 870 to 980 °C (1600 to 1800 °F). Currently, only one base alloy is used for the manufacture of P/M structural parts; it has nominal composition of 64Cu-18Ni-18Zn. The leaded alloy composition contains 1.5% Pb. Sintering characteristics are similar to those of the brasses; therefore, responses to sintering parameters that affect dimensional and mechanical properties of brass are equally applicable to nickel silver.

Sintered Properties. Dimensional and mechanical properties of brasses and nickel silvers are primarily affected by compact density and the amount of time at temperature, as well as the sintering temperature itself. As mentioned previously, other elements that affect dimensional and mechanical properties usually are not added to powders. However, sintered properties, especially dimensional change, can be effectively controlled by manipulation of sintering time at the appropriate temperature. Each alloy exhibits unique dimensional characteristics--a 90Cu-10Zn brass compacted at 414 MPa (30 tsi) and sintered for 30 min at 870 °C (1600 °F) may shrink 0.5%, while a 70Cu-30Zn brass similarly treated may shrink 2.5%.

Figures 37 and 38 show typical property relationships that can be controlled through manipulation of time at temperature. The leaded 80Cu-20Zn brass shown in Fig. 37 and 38 is commonly used for structural parts fabrication. The density of 7.6 g/cm³ is "average" for compacting lubricated prealloyed powders containing 0.375% lithium stearate and 0.375% zinc stearate at 414 MPa (30 tsi). As shown, close dimensional control can be obtained with a minimum reduction in mechanical properties after 15 min at temperature. Ductility is increased for subsequent forming operations, such as sizing, cold repressing for densification, or coining, by increasing sintering time.

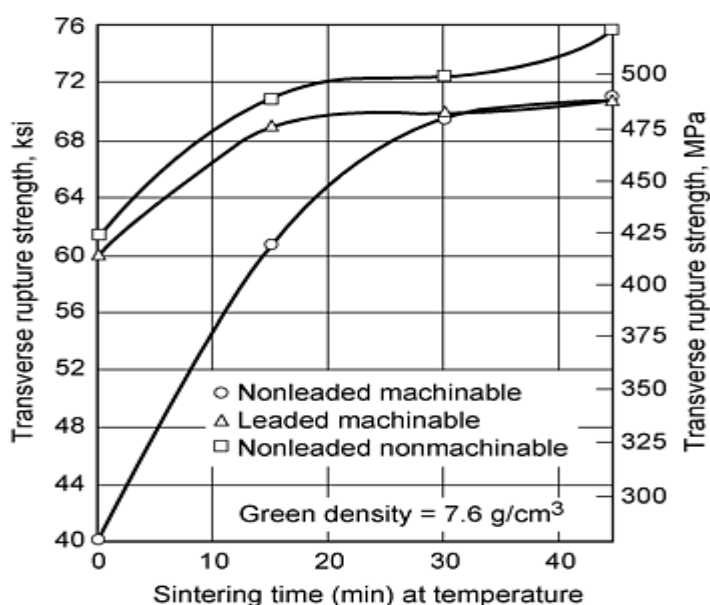

Fig. 37 Transverse strength of 80Cu-20Zn brasses. Sintered in hot zone at 870 °C (1600 °F) in DA

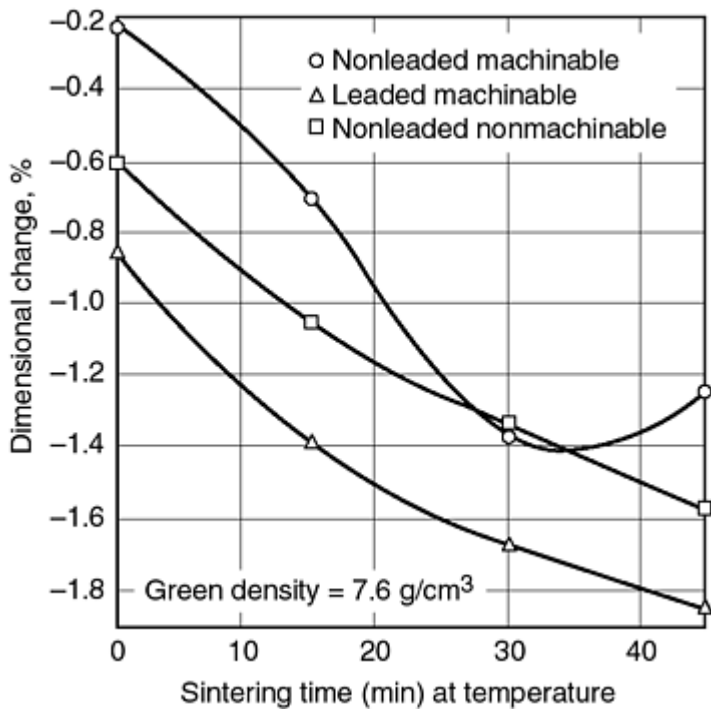

Fig. 38 Dimensional change of 80Cu-20Zn brasses. Sintered in hot zone at 870 °C (1600 °F) in DA

Non-leadable machinable brasses have been recently introduced on the market to reduce or eliminate lead. It has been shown (Ref 38) that by replacing lead with select alloy additions, brass parts still maintain similar mechanical and physical properties, while having improved machinability. Figures 37 and 38 illustrate the properties of non-leadable brass, leadable brass, and a non-leadable brass containing select alloy additions. Figure 39 also shows the machinability for those different types of 80Cu-20Zn brasses.

Fig. 39 Machinability of 80Cu-20Zn brasses. Sintered in hot zone at 870 °C (1600 °F) in DA

Atmosphere protection is required for sintering brasses and nickel silvers to prevent oxidation and to ensure effective sintering. Use of lithium stearate as the base lubricant allows the use of most common sintering atmospheres over a wide range of dew points. Although dry hydrogen or dissociated ammonia provides the best sintering atmosphere, comparable properties can be obtained with nitrogen-base or partially combusted hydrocarbon gas atmospheres.

When sintering, compacts should be protected from direct impingement of furnace flame curtains and atmosphere gases by partially or fully covering loaded trays to minimize zinc loss. Because it has a high vapor pressure at standard sintering temperature (boiling point of pure zinc is 906 °C, or 1663 °F), zinc may be lost to the atmosphere as it diffuses through to the particle surfaces. Loss of excessive surface zinc results in a change in surface composition. In the case of brasses, pink copper or zinc-depleted areas are apparent. Although superficial zinc losses do not adversely affect sintered properties, surface finish is diminished; finished parts may be rejected because of color differences.

Furnace Design. A variety of protective sintering tray arrangements can be used, including graphite trays with full covers and graphite-base plates with steel covers, for example. Sintering of brasses on open belts is not common practice for several reasons; for example, overheating can melt brass parts that can fuse to the mesh belt. Also, excessive heat and direct impingement of flame curtain gas through the mesh can impair effective sintering due to oxidation and premature partial lubricant removal. Direct exposure to the sintering atmosphere can also cause objectionable surface dezincing.

Conversely, extremely gastight protective sintering setups should be avoided, because lubricant decomposition products may not be completely volatilized. Excessive residual lubricant within the compact inhibits sintering; consequently, mechanical properties are adversely affected. Typically, compacts with excessive internal lubricant residuals cannot be salvaged by additional passes through a full sintering cycle. To avoid or minimize the deleterious effect of residual lubricants, covered tray setups should facilitate free venting of lubricant gases to the flowing furnace atmosphere.

Production Sintering Practices

*Sintering of Aluminum and Aluminum Alloys**

Conventionally pressed and sintered aluminum powder metal parts have been commercially available for many years. Sintered aluminum P/M parts are competitive with many aluminum castings, extrusions, and screw machine products that require expensive and time-consuming finishing operations. In addition, sintered aluminum P/M parts compete with other metal powder parts in applications where some of the attractive physical and mechanical properties of aluminum can be used.

Commercially available aluminum powder alloy compositions consist of blends of atomized aluminum powders mixed with powders of various alloying elements such as zinc, copper, magnesium, and silicon as follows:

Grade	Composition, %				
	Cu	Mg	Si	Al	Lubricant
601AB	0.25	1.0	0.6	bal	1.5
201AB	4.4	0.5	0.8	bal	1.5
602AB	...	0.6	0.4	bal	1.5

Aluminum P/M parts can be sintered in a controlled, inert atmosphere or in vacuum. Sintering temperatures are based on alloy composition and generally range from 595 to 625 °C (1100 to 1160 °F). Sintering time varies from 10 to 30 min. Nitrogen, dissociated ammonia, hydrogen, argon, and vacuum have been used for sintering aluminum; however, nitrogen is preferred because it results in high as-sintered mechanical properties (Table 17). It is also economical in bulk quantities. If a protective atmosphere is used, a dew point of -40 °C (-40 °F) or below is recommended. This is equivalent to a moisture content of 120 mL/m³ (120 ppm) maximum.

Aluminum preforms can be sintered in batch furnaces or continuous radiant tube mesh or cast belt furnaces. Optimum dimensional control is best attained by maintaining furnace temperature at ± 2.8 °C (± 5 °F). Figure 40 illustrates typical heating cycles for aluminum parts sintered in various furnaces.

Mechanical properties are directly affected by thermal treatment. All compositions respond to solution heat treating, quenching, and aging in the same manner as conventional heat-treatable alloys. Table 18 summarizes some typical properties of aluminum P/M alloys.

Production Sintering Practices

Sintering Atmospheres

Sintering in Nitrogen. Nitrogen at high purity and low dew point is particularly well suited for sintering aluminum P/M parts because of ready availability and moderate cost. Special handling is not required, nor are a generator and adsorbent dryer required to convert nitrogen to a dry, gaseous form. The highest sintered strength in both 601AB and 201AB parts is achieved in nitrogen.

Dissociated ammonia is used in many P/M applications for sintering brass and bronze parts. It can be used for aluminum as well (Ref 39).

Dissociated ammonia contains high concentrations of flammable hydrogen; consequently, care must be taken in handling, particularly for aluminum processing during which sintering temperatures are not high enough to ensure self-ignition upon contact with air. One precautionary method involves purging the furnace with an inert gas such as nitrogen prior to introducing dissociated ammonia.

Conditions and production rates for aluminum P/M parts sintered in dissociated ammonia were similar to those sintered in nitrogen; however, tensile properties of 601AB and 201AB alloys sintered in dissociated ammonia (Table 19) tend to be lower than for nitrogen sintered parts. The lower properties of parts sintered in dissociated ammonia appear related to the presence of hydrogen and/or undissociated ammonia in the sintering atmosphere. The tendency of hydrogen to cause gassing of aluminum has been well documented (Ref 40). Also, ammonia reacts with aluminum to liberate hydrogen. When 100% ammonia vapor was used as a heat treating atmosphere for aluminum, the tensile strength of 2024 alloy sheet was reduced 29%, and the elongation was reduced 82% (Ref 40).

- (a) Sinter 10 to 30 min at 620 °C (1150 °F) at a dew point of -40 to -50 °C (-40 to -60 °F).
- (b) Sinter 10 to 30 min at 595 °C (1100 °F) at a dew point of -40 to -50 °C (-40 to -60 °F)

Dimensional Change During Sintering. Dimensions of sintered aluminum P/M parts are affected by compact density, sintering atmosphere, temperature, and dew point. The effects of green density and atmosphere on sintered dimensions of 601AB and 201AB alloys are illustrated in Fig. 41(a) and 41(b). Dimensions increased with increased green density in all atmospheres. Shrinkage or a lack of growth was exhibited by 85% green density parts, whereas high-density compacts exhibited growth when sintered in dissociated ammonia and vacuum. Nitrogen-sintered parts experienced shrinkage over the full range of densities--except for 95% density 601AB, in which no change was noted.

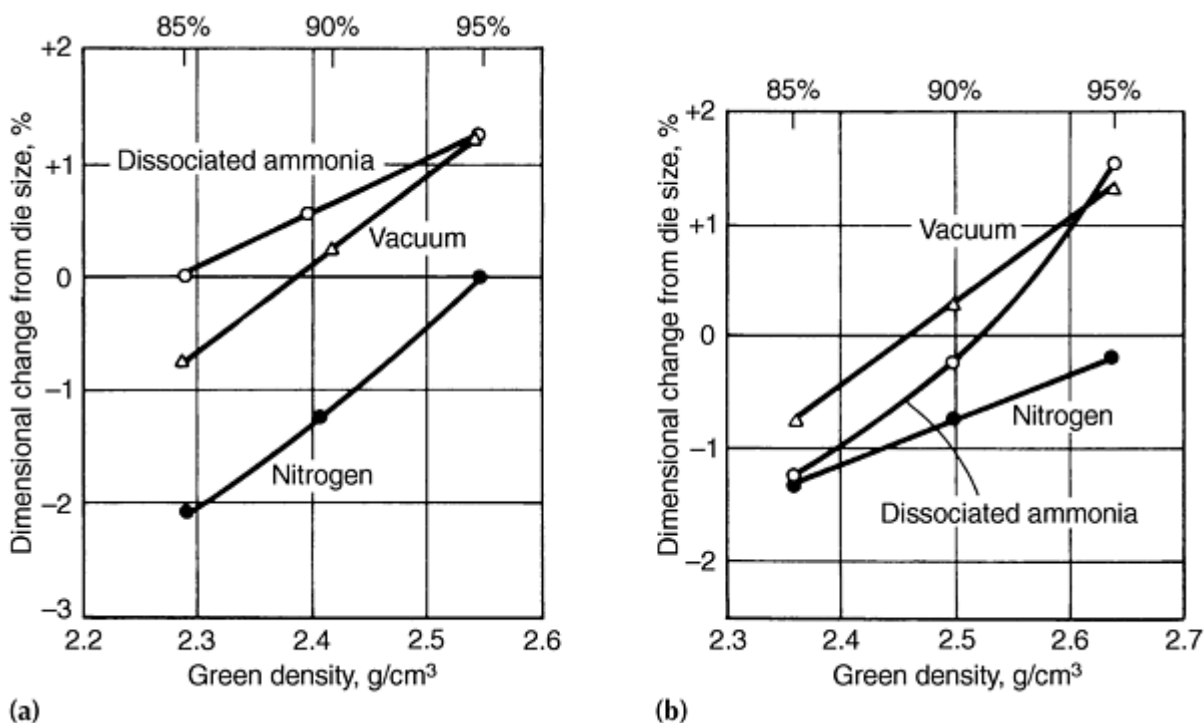

Fig. 41 Effect of green density and atmosphere on sintered dimensions. (a) 601 AB. (b) 201 AB

These dimensional changes were consistent as long as the sintering temperature was constant and the dew point in the furnace was at least -40 °C (-40 °F). Higher than normal temperatures caused excessive shrinkage and distortion or even

melting in extreme cases. Lower than normal temperatures produced parts with increased dimensions and reduced properties.

Thus, for example, lowering the sintering temperature of 201AB alloy from 595 to 570 °C (1100 to 1060 °F) caused 95% density specimens sintered in dissociated ammonia to change from 0.25% shrinkage to 1.0% growth. At 580 °C (1080 °F), 0.25% growth was observed. Mechanical properties were less affected, although a reduction in tensile strength of 2 to 10% was observed, depending on thermal treatment. High dew points in the furnace resulted in excessive part expansion and a significant reduction in properties.

Production Sintering Practices

Sintering of Cemented Carbides

Revised by Mack Greenfield and George Wolfe, Kennametal, Inc.

Cemented carbides consist of various mixtures of carbides and iron-group metals, such as tungsten carbide/cobalt, tungsten carbide/titanium carbide/tantalum carbide/niobium carbide/cobalt, or titanium carbide/molybdenum carbide/nickel. These materials typically are sintered to essentially 100% of theoretical density using a liquid-phase sintering process. The successful application of cemented carbides to high-stress operations such as metal cutting, oil well drilling, or metal forming dies depends on achieving low levels of residual porosity during sintering. Additionally, sintering must be controlled carefully to obtain desired microstructure and chemical composition.

Cemented carbides are used in many applications in the as-sintered condition. Frequently, the as-sintered surface acts as the critical wear/stress-bearing surface. In most metal-cutting applications, the tool is considered worn out when the wear scar depth exceeds 0.2 to 0.4 mm (0.008 to 0.016 in.). Consequently, control of surface properties is essential.

Production Sintering Practices

Sintering Methods

Two basic methods are used to sinter cemented carbides. Hydrogen sintering uses a hydrogen-base atmosphere at atmospheric pressure to dynamically control part composition. Vacuum sintering uses a vacuum or reduced-pressure environment to control composition through slowing of the reaction kinetics. The vacuum method enjoys wide commercial usage. The use of over-pressure sintering (i.e., sinter HIP) and hot isostatic pressing (HIP) are significantly influencing the production of cemented carbides for specialty applications.

Sintering of cemented carbides consists of removal of pressing lubricant, oxide reduction, densification, and microstructure development. Each of these phases is discussed below for hydrogen and vacuum sintering modes, sinter HIP, and the effects of HIP.

Hydrogen Sintering. During hydrogen sintering, an atmosphere of hydrogen provides a reducing environment which, when subsequently modified by reactions with the furnace walls and carrier devices, provides the correct carburizing and oxidizing potentials to maintain thermodynamic equilibrium with the cemented carbide. In conventional hydrogen sintering, carbon content of the carbide powder is adjusted to the nominal theoretical value, and the hydrogen atmosphere subsequently maintains that value throughout the sintering cycle. For example, a 94WC-6Co composition may enter the furnace with a carbon content of ~ 5.70 to 5.80 wt% and exit the furnace with $5.76 \pm 0.04\%$.

The atmosphere control capability of the hydrogen process is adequate for straight tungsten carbide/cobalt grades, but the oxidizing potential usually is too high to provide high-quality compositions containing titanium carbide, tantalum carbide, and/or niobium carbide additions suitable for steel machining. Such compositions usually are sintered in vacuum to achieve lower oxygen contents. Hydrogen sintering frequently is accomplished by mechanically stoking the parts through the furnace; a presintering furnace is required to remove pressing lubricant to prevent contamination from evolved lubricant vapors during the high-temperature stage of sintering. Presintering can also be used to partially sinter parts to green strengths that permit green forming operations, such as lathe turning or drilling. Peak presintering temperatures range from 500 to 800 °C (930 to 1475 °F), depending on the level of green strength desired.

Figure 42 shows a typical time-temperature curve for a mechanically stoked hydrogen sintering run. The combined hot zone profile and stoking rate resulted in a heating rate of ~ 6 °C/min (11 °F/min) up to 1350 °C (2460 °F), holding above 1350 °C (2460 °F) for 75 min, and a peak temperature of ~ 1460 °C (2660 °F).

Fig. 42 Typical time-temperature cycle for hydrogen stoking furnace

Vacuum Sintering. Vacuum sintering is the predominant industrial process for sintering cemented carbides. Compared to hydrogen atmosphere sintering, vacuum sintering has several major advantages. This process allows superior control of product composition. At pressures of 1.3 to 133 Pa (10^{-2} torr to 1 torr), the rate of carbon and oxygen exchange between the atmosphere and the cemented carbides is very low. The main factor controlling composition is the oxygen content of the carbide powder, not the rate of reaction with the atmosphere.

Because of the low oxidizing potential of the vacuum sintering atmosphere, the vacuum process is superior to the hydrogen process for the sintering of titanium carbide, tantalum carbide, and niobium carbide compositions that are sensitive to oxidizing potential. While capable of attaining low oxidizing potentials, most commercial hydrogen sintering furnaces have relatively high oxidizing potentials due to air leakage and reactions with ceramic furnace parts and fixturing.

Secondly, vacuum sintering offers greater flexibility and control of the thermal cycle, particularly the heating cycle. This is due to the fact that vacuum sintering is a batch process, while most hydrogen sintering is a continuous process. Slow heating rates are essential, usually followed by an intermediate temperature hold to obtain optimum product quality when titanium carbide, tantalum carbide, and niobium carbide additives are used in the carbide composition.

This allows sufficient time for the carbon-oxygen reactions to occur; a sufficient open-pore network exists to allow escape of the carbon monoxide gas that forms. If the temperature is raised too rapidly, gas becomes entrapped in the structure, thus forming pores. The heating cycle can be adjusted easily for vacuum furnaces; for mechanically stoked hydrogen furnaces, however, it is fixed by the hot zone design and the peak temperature time required to obtain the desired microstructure.

Conventional vacuum sintering offers low operating cost. Previous vacuum equipment used relatively small induction-heated furnaces that were characterized by high power consumption, long cooling times, and the need for separate

lubricant removal prior to sintering. Commercial vacuum sintering furnaces currently cost less to operate than hydrogen furnaces due to:

- Large batch size
- Resistance heating
- Forced gas cooling
- Built-in lubricant removal

Figure 43 shows a typical vacuum process time-temperature cycle. The most significant features are three temperature holds--the first at $\sim 500^\circ\text{C}$ (930°F) for lubricant removal, the second at $\sim 1200^\circ\text{C}$ (2190°F) for degassing, and a third at 1400 to 1500°C (2550 to 2730°F) for microstructure development.

Fig. 43 Cemented carbide vacuum sinter time-temperature cycle

Sinter Hot Isostatic Pressing. Overpressure sintering, more commonly referred to as pressure sinter or sinter HIP consists, in general, of a sintering furnace contained in a vessel of intermediate pressure capability. Argon pressures in the range of 1.5 to 10 MPa are employed at sintering temperature to reduce, or eliminate remnant porosity by the application of isostatic pressure to closed porosity parts. A single cycle includes delubing, oxide reduction, and sintering, followed by low pressure HIP with chamber pressure being increased to a higher level only after the carbide has sintered to the closed porosity range. The closure of clean porosity and macrovoids has been reported for straight WC-Co grades, that is, 3 to 6 wt% Co in the temperature range of 1420 to 1460°C (2590 to 2660°F) utilizing sinter HIP pressures of ~ 0.2 MPa, while temperatures in the 1430 to 1480°C (2610 to 2700°F) range yielded similar results for grades containing cubic carbides (Ref 41). The cost of single cycle sinter HIP units is substantially more expensive than conventional vacuum sinter units of similar capacity.

Hot isostatic pressing is completed as a post-sintering operation in a specially designed high-pressure vessel usually employing argon at pressures in the range of 100 MPa and a temperature in the same general range as that used in sintering. It is normally employed as a separate operation on cemented carbides after normal sintering has already removed most of the remnant porosity. Hot isostatic pressing can also be applied, in certain cases, to clad green preforms, that is, presintered product. Hot isostatic pressing units represent major capital investments, and their use as a post sintering operation adds to materials handling costs, utilities usage, and production lead times (Ref 42). The application of either sinter HIP or HIP to the manufacture of cemented carbide materials employing the appropriate time/temperature/pressure criteria results in increases in strength relative to both hydrogen or vacuum sintered product. This strength increase is greater for (a) fine-grain sized materials, (b) low cobalt grades, that is, 3 to 8 wt% Co, and (c) grades containing low additions of "cubic carbides" (Ref 43).

Production Sintering Practices

Lubricant Removal

Pressing lubricants used for cemented carbides range from low levels (0.5 to 2.5 wt%) of simple paraffins for pressed parts up to high levels of various synthetic polymers for extruded, injection molded, and slurry cast parts. The heating rate used for lubricant removal in a hydrogen atmosphere depends on the type and amount of lubricant used and the size of the pressed part. Heating rates as high as 15 to 20 °C/min (25 to 35 °F/min) to 500 °C (930 °F) can be used for pressed cutting inserts containing 1 to 2% paraffin. Much slower rates (0.5 to 4 °C/min, or 0.9 to 7 °F/min) are required for larger parts or for parts with higher lubricant contents.

Commonly used lubricants, such as paraffin, evaporate readily in vacuum at 100 to 250 °C (210 to 480 °F). Consequently, heating rate should be controlled in this temperature range to prevent excessive pressure within the compact due to evolving lubricant vapors. A condenser is used in the vacuum line to remove the portion of the lubricant vapor that condenses at ~10 to 90 °C (50 to 195 °F). The interior walls of the furnace are sometimes used to condense paraffin vapor to liquid, which is subsequently drained to the bottom of the furnace to enter the main condenser. Other furnaces employ carrier gases such as H₂, argon, or N₂ to completely remove paraffin vapors to external condensers. Carbowax is another common lubricant used in lieu of paraffin and is removed under atmospheric H₂.

Production Sintering Practices

Carbon Control

Carbon content of cemented carbides must be controlled to within very narrow limits, typically ± 0.04 wt%, to prevent formation of brittle lower carbides, such as the eta phase in tungsten carbide alloy systems on the low carbon side and carbon precipitates on the high carbon side.

Because carbon content can be changed substantially during sintering by reactions with oxygen-containing phases in the powder and by carbon exchange reactions with the furnace atmosphere, control of the furnace atmosphere carbon potential and the oxygen content of the powder is essential to produce high-quality P/M sintered parts.

During hydrogen presintering, reactions between the hydrogen atmosphere and cemented carbides are relatively sluggish at the lower end of the peak temperature range (400 to 600 °C, or 750 to 1110 °F), but reaction rates are sufficiently high at temperatures >600 °C (1110 °F) to cause significant changes in the carbon content of the part if the atmosphere is not properly adjusted.

This phenomenon is illustrated in Fig. 44, which shows the effect of varying the carburizing potential of the hydrogen atmosphere by methane additions on the carbon content of a 94WC-6Co composition held 1 h at the peak presinter temperature. The carburizing potential can be described as:

$$\frac{1}{k} \cdot \frac{\text{CH}_4}{\text{H}_2^2}$$

where k is the equilibrium constant for the reaction $2\text{H}_2 + \text{C} \leftrightarrow \text{CH}_4$, and CH_4/H_2^2 is a partial pressure ratio.

Fig. 44 Effect of carburizing potentials of hydrogen-methane mixtures on carbon content of WC-6Co. 1 h hold; 1 atm pressure. A_c is the thermodynamic carbon activity. Total carbon content is the sum of the compounded carbon in the carbide phase plus any graphite present. It does not include carbon present in the lubricant.

At temperatures up to 500 °C (930 °F), reactions causing carbon loss are too slow to noticeably change compositions. At 700 and 800 °C (1290 and 1470 °F), however, large carbon losses occur when the carburizing potential (relative to pure carbon) is less than ~ 0.05 .

Thus, even pure hydrogen can cause large carbon losses above ~ 600 °C (1110 °F). When the carburizing potential exceeds 1.0 (saturation value), large carbon increases occur at 500 °C (930 °F) and above, thus allowing buildup of the carbon-containing volatilized lubricant in the peak temperature portion of the furnace.

Above ~ 900 °C (1650 °F), hydrogen-base atmospheres can change the carbon content of cemented carbides substantially by:

To prevent the formation of undesirable carbon reaction phases, the carburizing potential (carbon activity) of the atmosphere must be carefully controlled. Table 20 shows experimentally determined activities required to maintain the desired carbon contents in tungsten carbide/cobalt cemented carbides at 1000 to 1450 °C (1830 to 2640 °F), with examples of typical gas compositions required to provide such carbon activities (Ref 44). The three major constituents of cemented carbide sintering atmospheres are hydrogen, carbon monoxide, and methane.

Table 20 Atmosphere compositions required to maintain neutral carburizing potentials for tungsten carbide/cobalt as a function of temperature and total oxygen content

(a) At pressure of 1 atm

Typical commercial practice for hydrogen sintering carbon control is based on partial reaction of the incoming gas (hydrogen plus impurity levels of water vapor and oxygen), which has zero carbon activity. Graphite fixturing is used to carry the carbide parts through the furnace to increase the atmosphere carbon activity. Fixturing may thus contain openings that are empirically sized to react the incoming gas to the proper degree with the graphite to obtain the desired carbon activity.

Alternately, the graphite carrier may completely enclose the parts, thus causing carbon activity to increase to near unity. Modifiers such as aluminum oxide sand are included within the carrier to react with the atmosphere to thus lower the carbon activity to the desired level. A common practice uses a packing mixture of aluminum oxide sand and a small amount of carbon that surrounds the cemented carbide parts inside graphite carriers. By adjusting the carbon addition, carbon activity can be adjusted to the desired level.

Because the rates of carbon and oxygen exchange between the atmosphere and cemented carbides are low during vacuum sintering, the final carbon content of the cemented carbide when vacuum sintered is determined primarily by the initial carbon content of the powder and the amount of carbon lost during heating due to reactions between carbon and chemisorbed oxygen in the powder. Much of the oxygen present as oxides of tungsten and cobalt reacts with carbon in the powder during the vacuum heating cycle and evolves as carbon monoxide and carbon dioxide gases, whereas in hydrogen sintering, those oxides are reduced by hydrogen and evolve as water vapor. Studies have shown that the cobalt binder phase is reduced of chemisorbed oxide between 550 to 650 °C (1020 to 1200 °F); tungsten oxides are reduced around 900 °C (1650 °F), while reduction of the oxides of the cubic carbides (Ta_2O_5 and TiO_2) occurs at 1000 °C (1830 °F) (Ref 45). When titanium carbides and tantalum carbides are present, much of the oxygen contained in these compounds is also removed by carbon reduction. To compensate for this carbon loss, vacuum-processed powder usually contains about 0.1 to 0.3 wt% added carbon than is used for hydrogen-processed powder.

Production Sintering Practices

Densification

During hydrogen sintering, densification of pressed cemented carbide parts usually is accomplished by mechanically stoking through a muffle-type electrically heated furnace held at a peak temperature of ~1400 to 1500 °C (2550 to 2730 °F). A densification curve for WC-10Co composition (Fig. 45) shows that significant densification begins at ~1000 °C

(1830 °F) and that greater than 90% theoretical density can be obtained at 1300 °C (2370 °F). Liquefaction of the cobalt phase occurs between 1280 and 1350 °C (2335 and 2460 °F) as a result of the formation of a tungsten carbide/cobalt eutectic or eutectic-like phase (approximately 35 wt% tungsten carbide that forms during heating, as discussed in Ref 46). Essentially, the part becomes fully dense soon after the liquid phase forms.

Fig. 45 Density-temperature relationship for WC-10Co. 30 min hold at each point

During densification, the pressed part undergoes a volumetric shrinkage of ~40 to 45% (16 to 18% linear shrinkage). Complete densification is readily accomplished for typical cemented carbide compositions that contain ~3 to 25 wt% Co (5 to 40 vol%). Complete densification is more difficult to achieve for cobalt contents of <3%. For cobalt contents greater than ~25%, part shape is difficult to maintain due to the presence of high liquid-phase fraction, which allows the part to sag.

Densification proceeds during vacuum sintering at about the same rate as it does for hydrogen sintering, reaching nearly 100% of theoretical density soon after the cobalt or nickel phase liquefies at 1280 to 1350 °C (2385 to 2460 °F); the exact temperature of liquefaction depends on the carbon content. When titanium carbide, tantalum carbide, and/or niobium carbide are present in the cemented carbide, the carbon-oxygen degassing reactions must be completed before densification closes the pores. If this does not occur, the evolving gases become entrapped in the interior of the compact, thus causing high residual porosity. Holding at ~1100 to 1250 °C (2010 to 2280 °F) for ~30 to 90 min ensures proper degassing of titanium carbide, tantalum carbide, and niobium carbide compositions.

Production Sintering Practices

Microstructure

At the beginning of peak temperature holding, the microstructure is nearly fully dense, and the carbide particles are nearly unchanged in size and shape from the original milled powder state. They are relatively small, irregularly shaped, and poorly dispersed, tending to agglomerate. The cobalt phase is also poorly dispersed, and many pools or lakes may be present (Fig. 46a). A noticeable amount of residual porosity also exists (Fig. 46a).

Fig. 46 Microstructure of WC-6Co. (a) Undersintered. (b) Normal structure. (c) Discontinuous grain growth

The main purpose of the final stage of the sintering operation is to develop the microstructure by holding at a temperature above the cobalt melting point for a time sufficient to develop a more uniform carbide structure with good cobalt phase dispersion and minimal residual porosity (Fig. 46b). This is usually accomplished by holding for 30 to 90 min above 1350 °C (2460 °F), reaching a peak temperature at ~1400 and 1600 °C (2550 and 2910 °F). During this period, the cobalt phase, driven by capillary forces, disperses more evenly. This process also improves carbide particle distribution.

Carbide distribution is further improved during holding by the dissolution of small particles into the liquid phase, with subsequent precipitation onto the larger particles during cooling. This results in a gradual increase in average particle size (Fig. 47a). Increasing the sintering temperature has a similar influence on grain growth (Fig. 47b).

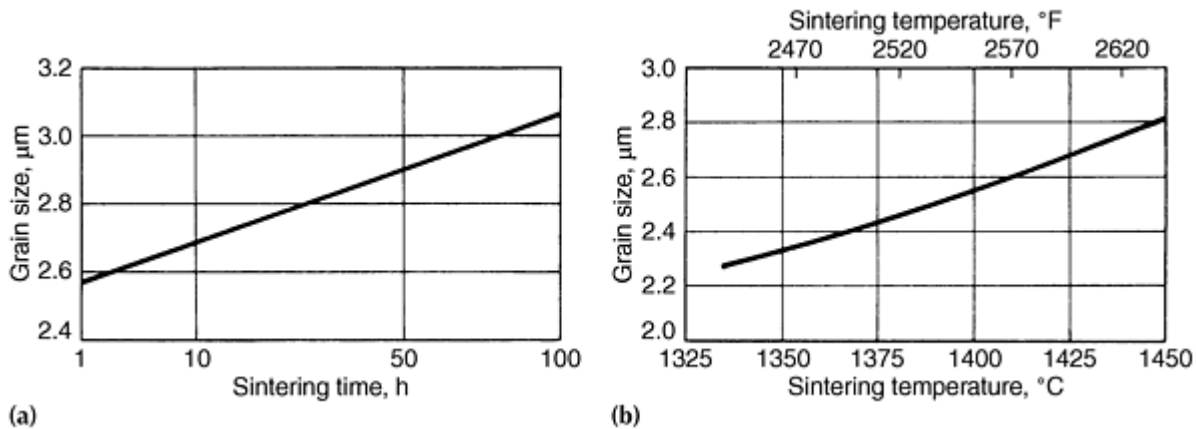

Fig. 47 Effect of sintering on grain growth of WC-25Co compacts. (a) Effect of sintering time at 1400 °C (2550 °F). (b) Effect of sintering temperature (1 h hold)

One undesirable consequence of grain growth by the solution and precipitation process is the tendency of large tungsten carbide grains to grow at a disproportionately high rate. This discontinuous grain growth (Fig. 46c) occurs more readily at lower cobalt contents (3 to 6 wt%) with finer average particle size mixes. It is most pronounced when tungsten carbide is the only carbide phase present. Small additions (0.1 to 0.5%) of group VB carbides (vanadium carbide, niobium carbide, and tantalum carbide) undergo significant grain growth in fine-grained tungsten carbide/cobalt compositions. Titanium carbide is also a strong grain growth inhibitor (Ref 46), as well as chromium carbide.

During vacuum sintering, cobalt losses by evaporation should be controlled. If uncontrolled, as much as 10 to 20% of the cobalt content of the part may be lost, thus resulting in a loss of mechanical strength and the formation of a rough, coarse-grained surface structure caused by the precipitation of tungsten carbide from the evaporating cobalt (Ref 47 and 48). Cobalt evaporation can be minimized by completely enclosing the pressed parts in graphite fixturing, the walls of which are maintained at the sintering temperature.

The enclosure causes a buildup of cobalt vapor pressure around the cemented carbide parts, which reduces the evaporation rate. Cobalt losses can also be controlled by operating at pressures of at least 66 Pa (0.5 torr), rather than in the range of 1.3 to 13 Pa (0.01 to 0.1 torr) that mechanical vacuum pumps and blowers are capable of maintaining. Higher pressures can be maintained by placing a throttling valve between the furnace and the pump or by injecting an inert gas into the furnace.

Sinter HIP results in the closing of pores and macrovoids with microstructure typical of the surrounding material. Similar results can be obtained through the use of HIP provided that judicious selection of time and temperature is employed in conjunction with HIP pressure for the specific binder level of the material undergoing post-sintering treatment. Early attempts at HIP resulted in the extrusion of binder material into the pores and macrovoids once the melting point had been reached and the formation of cobalt "lakes" or "pools" in the microstructure (Ref 49).

Production Sintering Practices

Cooling

After holding at sintering temperature, loads containing small parts can be cooled to room temperature in ~2 to 4 h by circulating inert gas (argon or helium) through the load at or near atmospheric pressure. Cooling of large parts is prolonged to minimize thermal stresses. When all significant material and process parameters, such as powder preparation, chemical composition, heating rate, holding times and temperatures, and cooling procedures, are properly adjusted, the as-sintered surfaces of all pieces in the load achieve the same composition and structure as the interiors of the pieces. This eliminates scrap or rework associated with compositional imbalances and reactions with the furnace atmosphere.

Production Sintering Practices

Sintering of Tungsten and Molybdenum

Richard Cheney, GTE Products

Tungsten and molybdenum sintering practices are similar; consequently, they will be described together in this section. The achievement of high density is a primary goal when sintering tungsten and molybdenum, because high density is frequently required for performance. It is also required if metalworking operations are necessary, in which case at least 90% of theoretical density is essential. High-density values indicate that compact shrinkage has been significant, because pressed densities are seldom >75% of theoretical. In addition to ensuring high density, purification occurs during sintering, and the resultant microstructure is established.

Sintering Variables

Several factors influence the sintering of tungsten and molybdenum, including time, temperature, particle size, atmosphere, purity of powders and compacts, compacted density, thermal gradients, heating rate, cooling rate, particle size distribution, compact weight, gravity, and friction, and additives such as dispersed oxides and sintering activators. These variables and their interrelationships are discussed in the following sections.

Time and temperature are the fundamental determinants of the sintering kinetics for tungsten and molybdenum--in addition to particle size, which is discussed below. Mass transport by diffusion is very slow for refractory metals at most conventional sintering temperatures that are economically or technically feasible. Therefore, the effects of time, temperature, and particle size are more significant for these metals than for metals where temperatures up to and exceeding their melting points are readily attainable.

Figure 48 shows sintering rates, in terms of relative density, achieved for tungsten and molybdenum at temperatures from 1400 to 1800 °C (2550 to 3270 °F) for particle sizes of 4 μm. The temperature of 1800 °C (3270 °F) is a practical limit for furnaces that use molybdenum or tungsten heating elements and aluminum oxide refractory materials. Note the long sintering time (50 h at 1800 °C, or 3270 °F) required to attain 92% density for tungsten. At the same temperature, molybdenum sinters to a similar density in 1 to 2 h.

Fig. 48 Relative density versus the logarithm of sintering time for 4 μm tungsten and molybdenum powders

Powder particle size is extremely important to the sintering of tungsten, but less so for molybdenum. Figure 49 shows the effect of particle size on the density of tungsten sintered in hydrogen at 1800 °C (3270 °F). Figure 50 compares the effect of several particle sizes on the sinterability of tungsten, as expressed by the relative shrinkages of compacts pressed to the same starting density and sintered at 1800 °C (3270 °F).

Fig. 49 Relative density versus the logarithm of sintering time for several tungsten powder sizes

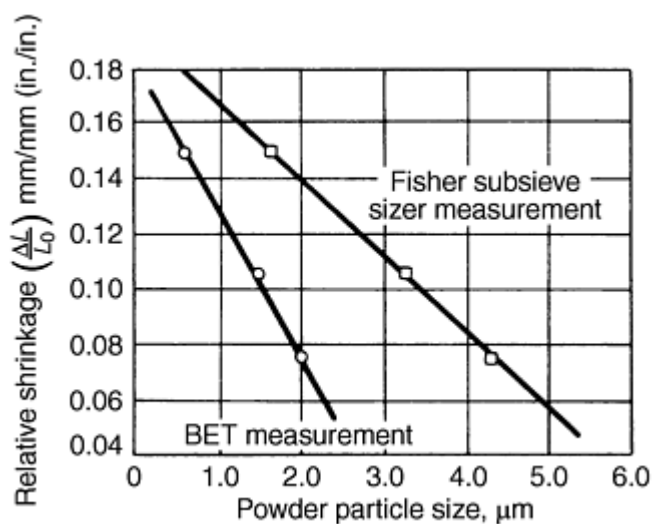

Fig. 50 Relative shrinkage versus tungsten powder particle size. Relative shrinkage ($\Delta L/L_0$) is the change of length over the original length.

Induction and tungsten mesh heating can be used to attain temperatures up to 2400 °C (4350 °F). At these temperatures, sintering can proceed to high density in 1 to 2 h if other factors are not rate limiting. These other factors include heating and cooling rates and billet outgassing.

Self-resistance heating permits attainment of temperatures >3000 °C (5430 °F), and complete sintering cycles require only 20 to 30 min, depending on compact size. Compact size is limited by the available electrical power; the

largest practical compact has a maximum cross section of 645 mm² (1 in.²) and ranges from 610 to 915 mm (24 to 36 in.) in length.

Atmosphere. Tungsten and molybdenum are always sintered in a hydrogen atmosphere. Vacuum sintering generally is unsuccessful. The only exception to this rule is initial exposure of compacts to hydrogen up to ~1200 °C (2190 °F) before furnace chamber evacuation. Tungsten and molybdenum are highly reactive with carbon and oxygen at almost all sintering temperatures, and the presence of either is usually catastrophic to sintering and billet properties.

Dissociated ammonia generally can be used as a source of hydrogen with no detrimental effects. Nitride formation appears nonexistent for either pure molybdenum or tungsten. However, in some applications, entrapped or dissolved nitrogen may cause a reduction in properties in worked rods and wire.

Powder and Compact Purity. Impurities greatly affect the sintering of tungsten and molybdenum. Because tungsten and molybdenum are sintered at such high temperatures, most impurities are molten, and many exhibit high vapor pressures. Other impurities, however, may react with the sintering atmosphere to form new compounds, while some may alloy with the base metal--all leading to undesirable influences on properties.

Tungsten and molybdenum powders are fine, typically with particle diameters of 1 to 10 μm and have 0.1 to 0.2% of adsorbed gases (oxygen, nitrogen, and water vapor) on particle surfaces. Entrapment of gases prevents achievement of high density. Additionally, densification does not proceed satisfactorily until surfaces are purged of these gases. Heating and holding periods of sintering schedules should be designed to allow sufficient time for entrapped gases to be released, particularly for large billets. An adequate hold at ~1200 °C (2190 °F) ensures uniformly low gas concentrations and thus uniform density and microstructure. Large compacts and loads require significantly longer hold times.

Control of Carbon Content. Typically, carbon should be avoided. Carburization begins at 800 °C (1470 °F) for molybdenum and at 1100 °C (2010 °F) for tungsten. Small amounts of carburization greatly inhibit densification and may greatly affect the ductility and/or workability of the part. Common carbon sources include vacuum pump oils and heating elements.

Metallic elements are used as sintering activators, or they may form alloys or oxides. As liquids, metallic elements such as nickel, cobalt, and iron activate localized grain growth and may leave large voids where the contaminant was originally located. As alloys or oxides, they usually retard local grain growth and frequently inhibit sintering. Generally, contaminants make uniform densification impossible and further working difficult.

Compacted Density. Generally, higher compacted densities are desirable, as long as entrapped gases do not result. Figure 51 shows the effect of cold isostatic compaction pressure on the compacted density of three tungsten powders of different sizes. Figure 52 shows the effect of higher compacted density on the sintered density for a 4.4 μm tungsten powder after various sintering times in hydrogen at 1800 °C (3270 °F). Higher compacted density significantly shortens the sintering times needed to produce a given density. From a practical viewpoint, pressures greater than 517 MPa (75 ksi) are economically difficult to obtain, and compacted billet densities therefore usually range from 65 to 75% of theoretical.

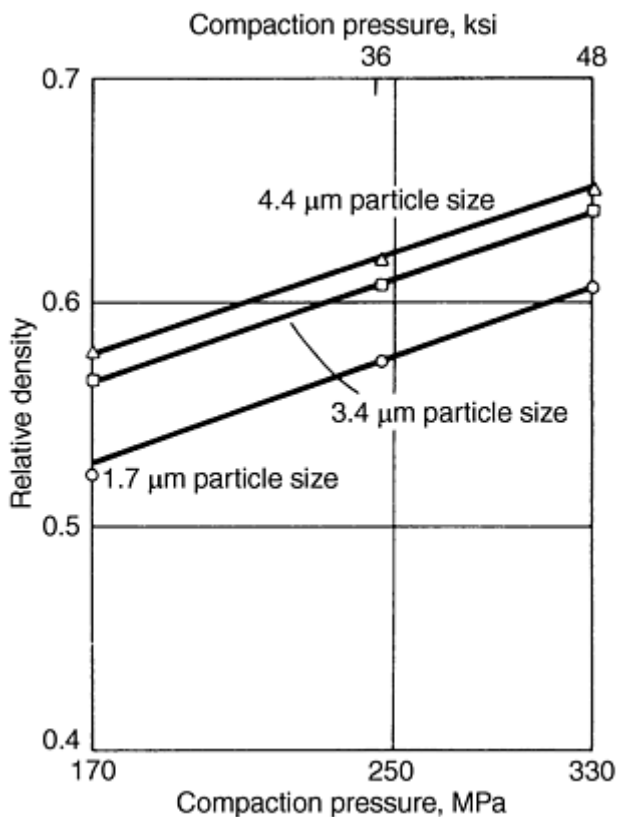

Fig. 51 Relative compact density versus the logarithm of compaction pressure for tungsten powders of various sizes

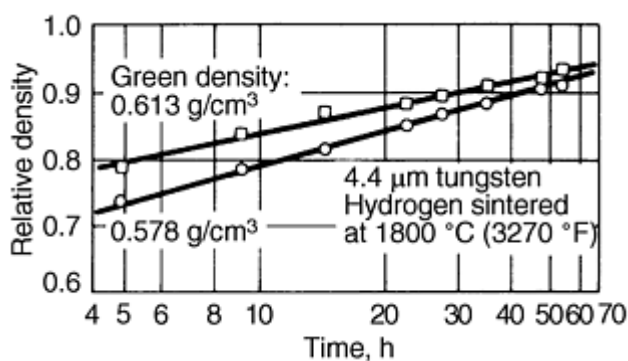

Fig. 52 Relative density versus the logarithm of sintering time for tungsten powders compacted at different pressures

Thermal gradients and heating rates are particularly important when sintering large furnace loads, which is frequently the case with tungsten and molybdenum. Because sintering rates are so sensitive to temperature, thermal gradients greatly affect the density attained in a given time. This in turn affects property and dimensional control. From empirical rate equations, it can be calculated that sintering at 1775 °C (3225 °F) rather than at 1825 °C (3315 °F) will require 110 h (4.6 days) rather than 40 h (1.66 days) to reach 92% density, a difference of 275%.

Temperature gradients are particularly detrimental when sintering large compacts such as 130 mm (5 in.) diam by 250 mm (10 in.) long tungsten billets for forging. At 1800 °C (3270 °F), radiation is the predominant mode of heating, and billet surfaces reach sintering temperatures rapidly compared to billet interiors. Sintering thus begins sooner at the billet perimeter; if uncontrolled, a thin high-density shell forms, which effectively restricts further densification of the interior of the billet.

Furnace heating rate is the primary method of controlling exterior shell formation. Proper choice of powder particle size is also important--coarser sizes decrease the effect of temperature gradients at the expense of lowering the initial rate of sintering.

The rate of outgassing of impurities is also related to temperature gradients in large compacts. Surface outgassing proceeds more rapidly than outgassing from interior volumes. The inhibiting effect of these gases allows surface volumes to sinter more rapidly, thus creating a high-density shell. Proper control of furnace heating prevents shell formation.

Cooling rate is particularly important with very large parts (305 mm, or 12 in. diam or more). Excessively rapid cooling causes cracking due to thermal stresses.

Particle size distribution is of secondary importance to the sintering variables mentioned previously. It is also difficult to quantify these effects to provide general guidelines. Consequently, they will not be discussed in this section.

Compact weight, gravity, and friction are important considerations when large or heavy parts are being sintered. Tungsten cylinders weighing 23 kg (50 lb) or more shrink less at their bases than at their tops when sintered on end. This tendency is mainly due to restricting friction forces. A 12.7 mm (0.5 in.) thick pedestal of compacted tungsten placed under the cylinder alleviates this problem.

Gravity is a significant factor in only a few sintering applications. Rounds may become slightly elliptical when sintered on their sides. Rods suspended from their top ends shrink more across top sections and less along lengths because of their suspended weight. These shrinkage disparities diminish as the bottom of the rod is approached.

Furnace Loading. The use of radiative heating necessitates loading of furnaces to minimize nonuniform heating. Heating rates are important. Parts partially shielded by other parts heat slower and with less uniformity. Parts partially buried in a refractory sand also experience nonuniform heating.

Oxide-Dispersed Additives. Typically, these additives, or dopants, may be thorium dioxide or the so-called KAS dopant, which is a combination of potassium oxide, aluminum oxide, and silicon dioxide. Their presence inhibits sintering, which can be useful in promoting outgassing of other impurities, in minimizing the effects of thermal gradients, and in controlling microstructure. The silicon dioxide and KAS compounds usually vaporize when sintering occurs at ≥ 2000 °C (3630 °F).

Sintering Activators. The sintering of tungsten and molybdenum can be activated to a considerable degree, but at the expense of significant losses of ductility and workability (Ref 50). Nickel additions to tungsten ranging from 0.2 to 0.5% result in densities of >90% of theoretical in only several hours at temperatures as low as 1100 °C (2010 °F), compared to 50 h for unactivated tungsten at 1800 °C (3270 °F). Molybdenum is also activated, but to a lesser extent. The activating elements for both tungsten and molybdenum include palladium, nickel, cobalt, iron, rhenium, ruthenium, iridium, and osmium.

Effects on Microstructure. Sintered grain size is primarily a function of sintered density and starting powder size, as shown in Fig. 53 for tungsten. Grain growth typically proceeds at a more rapid rate above about 95% density, as shown by the lower line. This is due to the decreased effectiveness of grain boundary pinning by the pores. Once the grain boundaries break away from the pores, sintering rates decrease significantly.

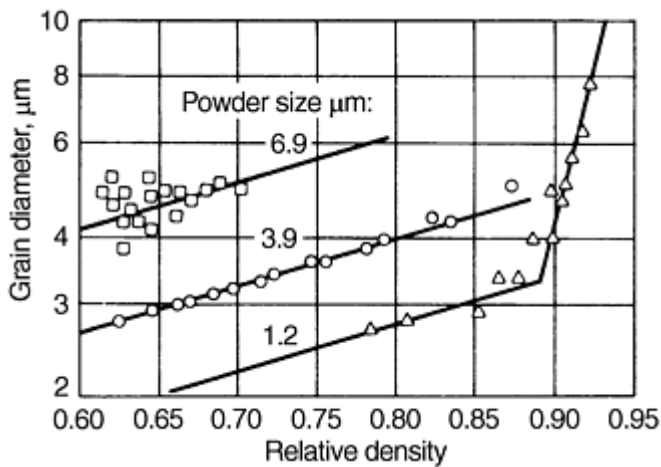

Fig. 53 Logarithm of grain diameter versus relative density for tungsten powders of various sizes. Data cover a range of sintering temperatures (1600 to 1800 °C, or 2910 to 3270 °F)

The workability of compacts of tungsten and molybdenum is highly dependent on sintered density and, to a lesser extent, on grain size. Densities should be a minimum of 90% of theoretical, and values ranging from 92 to 95% are more desirable. Typical grain sizes are 10 to 30 μm.

Production Sintering Practices

Sintering Equipment

Self-resistance heating has been used extensively for tungsten because of the extremely high temperatures required for practical sintering. Typically, rods with cross sections less than 645 mm² (1 in.²) are heated to 3000 °C (5430 °F) or higher. Densification to greater than 90% of theoretical can occur in less than $\frac{1}{2}$ h.

Sintering is done under a hydrogen atmosphere in a water-cooled, copper-jacketed enclosure. Tungsten contacts are required, and one contact must be able to move as the bar shrinks. Bar cross sections must be uniform or sintering temperature will vary along the bar length. Temperatures and densities are always low within several inches of the clamped ends because of the heatsink effect of the contacts. Sintering of molybdenum by this method has been replaced by resistance and induction heated furnaces.

Resistance element heating furnaces are frequently used for hydrogen sintering of molybdenum and tungsten at 1800 °C (3270 °F). Furnaces having uniformly hot zones up to 1.2 m (4 ft) long and 0.14 m² (1.5 ft²) are available. Loads of up to several thousand pounds can be sintered.

A typical furnace consists of water-cooled entrance and exit zones and a central zone of alumina refractory brick that supports molybdenum heating element rods. Furnace loads are supported on molybdenum slabs that are conveyed through the entrance and exit zones by powered rolls. The load is moved through the hot zone by a walking beam that oscillates above and below the hearth and that carries the load forward during the portion of the cycle that is above the hearth. Varying the frequency of oscillation varies the rate of forward movement of the parts in the furnace. Smaller furnaces with lighter loads can be operated by mechanically stoking a series of boats through the furnace.

Induction radiant heating is used when temperatures above 1800 °C (3270 °F) are required and also when very large (greater than 405 mm, or 16 in. diam) parts are involved. Molybdenum alloy billets weighing up to 4500 kg (10,000 lb) have been sintered with this type of heating mode.

A typical furnace consists of a large-diameter water-cooled chamber that contains a cylindrical susceptor ring of tungsten or molybdenum. The susceptor is inductively heated, and the compact is heated by radiation from the susceptor. Depending on the construction materials and loads, sintering temperatures ≤ 2400 °C (4350 °F) can be obtained.

Production Sintering Practices

Sintering of Tungsten Heavy Alloys

Tungsten heavy alloys are W-Ni-Fe or W-Ni-Cu alloys containing 90 to 98% tungsten. Typical nickel-to-iron ratios range from 1-to-1 to 4-to-1, while nickel-to-copper ratios generally range from 3-to-2 to 4-to-1. Minor amounts of other metals can also be added. Because of the liquid-phase sintering, these alloys achieve essentially full theoretical density. They exhibit good machinability and can exhibit substantial ductility. For example, a 90W-7Ni-3Fe alloy may exhibit elongation as high as 40%. Copper-containing alloys are less ductile and are more difficult to sinter to full density, especially in larger cross sections. One advantage of copper-containing alloys is that they are nonmagnetic. Primary uses for tungsten heavy alloys are as counterweights, radiation shielding, and kinetic energy penetrators.

Tungsten heavy alloys are made from blends of elemental powders. Homogeneity is of prime concern, so fine tungsten powders in the 2 to 8 μm range are used. Standard production procedures for tungsten powder yield fine particle sizes. Carbonyl powders are used in iron and nickel blends, and fine electrolytic powder is used in copper blends. As a precaution against impurities and agglomerates, powders are screened to -200 mesh prior to blending. Any standard powder blending procedure can be used.

Likewise, almost any P/M procedure for compacting powders can be used. If die pressing is used, a binder must be added to the powder. Like pure tungsten powder, high pressed densities cannot be achieved in tungsten heavy alloys. Consequently, allowance must be made for considerable shrinkage during sintering. A die-pressed piece typically is $\sim 55\%$ dense, while an isostatically pressed piece is $\sim 65\%$ dense.

Sintering Furnaces and Atmospheres. Sintering can be carried out in any furnace capable of sustaining the temperature and atmosphere required. Generally, the pieces are supported on aluminum oxide sand or aluminum oxide fixtures. Good control of temperature and heating rates is essential to produce consistent, high-quality tungsten heavy alloys.

Tungsten heavy alloys usually are sintered in pure hydrogen, but hydrogen and nitrogen mixtures, dissociated ammonia, or vacuum also can be used. Argon or mixtures of argon and hydrogen are not used, because the presence of argon during sintering results in a lower density product. With some tungsten powders, blistering of the heavy alloy parts occurs during sintering. The use of wet hydrogen through the sintering schedule usually corrects this problem.

Regardless of the atmosphere used during sintering, a cleanup step in hydrogen at ~ 1000 °C (1830 °F) is advised. For small pieces, only a few minutes at temperature are required; large pieces may require an hour or more.

During vacuum sintering, hydrogen cleanup is essential. For die-pressed pieces, hydrogen cleanup must be used to remove any residual carbon remaining from lubrication removal. If substantial carbon is still present when the liquid phase forms, serious density and mechanical property problems result.

Solid-State Sintering. At 1200 to 1430 °C (2190 to 2605 °F), it is possible, and sometimes desirable, to solid-state sinter W-Ni-Fe alloys to near-theoretical density. Solid-state sintering is not possible with W-Ni-Cu alloys because of the low melting point of copper. Once near-theoretical density is achieved, only minimal holding at liquid-phase temperatures is required to complete sintering.

Liquid Phase Sintering. During liquid-phase sintering, alloys densify as tungsten particles grow by dissolution and subsequent precipitation and coalescence of the tungsten grains. Tungsten particles grow from 3 to 8 μm to rounded grains 50 to 150 μm in diameter. As the tungsten content of the alloy increases, grain size tends to increase.

In W-Ni-Cu alloys, the low melting point of the copper and the wide liquidus temperature range of the matrix make it difficult to achieve full density in large parts. Normally, these alloys are sintered at 1380 to 1450 °C (2515 to 2640 °F). Very low heating rates that begin near the melting point of copper are required to properly sinter these alloys. Sintering times vary from less than an hour for small parts to several hours for large billets. One advantage of sintering these alloys is that they do not have the strong tendency to slump (distort) as do W-Ni-Fe alloys.

Liquid-phase sintering of W-Ni-Fe alloys is carried out at 1450 to 1600 °C (2640 to 2910 °F). Generally, sintering temperature increases with tungsten content. Heating rates are not as critical as with W-Ni-Cu alloys. With large parts, however, heat should proceed slowly to the temperature where the liquid phase first forms (1450 to 1560 °C, or 2640 to 2840 °F). Large temperature gradients within the part resulting from too rapid heating can cause compositional variations and porosity.

Sintering times are relatively short; 30 min at temperature is sufficient in most cases. Some large parts and alloys with tungsten contents >97% may require sintering times as long as 2 h. One limitation experienced in sintering of W-Ni-Fe alloys is slumping of the parts. As tungsten content decreases, slumping increases. For example, a 97% tungsten alloy experiences minimal slumping, while a 90% tungsten alloy may exhibit severe slumping. Slumping can be controlled by using the lowest sintering temperature possible and by supporting the parts during sintering.

Cooling. On cooling from liquid-phase temperatures, some problems may be experienced. If a long bar is directionally cooled, the composition of both the solute and the resulting solid are likely to change during solidification, thus causing end-to-end variations in composition. Gases released during solidification also can collect near the tail end of the bar, which is the last section to solidify.

If small pieces are cooled rapidly from the liquid phase, a solid shell forms around the part, thus causing the liquid matrix to be drawn from the center of the part in an effort to compensate for solidification shrinkage. Porosity is subsequently produced at the centers of thicker sections.

Heat Treatment. For maximum tensile elongation, W-Ni-Fe alloys must be heat treated after sintering. Typical heat treatment involves heating in nitrogen, vacuum, or inert atmosphere at 900 to 1300 °C (1650 to 2370 °F). Time varies with temperature and cross section. One hour at 1200 °C (2190 °F) is sufficient for a 12.7 mm ($\frac{1}{2}$ in.) diam bar, but a 50 mm (2 in.) diam bar requires ~24 h.

Mechanical properties of tungsten alloys vary greatly, depending on processing. For example, a MIL-T-21014B specification calls for 2% minimum elongation for a 95W-Ni-Fe alloy. However, if this alloy is properly processed, it exhibits a typical elongation of 28 to 32%.

As-sintered hardness and yield strength are affected only slightly by tungsten content. Typical hardness is 28 to 31 HRC, and yield strength ranges from 550 to 620 MPa (80 to 90 ksi). Elongation ranges from a maximum of 40% for a 90% tungsten alloy to 18% maximum for a 97% tungsten alloy.

Production Sintering Practices

Sintering of Titanium

Sintering practice (as opposed to hot pressing techniques) generally is applied only to fine titanium powders, which are the by-products of the production of titanium sponge. Such powders, referred to as "sponge fines," are produced by the reduction of titanium tetrachloride with sodium or magnesium. Particles are soft and irregularly shaped, thus well suited to cold compaction. Although sodium-reduced sponge fines are preferred for titanium P/M sintering in the United States, similar powders made by molten salt electrolytic reduction are reported in Russian literature.

Another class of titanium powder, prealloyed powder, is made from alloy ingot by ultraclean processes such as the plasma-rotating electrode process. Such powders are spherical and are not compactible at room temperature by ordinary means. These powders can, however, be sintered in loose form to produce a porous structure or coating. This section concentrates primarily on the sintering practices and resultant microstructures and property relationships for parts manufactured from sponge fine types of powders.

Titanium Powder and Compacts

Titanium is very reactive, forming very stable oxides and nitrides. Unlike many metals, titanium is capable of dissolving its own surface oxides at sintering temperatures. Consequently, these oxides do not have to be reduced through the use of a reactive atmosphere. The formation of additional oxides should be avoided; consequently, the use of high vacuum or high-purity inert gas atmosphere is common practice.

Titanium sponge fines used for P/M parts typically range from -80 to -100 mesh. Sodium-reduced sponge fines contain ~ 0.23% residual sodium chloride entrained in the particles. Although it is impossible to remove this residual salt by leaching, some salt usually is liberated at high temperatures and condenses in cooler parts of the sintering system.

Sponge fines can be compacted at room temperature in rigid dies or isostatically pressed in elastomeric tooling. Due to the reactive nature of titanium, admixed lubricants are not used, but die-wall lubrication is required with rigid dies. The irregular particle shape of sponge fines provides compacts with excellent green strength, and green densities can range from 60 to 85%, the latter at die pressures of 552 MPa (40 tsi) or isostatic pressures of 414 MPa (60 ksi).

When additional sintered strength is required, alloying powders can be elemental or master alloys; in the case of Ti-6Al-4V, for example, a master alloy powder of 60Al-40V is frequently used. Sponge fine powders exhibit strengthening from sintering at temperatures as low as 1000 °C (1830 °F), but higher temperature and sufficient time must be used when alloying powders are added to allow for complete interdiffusion and to obtain the strengthening benefit of the alloy additions. Temperatures in the range of 1200 to 1260 °C (2200 to 2300 °F), with holding times of 1 to 4 h, are sufficient to homogenize admixed alloy powders.

Vacuum Sintering

The use of cold-walled vacuum furnaces generally is preferred for sintering of titanium powders. The furnace should be equipped with a diffusion pump that has a sufficient capacity to accommodate outgassing during heat up and maintenance of high vacuum (133 MPa, or 1×10^{-3} mm Hg) at peak temperatures. Heating elements of molybdenum or graphite cloth with a temperature limit of at least 1245 °C (2275 °F) can be used.

The use of cold traps is necessary to condense vaporized sodium chloride and other impurities that may impair diffusion pump performance. Because significant outgassing occurs during heating, a control system that cuts power to the furnace when a preset pressure level (400 MPa, or 3×10^{-3} mm Hg) is reached should be used. Heating may be restored when higher vacuum is achieved again.

This type of system automatically compensates for variations in furnace load, lubricants, or compact density, for example. The use of an inert gas recirculating system for cooling is optional, except for alloys requiring rapid cooling through the β - α temperature range. While a cooling system can improve furnace throughput, the added difficulties and costs of additional valving (sources of leaks) and maintenance of a water-cooled heat exchanger should be considered carefully before making the installation.

Furnace Loading

Due to reactivity, titanium adheres to most support materials after sintering. The preferred support or racking material is molybdenum, which has a very low solubility in titanium and is able to maintain strength at high temperatures. Ti-6Al-4V plate can also be used by placing sheets of felted ceramic between the work and support. At lower temperatures (1000 to 1080 °C, or 1830 to 1975 °F), high-density graphite, coated with a wash of yttrium oxide, can be used. It must be dried separately and outgassed prior to sintering. To help ensure against contamination of the parts being sintered, some loose titanium powder can be included with each load to act as a "getter" for gases. Molybdenum foil placed on top of the load can be used to contain the powder.

Leak Testing. Prior to heating, the furnace should be leak tested for each load. This can be accomplished by pumping the furnace down at room temperature to diffusion pump levels, then isolating the furnace chamber from the pumping system. The leakage, or drop in vacuum, is read on the tank vacuum gauge. The leakage rate constant should not exceed a value of 40 calculated by multiplying the observed leakage rate ($\mu\text{m Hg/h}$) by the furnace chamber volume (ft^3). Thus, for a furnace 3 ft in diameter by 3 ft long, with a volume of 21.2 ft^3 , the maximum allowable leakage rate would be $1.89 \mu\text{m Hg/h}$. This procedure helps to ensure against contamination of the work load, as a high-capacity pumping system can maintain a good vacuum even with a leak. However, continuous introduction of a stream of air over the work rapidly saturates the getter and begins to contaminate the work.

Sintering Cycles. Care must be taken during heating to avoid excessive outgassing of the work, furnace walls, and elements, unless the system pumping capacity is sufficiently large compared to the furnace volume. Heat transfer in vacuum furnaces is primarily by radiation; therefore, a "shadowing" effect occurs with workpieces close to the heating elements--they heat before pieces in the center of the load are heated. Because a heating cycle can be relatively long (~ 8 h), peak temperature should be maintained for 2 to 3 h to ensure equalization of the load temperature before cooling.

The use of load-monitoring thermocouples at several locations in the load is recommended, particularly with large loads. Sintering temperatures of 1000 to 1300 °C (1830 to 2370 °F) are commonly used. Lower temperatures are usually used for porous and commercially pure products, and higher temperatures are used to produce alloy products.

Production Sintering Practices

Alternative Practices

While vacuum sintering is the most widely used sintering practice for titanium, an alternative method uses purified argon for sintering powder-rolled titanium strip product. Argon is purified by passing it over titanium chips heated to 800 to 900 °C (1470 to 1650 °F).

The use of temperature cycling through the α - β transformation--880 °C (1620 °F) for unalloyed titanium--can promote densification; the effect is the most significant when heating from α to β , which lasts for ~ 2 min.

Because large thermal lags exist in most vacuum furnaces, this technique is not practical for large production loads. In addition to normal sintering, a supplementary containerless HIP cycle can be used to improve density and mechanical properties (Ref 35, 39). Because the as-sintered density of P/M Ti-6Al-4V is 94 to 96% of theoretical, the porosity is not interconnecting, and densification can be achieved through the application of gas pressure and heat.

Production Sintering Practices

Microstructure and Properties

Because diffusion rates are higher in the beta-phase, body-cubic centered (bcc) region, sintering is generally completed at >880 °C (1620 °F). The microstructure following slow cooling is a transformed beta microstructure, which is considered an inferior structure for conventional wrought material. In the case of commercially pure titanium parts, this limitation is not significant, because static strength and corrosion resistance are of prime importance. Only fatigue and fracture toughness-related properties are affected by this microstructure.

Static properties of pressed-and-sintered P/M titanium are comparable to those of wrought material, as shown in Table 21. Fatigue resistance is not quite as good as for wrought alloys, primarily due to the presence of salt-related residual porosity and to a lesser extent the transformed beta microstructure. More current information of P/M titanium alloys is in the article "Titanium Powder Metallurgy Alloys" in this Volume.

Table 21 Comparative properties of P/M and wrought titanium

Property	Commercially pure		Ti-6Al-4V		
	P/M	Wrought grade II	Cold pressed, sintered blend	Wrought

Production Sintering Practices

Sintering of Nickel and Nickel Alloys

Sintered nickel-base materials enjoy wide commercial usage due to their unique properties, such as corrosion resistance, wear resistance, mechanical strength at low and elevated temperatures, thermal expansion, electrical conductivity, and magnetic permeability. Commercial products represent a wide range of shapes, sizes, and microstructures. Sintered products with $\leq 90\%$ porosity are technologically as important as fully dense products. Sintering practices aimed at achieving such diverse properties represent a variety of manufacturing technologies.

Depending on the end product, sintering operations can be performed on a loose powder bed, a thin layer applied to a substrate, a lightly compacted coating, a roll-compacted strip, or die-compacted preforms. Sintering temperatures range from those at which the material is completely solid to those at which $\leq 60\%$ of the material is in the liquid state.

Conventional sintering practices generally are useful, although more recent techniques such as HIP are required in specialized applications. Sintering atmospheres are generally reducing; in some applications, however, nonreactive environments such as vacuum or an inert gas are required. Physical and chemical characteristics of the starting powders, such as moisture content, degree of oxidation, segregation, morphology, and purity, are equally as important as the green compact microstructure prior to sintering.

Sintered porous nickel products of commercial interest include electrodes of alkaline nickel-cadmium, nickel-zinc, and nickel-iron rechargeable batteries, electrodes of alkaline fuel cells and metal-air (zinc-air or iron-air) cells, electrolyzers, and filter elements. Table 22 lists the functions and structural requirements these components must meet for efficient operation.

Table 22 Functional, service, and structural requirements for sintered porous nickel products

Product	Function	Service conditions of service requirements	Structural requirements
Electrodes of alkaline nickel-cadmium, nickel-zinc, and nickel-iron rechargeable batteries	Hold active mass (nickel hydroxide or cadmium hydroxide) of the battery	Pores in the electrodes are impregnated with the active mass before battery assembly. Electrodes are in contact with a highly caustic solution of potassium hydroxide. Contraction and expansion of the active mass during discharge and charge cycles leads to ~ 25 vol% change.	75-85% porosity for holding the active mass, mechanical strength to withstand handling during assembly and volume changes during battery operation
Electrodes of alkaline fuel cells and metal-air cells	Provide a barrier between the electrolyte and gases	Must provide the largest electrolyte/gas interface. Must avoid complete wetting of pores or bubbling of gases through pores	Small pore sizes; very narrow pore size distribution; total pore volume of about 48%
Filter elements	Filter highly caustic solutions	Depends on specific applications	Depends on specific applications. Both pore volume and pore size distribution are important.

Highly porous electrodes for alkaline rechargeable batteries are made from nickel powders that have low bulk densities ($<1 \text{ g/cm}^3$). These powders are produced by carbonyl processes. Slurries made from these powders are coated onto a support strip and then sintered. Alternatively, loosely packed beds of powder can be sintered. For all other porous structures, a carbonyl nickel powder with higher bulk density is suitable. Finer nickel powders can also be used by lightly compacting in a die or by roll compacting to produce the desired high green density.

Sintering temperatures between 850 and 1050 °C (1560 and 1920 °F) are commonly used to produce porous nickel products. The reducing conditions required for sintering are obtained easily with nitrogen-hydrogen gas mixtures or a burnt natural gas with low combustibles.

During sintering, loosely packed beds or compacted preforms of carbonyl nickel powders do not densify at $<600 \text{ °C}$ (1110 °F). However, considerable strengthening of compacted materials occurs at $<600 \text{ °C}$ (1110 °F) due to surface diffusion. As the temperature increases above 600 °C (1110 °F), volume diffusion increases. At $\sim 950 \text{ °C}$ (1740 °F), filaments in the porous structures become smooth and broadened, while in consolidated structures the pores become rounded. To attain adequate strength without excessive loss of porosity, sintering temperatures between 950 and 1000 °C (1740 and 1830 °F) are optimum.

Table 23 gives typical porosity, strength, and electrical resistivity values for loose sintered and pressed-and-sintered materials. Table 24 shows reduction in surface area as a result of sintering. Figure 54 shows pore size distributions of sintered porous nickel structures.

Table 23 Typical physical properties of sintered porous nickel structures

Material	Condition	Porosity, %	Electrical resistivity, $\mu\Omega \cdot \text{cm}$	Bend strength	
				MPa	psi
Nickel 287	Loose sintered	83	150-200	5.8	840
Nickel 255	Slurry sintered	82	100-150	12.7	1,840
Roll compacted strip	Sintered (49% porosity)	38	30-40	137	19,865
Nickel 123	Loose sintered	60	60-70	24.5	3,550

All materials were sintered at 950 °C (1740 °F) for 5 min.

Table 24 Surface area of sintered porous nickel structures

Powder type	Surface area, m^2/g		
	Loose powder	As sintered at 850 °C (1560 °F) for 5 min	As sintered at 950 °C (1740 °F) for 5 min
Nickel 255	0.6	0.18	0.16
Nickel 123	0.3	0.11	0.10

Surface area determined by BET method using krypton

Sintered Dense Nickel Products. Sintered high-density nickel products generally are used as preforms for further working operations. Additional densification occurs as the preform is hot and/or cold worked into a useful commercial shape. Preforms can be round or square billets or strips. Conventional compacting and sintering of individual small components is also used commercially.

A typical example of a high-density billet for further hot working involves extremely high-purity (99.97% Ni), inclusion-free nickel for electronic applications. Commercial melting and casting practices previously used could not guarantee the high purity and freedom from inclusions required for this application. Powder metallurgy processing, however, provides extremely high-purity nickel powders produced by techniques other than atomization. As a result, various mill shapes such as plates, rod, bar, and tube were manufactured from sintered billet stock.

The optimum starting powder for this application is a high-purity nickel powder with a carbon content below 0.1%, oxygen content below 0.15%, and sulfur content below 7 ppm. A high degree of compressibility is desirable. Powder is typically compacted by cold isostatic pressing to a density of approximately 6 g/cm³. Sintering is carried out in a sulfur-free, reducing atmosphere such as hydrogen, dissociated ammonia, or a mixture of 90% nitrogen and 10% hydrogen. The prime objectives of the sintering operation are densification, development of strength (for subsequent hot working operations), and reduction of carbon and oxygen levels to below 0.01% and 0.005%, respectively.

During heat up of the green billet, gases adsorbed on powder surfaces are liberated. Carbon and oxygen in the powder then begin to react and produce gaseous products such as carbon dioxide and carbon monoxide. Sufficient time must be allowed at low and intermediate temperatures to permit the escape of these gases and the resulting decarburization before densification begins. For billets to reach a density above 96% of theoretical, sintering temperature is raised to 1100 to 1200 °C (2010 to 2190 °F) following decarburization. Depending on sintering temperature, sintering time may vary from 4 to 12 h.

Coinage strip represents another application in which conventional P/M operations are combined with conventional metalworking operations to yield a unique product. While coin blanks can be compacted from powders using high-speed presses, considerations such as economy and productivity may favor punching of the coin blanks from powder-rolled strip. Green strip is produced by roll compacting nickel powder that is sintered in a continuous sintering furnace to a reasonably high density. The density must be high enough (generally >80% of theoretical) to facilitate handling and coining operations. Following sintering, the strip is hot and/or cold worked to full density and to the desired thickness of the final product. See the article "Roll Compacting of Metal Powders" in this Volume for additional information.

Nickel powders with consistent high flow rates and compressibility are required so that high volume production units with automatic powder-feeding mechanisms can be used. Water-atomized nickel powders usually are used for this purpose, although powders produced by other techniques are also used commercially. Water-atomized nickel powder typically contains ~0.1 to 0.2% oxygen. A major portion of this oxygen is present on or near the surfaces of the powder particles.

Conventional reducing atmospheres (hydrogen, dissociated ammonia, or burnt natural gas) can be used for sintering. The purpose of sintering is to increase the strength of the roll-compacted strip. Sintering time-temperature cycles are designed to obtain the desired strength and density, while matching the speed of the roll compacting operation.

The same considerations that apply to high-purity, electronic-grade nickel (high purity and freedom from inclusions) are responsible for commercial interest in the production of magnetic and low-expansion P/M alloys. Soft magnetic alloys such as Ni-50Fe, Ni-17Fe-4Mo, and Ni-117Fe-5Cu-4Mo are commercially produced from high-purity elemental metal powders. Carbonyl nickel and iron powders and high-purity copper and/or molybdenum powders are mechanically blended, isostatically compacted, and sintered in hydrogen at 1200 to 1400 °C (2190 to 2550 °F). During sintering, the density increases from ~70% in the as-pressed condition to 90 to 95% in the sintered condition. Bulk liquid hydrogen gas with an incoming dew point of approximately -73 °C (-99 °F) is used for sintering. Sintered billet is subsequently converted to a wrought product by hot and cold working.

Selection of Sintering Atmosphere. Composition and dew point of a sintering atmosphere determine whether reducing or oxidizing conditions prevail during sintering of a given material. The Richardson free energy chart should be consulted for proper conditions. For example, in sintering of nickel at 1000 °C (1830 °F), according to the Richardson free energy chart, the hydrogen-to-water and carbon monoxide-to-carbon dioxide ratios must be >0.01 to prevent oxidation of nickel. A reducing gas containing approximately 5% hydrogen, 5% carbon monoxide, 8% carbon dioxide, and the remainder nitrogen easily meets these requirements.

However, if nickel is alloyed with reactive elements such as silicon, manganese, chromium, vanadium, titanium, aluminum, zirconium, magnesium, and calcium, much higher ratios must be maintained to prevent oxidation of the reactive elements. Thus, for instance, the hydrogen-to-water and carbon monoxide-to-carbon dioxide ratios must be greater than 8×10^3 to prevent oxidation of chromium. Very pure hydrogen with a dew point of -45 °C (-49 °F) or lower is required for sintering nickel-chromium alloys. Also, time and temperature during heat up to sintering temperature must be carefully controlled so that the material being sintered is surrounded by an atmosphere with the required ratios. Additionally, alloys containing nitride-forming elements (chromium, titanium, and zirconium, for example) must be sintered in nitrogen-free atmospheres. In some cases, vacuum sintering may be necessary.

Nonconventional Sintering Practices. Many modifications to conventional pressing and sintering to produce dense bodies from metal powders are commercially important, as discussed below.

Hardfacing and brazing rods of nickel-base alloys classified by the American Welding Society as AWS BNi-1 (13 to 15% Cr, 2.75 to 3.50% B, 4.0 to 5.0% Si, 4.0 to 5.0% Fe, 0.6 to 0.9% C, remainder Ni), AWS BNi-3 (2.75 to 3.50% B, 4.0 to 5.0% Si, 0.5% Fe, remainder Ni), AWS BNi-4 (1.5 to 2.2% B, 3.0 to 4.0% Si, 1.5% Fe, remainder Ni), and low-carbon variations of AWS BNi-1 are customarily cast products.

These alloys can be produced more economically from water-atomized powders of these compositions. The process consists of packing graphite molds with powders to a packed bed density of 50 to 60% and heating them in a reducing atmosphere to a temperature between the solidus and liquidus temperatures--977 to 1030 °C (1790 to 1886 °F) for BNi-1, 982 to 1038 °C (1800 to 1900 °F) for BNi-3, and 982 to 1066 °C (1800 to 1950 °F) for BNi-4. Typically, 40 to 60% mushy liquid is produced at the sintering temperature. Sintering cycles are adjusted so that cooling begins as soon as the mushy liquid is produced. The sintered product is typically 85 to 95% dense. Sintered rods up to 1350 mm (53 in.) long are routinely produced. In some applications, further mechanical working, such as extrusion and wire drawing, is required.

Production of high-temperature corrosion-and creep-resistant P/M nickel-base alloys is also an established practice. The presence of large amounts of highly reactive elements in these alloys makes it difficult to produce fully dense shapes by the conventional press-and-sinter method. Powders of these alloys are produced by inert gas (argon) atomizing a vacuum-induction-melted alloy, so as to exclude any oxygen and nitrogen. In addition, they are sized and encapsulated in an inert atmosphere such as argon.

Consolidation by HIP to produce fully dense, complex near-net shapes components, such as gas turbine engine disks, has become commercially viable. Other consolidation practices for nickel-base superalloy powders include hot isostatic pressing plus forging, hot extrusion, and extrusion plus rolling. Techniques of producing thin, hollow shapes of reactive metals by plasma spraying onto a disposable mandrel are being applied to production of large integral gas turbine engine components. Alloy powder, usually -400 mesh, is sprayed onto acid-leachable steel preforms by low-pressure plasma spraying.

Consolidation of Ultrafine and Nanocrystalline Powder

David L. Bourell, The University of Texas at Austin; Joanna R. Groza, University of California at Davis

Introduction

Ultrafine or nanocrystalline powder has either particle size or grain size less than about 100 nm (0.1 μm). The synthesis techniques are described in the article "Ultrafine and Nanophase Powders" in this Volume. Ultrafine powder forms are of two types. The first is particulate, generally a single crystal, whose size is less than about 100 nm (Fig. 1). Synthesis routes include evaporation/condensation, sol-gel, and other precipitation techniques. The other powder form has conventional powder size but is composed of a fine, nanocrystalline grain structure. This structure is obtained through a deformation processing technique, such as high-energy, attrition ball milling (Ref 2), or severe plastic deformation consolidation.

Fig. 1 Nanocrystalline particulate zirconia. Source: Ref 1

Consolidation of these materials into bulk form with retention of the fine structure is the subject of this article. Particle curvature is the dominant feature affecting consolidation. It produces a large driving force for densification and enables surface/boundary diffusion mechanisms to operate at substantial rates. Densification takes place at temperatures consistently below those of larger grained powders by up to hundreds of degrees, and the activation energies for sintering are lower. Low sintering temperature may result in retention of fine grain size, elimination of sintering aids, avoidance of undesirable phase transformations, and absence of deleterious interfacial-reaction decomposition.

Understanding and controlling grain growth and particle coarsening are critical to successful consolidation of nanocrystalline powder. Pressureless sintering has been used to produce bulk materials with nanocrystalline structure, but control of particle agglomeration is critical to its success. Other manufacturing processes involve applied pressure of the order of the curvature stresses or greater: sinter forging, HIP, hot/warm pressing, extrusion, and high-pressure consolidation. Molecular dynamic simulations enhance our understanding of the fundamentals of sintering, including particle rotation and neck formation as sintering mechanisms.

Consolidation of Ultrafine and Nanocrystalline Powder

David L. Bourell, The University of Texas at Austin; Joanna R. Groza, University of California at Davis

Consolidation Processes

Nanocrystalline powder synthesis, consolidation, and properties are the subjects of several reviews (Ref 3, 4, 5, 6, 7, 8). Densification of both types of nanocrystalline powder (as previously described) generally follows the same rules of consolidation and sintering applicable in conventional powder processing if the effects of fine powder size and powder agglomeration are incorporated. Fine powder possesses extremely large surface area, given for spherical particles as:

$$S = 6/\rho_{th}D \quad (\text{Eq 1})$$

where S is the specific surface area (per unit mass), ρ_{th} is the material theoretical density, and D is the particle diameter. For example, a powder mass of 25 μm iron powder has a surface area of 0.03 m^2/g , compared to a 10 nm ceramic powder that might have a specific surface area as high as 260 m^2/g . Associated with this high surface area is large particle curvature, which, along with optional applied pressure, acts as a driving force for densification. Ashby (Ref 9) developed an equation for the effective surface driving pressure, P_s , due to particle curvature during initial consolidation, based on a work argument for spherical particles:

$$P_s = \frac{6\gamma}{D} \Delta^2 \left(\frac{2\Delta - \Delta_o}{1 - \Delta_o} \right) \quad (\text{Eq 2})$$

where γ is the material surface free energy, Δ is the relative density (ρ/ρ_{th}) at some point during the consolidation process, and Δ_o is the relative density (ρ_o/ρ_{th}) at the onset of consolidation. This relation yields surface pressures of approximately 1 to 10 MPa for nanocrystalline powder.

Particulate nanocrystalline powder is usually loosely agglomerated. Magnetic nanocrystalline powder and β -SiC align in a one-dimensional fashion typified in Fig. 2 (Ref 10, 11). Because the particle mass to surface area ratio is small for nanocrystalline powder, interparticle friction effects dominate, producing low tap densities of approximately 10 to 30% of theoretical density (Ref 5, 12, 13). These effects have a negative impact on consolidation. For pressureless sintering, agglomerates densify quickly, leaving large interagglomerate porosity that densifies at much reduced rates. For pressure-assisted methods, pressures exceeding 1 GPa are required to overcome the large interparticle friction effects.

Fig. 2 Chainlike or necklace particulate orientation of nanocrystalline iron. Source: Ref 10

Grain Growth. The greatest obstacle to consolidation of nanocrystalline powder is retention of the fine structure in the bulk. Grain growth and particle coarsening are thermally activated processes. Therefore, the use of thermal excursions to assist in consolidation are always accompanied to some degree by particle coarsening. Figure 3 shows the effects of sintering on grain size in nanocrystalline zirconia (Ref 1). Pressure-assisted consolidation methods are tailored to minimize coarsening during consolidation.

Fig. 3 Grain growth of 10 nm particulate yttria-stabilized zirconia (Fig. 1a). Powder was HIP at 1500 K for 1 h. Source: Ref 1

Grain growth/particle coarsening in nanocrystalline materials can be described:

$$D^n - D_0^n = (k_0 t) \exp\left(-\frac{Q}{RT}\right) \quad (\text{Eq 3})$$

where D is the grain/particle size after time t at temperature T , D_0 is the initial grain/particle size, k_0 is a constant, Q is the activation energy for coarsening, R is the universal gas constant, and n is a constant ranging from 2 to 10 (Ref 6, 7, 14). Figure 4 shows the reciprocal of n as a function of homologous temperature for many nanocrystalline materials. The activation energy for coarsening in nanocrystalline materials is associated with grain boundary diffusion, approximately half the value for lattice self-diffusion (Ref 14). When external pressure assists densification, grain boundary sliding is also suggested as an assisting mechanism (Ref 15, 16).

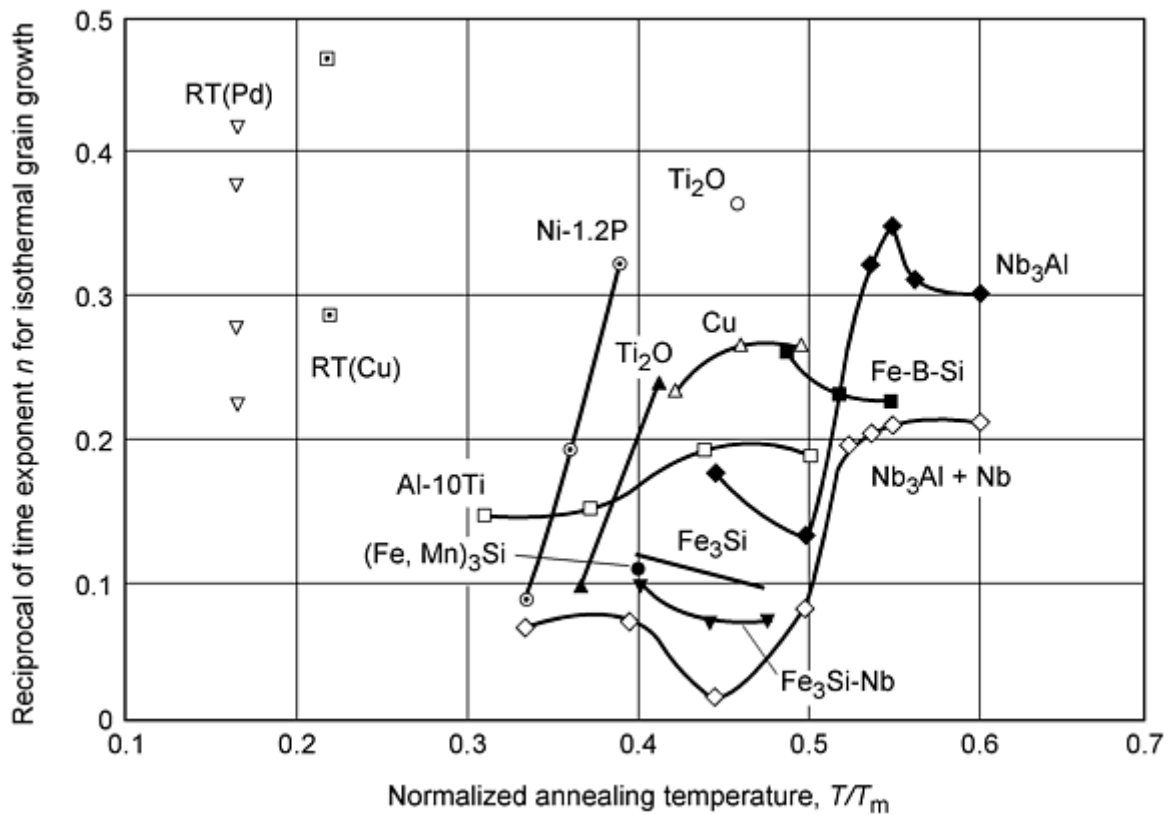

Fig. 4 Reciprocal of the grain coarsening exponent ($1/n$) as a function of temperature for nanocrystalline materials. RT, room temperature. Source: Ref 14

Experimentally, a strong correlation exists between the closure of open porosity and the onset of exaggerated grain growth (Ref 17, 18, 19, 20, 21, 22, 23, 24, 25). As shown in Fig. 5 for nickel and TiO_2 , accelerated grain growth occurs at densities above about 90% when the pores become isolated or closed. Often, the final grain size upon full densification is close to $1 \mu m$. In contrast, grain growth is much less exaggerated at high densities for nonagglomerated Al_2O_3 powders (Ref 26). Abnormal grain growth, localized excessive growth of a few grains, has been observed in alumina-zirconia nanocomposites (Ref 27), silicon (Ref 28), and iron (Ref 10). It is illustrated for iron in Fig. 6.

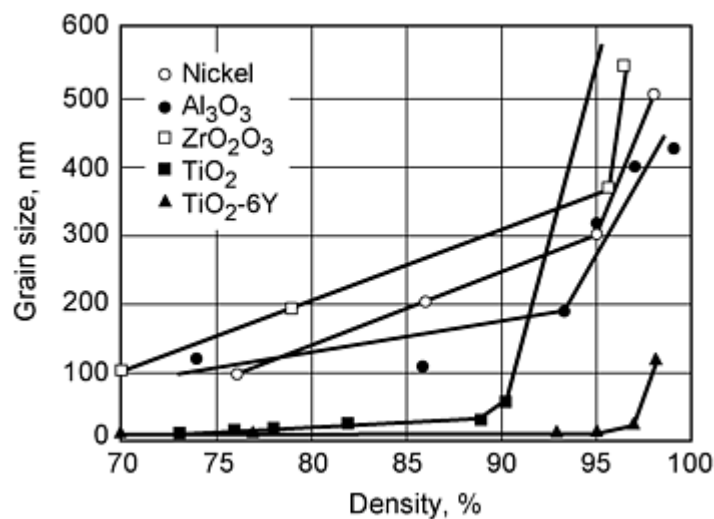

Fig. 5 Grain size as a function of density for pressureless sintering of selected nanocrystalline materials

Fig. 6 Abnormal grain growth in 15 nm iron close-die sintered at 810 K (10 MPa, 1 h) followed by pressureless sintering at 1080 K for 1 h. Source: Ref 10

Fine pore size throughout the sintering process is also critical in controlling the final grain size. For these purposes, a small and uniform pore population is desired in the green compact. Most often, this pore distribution is associated with a high green density in nonagglomerated or weakly agglomerated powders. For example, it has been shown that deagglomeration of a commercial ZrO_2 may reduce sintering from 4 h at 1775 K to 1 h at 1375 K (Ref 29). Efforts to produce nonagglomerated powders have intensified. A good summary of the progress for ceramics can be found in Ref 5. The effects of fine pore size and narrow pore size distribution on obtaining high densities and fine structure are well correlated (Ref 18, 26, 30, 31, 32, 33, 34).

Considerable coarsening can occur in nanocrystalline materials during heating to and cooling down from the pressureless sintering temperature. A relationship has been proposed to describe the extent of coarsening based on a modification of Eq 3 (Ref 35, 36):

$$D^n - D_0^n = \left[\frac{k_0 R}{v_0 Q} \right] \left[T_f^2 \exp\left(\frac{-Q}{RT_f}\right) - T_i^2 \exp\left(\frac{-Q}{RT_i}\right) \right] \quad (\text{Eq 4})$$

where v_0 is the heating or cooling rate, T_f is the final sintering temperature, and T_i is the initial temperature. This relationship is verified in heating/quenching experiments for nanocrystalline zirconia (Ref 36). In general, the degree of coarsening occurring during heating in time t to the sintering temperature is approximately equivalent to one third of the grain size obtained for an isothermal anneal (Eq 3) at the sintering temperature for time t (Ref 35).

Pressureless Sintering. Pressureless sintering of nanocrystalline powder occurs generally by surface-assisted and boundary-diffusion-assisted mechanisms. One feature of pressureless sintering is rapid densification of agglomerated regions followed by removal of interagglomerate porosity. Densification rates for the latter stage are associated with sintering of polycrystalline powder whose particle size is associated with the densified agglomerate. The overall effect is rapid initial densification that slows to conventional rates as the agglomerates become fully dense. This effect is mitigated by application of external pressure.

Nanocrystalline powders densify at sintering temperatures significantly lower than conventional powders, as exemplified in Fig. 7 for titania. Generally, densification occurs at 0.2 to 0.4 T_m , compared with 0.5 to 0.8 T_m for conventional powder. To rationalize this decrease in the sintering temperature, different scaling laws have been applied. For particles under 100 nm, Alymov et al. (Ref 37) developed an empirical relationship for the dependence of the sintering onset temperature, T_s , on the mean particle size D :

$$\ln T_s = 1/D \quad (\text{Eq 5})$$

They calculated a ratio of sintering onset to melting temperature that is in good agreement with experimental data for sintering of nanocrystalline metals. In 1950, Herring developed the classical scaling rule for the effect of the particle size

on sintering time (Ref 38). Assuming operation of a single sintering mechanism, the time t to achieve the same sintering condition is related to the powder particle size D by:

$$t_1/t_2 = (D_1/D_2)^n \quad (\text{Eq 6})$$

where n is the exponent that has a value of 3 if the main sintering mechanism is volume diffusion and a value of 4 if the main sintering mechanism is grain boundary diffusion. Considering an Arrhenius expression for temperature, the sintering temperature dependence on the particle size becomes:

$$n \ln(D_1/D_2) = Q/R[(1/T_1) - (1/T_2)] \quad (\text{Eq 7})$$

where Q is the activation energy for the predominant sintering mechanism, R is the universal gas constant, D_1 and D_2 are the different powder particle sizes, and T_1 and T_2 are the respective sintering temperatures. Reasonable agreement of experimental and calculated data has been found for Al_2O_3 and TiO_2 (Ref 26, 39).

Pressure-Assisted Consolidation. Classical temperature-pressure interactions offer distinct advantages to nanocrystalline powder consolidation due to the ability to restrict grain growth by lowering consolidation temperature. Illustrations of the pressure effect on nanopowder densification are shown in Fig. 8, 9, and 10. Applied pressure adds an additional component to the curvature related driving pressure for densification described earlier. At elevated temperature, it activates new plasticity-driven densification mechanisms, such as local yielding, creep, and stress-assisted diffusion. Applied pressure can induce particle rearrangement and large pore collapse, increasing the number of particle contacts and thereby accelerating densification.

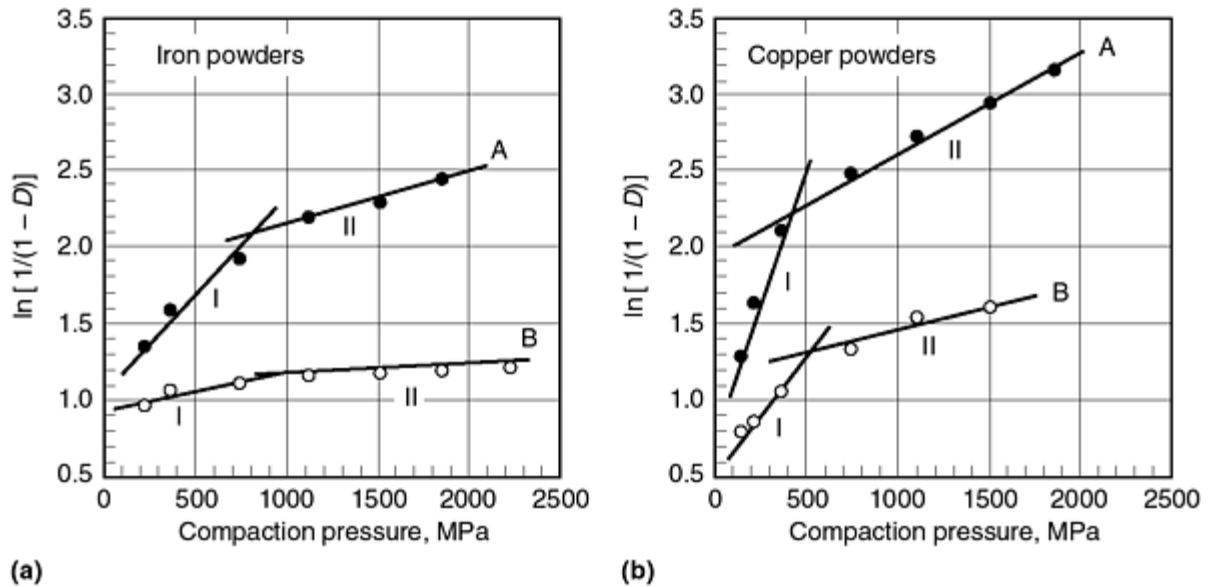

Fig. 9 Effect of compaction pressure on density of (a) iron and (b) copper powder. In each figure, "A" refers to micrometer-sized powder (2 μm Fe, 50 μm Cu) and "B" to nanocrystalline powder (50 nm Fe, 58 nm Cu). Two regions of consolidation are evident from the plots. Low-pressure Region I is associated with particle sliding and elastic deformation between adjacent particles. High-pressure Region II is associated with plasticity at interparticle necks. Source: Ref 41

Fig. 10 Cold compaction of 13 nm γ -alumina. Source: Ref 42

The role of room temperature compaction pressure, P , on relative density, Δ , has been studied extensively (Ref 43). The generally accepted form is:

$$\ln[1/(1 - \Delta)] = -\ln(\varepsilon) = kP + B \quad (\text{Eq 8})$$

where k and B are constants, and ε is the fractional porosity (Ref 44). Changes in densification mechanism, such as particle rearrangement, plastic deformation, and agglomerate fracture, effect changes in the constants as demonstrated in Fig. 9.

Pore collapse scales with the shear stress level. The shear component of stress is minimal in hot isostatic pressing (HIP) and is present increasingly in quasi-isostatic pressing, hot pressing, sinter forging, and extrusion (Ref 45). Additionally, shear stress is beneficial for mechanical disruption of surface oxide layers, which improves interparticle bonding.

Most pressure-assisted consolidation methods have been applied to nanocrystalline powder: HIP, forging and hot pressing, extrusion consolidation, cold sintering (high-pressure consolidation), dynamic consolidation, and field activated sintering. Details of these techniques are discussed in other articles.

The classical pressure-assisted sintering diagrams developed by Ashby and coworkers (Ref 46, 47, 48) have been used to describe nanocrystalline powder consolidation (Ref 49, 50, 51). Densification maps illustrate both the change in mechanism and accelerated densification relative to conventional powders. This is shown for HIP of nanocrystalline zirconia in Fig. 11(a) (Ref 50). The primary densification mechanism is boundary diffusion driven primarily by curvature effects, even though 25 MPa external pressure was applied. Densification was complete after 1 h at 1500 K. Figure 11(b) shows the computed densification behavior under identical conditions for 2 μm zirconia. Densification is controlled by creep and volume diffusion driven by the applied pressure, and full density is not obtained below about 2200 K.

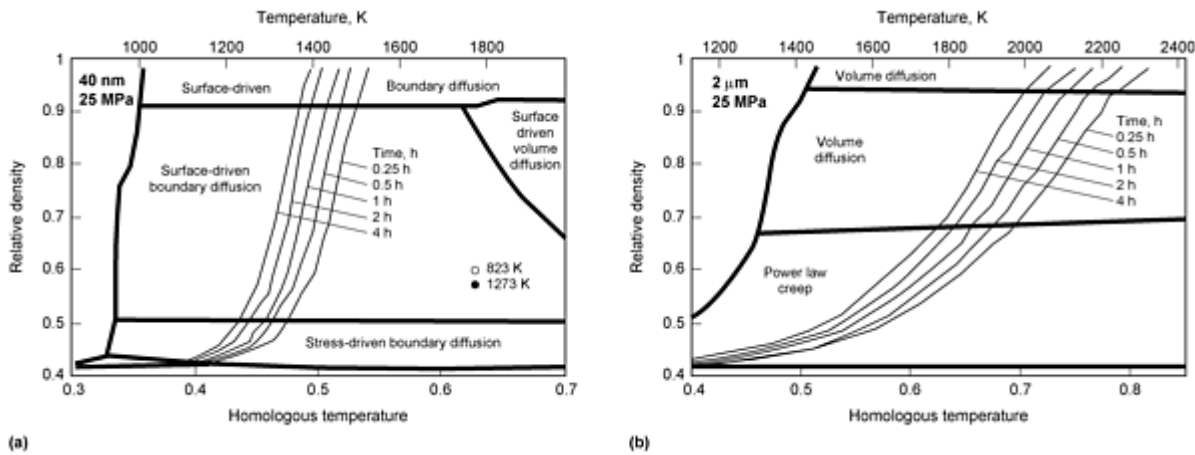

Fig. 11 Densification maps computed for zirconia HIPed with 25 MPa pressure. (a) 40 nm particulate. (b) 2 μ m particulate. Symbols represent experimental data for 1 h HIP of 40 nm zirconia calcined at 823 K and 1273 K. Source: Ref 50

Consolidation of Ultrafine and Nanocrystalline Powder

David L. Bourell, The University of Texas at Austin; Joanna R. Groza, University of California at Davis

Metals

Nanocrystalline metallic powder can be densified using conventional sintering. The largest departure from nonnanocrystalline powder sintering behavior is seen in the initial sintering stages. Here, lower activation energies and sintering onset temperatures are observed. For instance, an activation energy of 134 kJ/mol was reported for 40 nm tungsten (Ref 52), which is lower than the value for volume diffusion (580 kJ/mol) and surface diffusion (~ 300 kJ/mol) (Ref 53). Two apparent activation energy values were calculated in nanocrystalline iron: a low value for low-temperature sintering (125 kJ/mol) and a high value (248 kJ/mol) corresponding to high-temperature densification (Ref 54). The latter value is close to that of volume diffusion in iron and is similar to the value for coarse-grained iron. The low-temperature value is less than the grain boundary diffusion value.

The sintering onset temperature is particle-size dependent (Eq 5). In pure tungsten, the onset is 1100 K ($0.3 T_m$) for 31 nm particles and 900 K ($0.24 T_m$) for 9 nm particles (Ref 55). The onset temperature for densification of 40 nm iron powder is as low as 370 K ($0.21 T_m$), as compared to ~ 900 K ($0.5 T_m$) for 2 μm iron powder (Ref 10, 56), as shown in Fig. 12. Alloying iron with aluminum improves fine structure after sintering (Fig. 13) due to formation of AlN dispersoids (Ref 56).

Fig. 12 Effect of sintering temperature on density for 15 nm iron powder hot pressed at 10 MPa for 1 h. Dashed lines show the powder density before (11%) and after (23%) compaction. Source: Ref 10

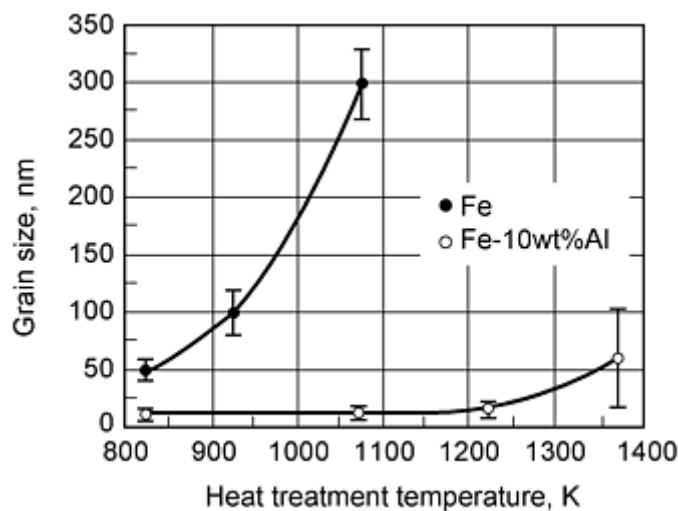

Fig. 13 Effect of fine-particle AlN as a grain-growth retardant for nanocrystalline iron cryomilled in nitrogen. Source: Ref 56

Sintering of iron-nickel nanocrystalline powder is initiated when oxide layers are reduced (Ref 57). This occurs above 500 K in hydrogen. When vacuum is used, no sintering takes place up to 725 K. To avoid further contamination, as-produced nanocrystalline powder can be either consolidated in situ or handled in a controlled environment prior to sintering. The oxygen role in nanocrystalline, evaporation-condensation, iron sintering is important (Ref 10). Although sintering is carried out in a reducing hydrogen atmosphere, oxygen is present in the final product as fine, grain-refining oxides. This is due to adsorbed oxygen entrapment at pore closure.

Iron, nickel, copper, and aluminum have been consolidated using high-pressure densification. The data conform to the compaction law given as Eq 8 and illustrated for iron and copper in Fig. 9. The transition point at which the slope changes (Fig. 9) is associated with agglomerate failure. When agglomerates are strong, they do not break and consequently, no transition point is seen. Rate controlled sintering of pure nickel resulted in 99% density with 70 to 80 nm grain size (Ref 58). Densities up to 97% at room temperature and 99% at 575 K in nickel (65 nm), iron (30 to 50 nm), and copper (58 nm) have been obtained using 3 GPa in a high pressure cell, as seen in Fig. 14 (Ref 41, 59). Historically, high pressure consolidation has been the preferred in situ consolidation method for classical nanocrystalline powders synthesized using inert gas condensation (Ref 60, 61, 62, 63, 64). A dense product with 22 nm final grain size has been achieved in Al-Fe (Mo, Si, B) alloys by high pressure consolidation (3 GPa at 1073 K) of alternating amorphous layers of constituent metals (Ref 65). Fully dense iron, nickel and Cu-50Ag specimens with less than 20 nm grain size were produced by severe plastic deformation consolidation in which torsional true strains of the order of 7 are imposed (Ref 66, 67, 68).

Fig. 14 Bright-field transmission electron microscopy image of 58 nm copper powder cold compacted at 750 MPa. Arrows indicate deformed particles presenting flat surfaces. Source: Ref 41

Sinter Forging. In numerous cases, sinter forging is shown to be very effective in achieving full or near full densities and grain sizes less than 100 nm in metals, as shown in Fig. 15 (Ref 49, 69, 70, 71). The composite Fe-10Cu has been densified by sinter forging (Ref 49). The benefits of sinter forging in comparison to HIP are evident, as sinter forging produced material with 45 nm grain size at 800 K and 525 MPa compared to HIP at 975 K and 170 MPa with a final grain size of 130 nm (Ref 49, 72). Sinter forging of ceramics is equally effective (see the section "Zirconia" in this article).

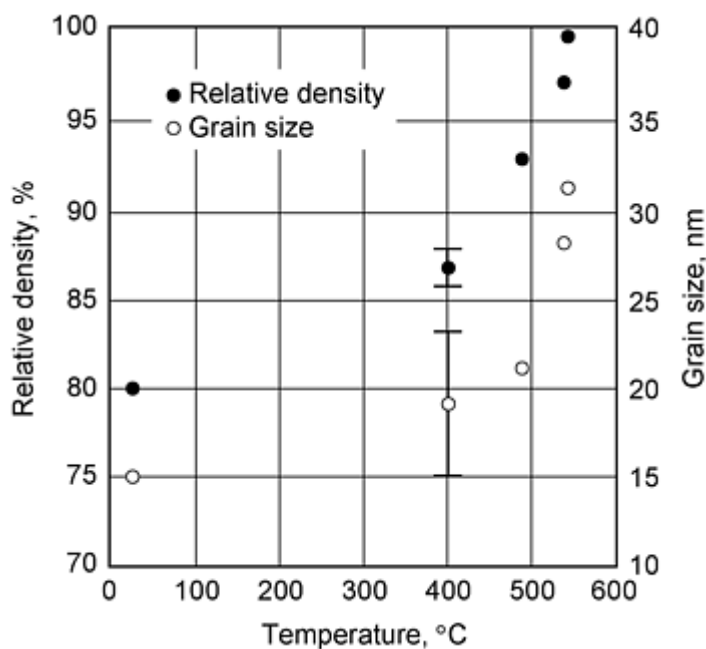

Fig. 15 Effect of sinter-forging temperature on the density and grain size of mechanically milled Fe-29Al-2Cr. The initial particle size was 30 nm and forging was affected with 1.25 GPa for 5 h. Source: Ref 71

Shock wave consolidation has been applied to consolidation of metallic nanoparticles. For example, fully dense specimens were obtained from ball-milled Fe-C and Fe-N solid-solution, powders by shock wave consolidation (Ref 73, 74). The ball-milled iron powder (20 nm grain size) was consolidated by dynamic compaction (12-19 GPa) followed by 1 h anneal at 500 °C (930 °F).

Hot extrusion usually involves high stresses that can be applied at relatively lower temperatures than in other pressure-assisted techniques, such as HIP. A compromise is usually sought between the strength, which requires high temperatures, and final grain size, for which low temperatures are desired. Hot extrusion has been primarily used to consolidate metallic nanopowders (Ref 75, 76, 77, 78). Grain sizes less than 100 nm have been achieved at 1120 K using a 0.5 GPa stress in nickel and iron (Ref 75), Al-Ni-Zr with mischmetal additions under an extrusion ratio of 10 to 1 (Ref 70), and in Mg-10Y-5Cu at 323 to 773 K with extrusion ratios of 5 to 1 to 10 to 1 (Ref 70).

Consolidation of Ultrafine and Nanocrystalline Powder

David L. Bourell, The University of Texas at Austin; Joanna R. Groza, University of California at Davis

Ceramics and Intermetallics

Alumina. Room-temperature phases other than α -Al₂O₃ are usually observed in the nanocrystalline Al₂O₃ system. These include the γ polymorph (Ref 79, 80), as well as bayerite, pseudoboehmite, and θ -Al₂O₃ (Ref 80). Nanocrystalline alumina is pressureless sintered by a surface-diffusion mechanism (Ref 81, 82, 83). Colloidally processed alumina sintered to 99.5% density at 1425 K (Ref 80). Early densification activation energy for pressureless densification of 13.5 nm Al₂O₃ was reported to be 234 kJ/mol (Ref 80), compared to 500 kJ/mol for volume diffusion of bulk alumina. Toward the end of the densification cycle, activation energies correspond to volume diffusion (Ref 26).

Densification maps for HIP of nanocrystalline Al₂O₃ powders confirmed boundary diffusion as the primary densification mechanism (Ref 51). However, comparison with experimental HIP results indicated that the calculated densification rates were consistently higher than experimental rates. For instance, 20 nm Al₂O₃ HIPed for 1 h at 1625 K under 300 MPa pressure resulted in a dense sample of only 84% compared to a full-density prediction for the same time at 1170 K and 20 MPa. Among the possible reasons is retarded densification due to large interagglomerate pores.

Both alumina (Ref 84, 85) and zirconia-toughened alumina (Ref 86) have been sinter forged successfully. Hot pressing has been performed (Ref 80, 87, 88), but under certain conditions it posed difficulties due to the formation of a high-density surface layer that reduced the pressure internally (Ref 80). In cold isostatic pressing at very high pressures up to 5.6 GPa, densities in excess of 90% have been achieved (Fig. 10) (Ref 42). Dynamic magnetic compaction (DMC) is an electric pulsed power method that induces short high pressure pulses up to 5 GPa (Ref 89, 90). Alumina powders were consolidated using DMC to 83% density while retaining a nanocrystalline structure (Ref 89). This method has also been applied to sintering of large parts of nanocrystalline alumina (Ref 90).

Microwave sintering is useful in densification of nanocrystalline alumina because grain boundaries are the primary sites for electric dipoles and resultant heating (Ref 91, 92, 93, 94, 95). In these materials, densities of about 95% have been achieved with retention of fine structure.

Titania. Nanocrystalline TiO₂ has been densified by pressureless sintering with restrained grain growth through improvements in nanocrystalline powder synthesis, particularly the control of agglomeration (Ref 5, 96, and 97). A sintering onset below 950 K was reported for titania with 40 nm initial particle size (Ref 39). The sintering onset was later measured to be 823 K (0.4 T_m) for 12 to 14 nm TiO₂ (Ref 17). Elimination of small pores by rapid surface diffusion occurred between 425 K and 775 K. Densification was complete at 1300 K as compared to more than 1670 K for 1.3 μ m TiO₂ (Fig. 7). For gel-derived TiO₂ powders, near full density is achieved at 1075 K (Ref 98).

A large green density may not always reflect a uniform pore size and distribution. When large agglomerates are present, the green density can be larger than in nonagglomerated powders. For instance, a relatively high density of 75% in as-compacted nanocrystalline TiO₂ at 425 K (2 GPa pressure, 2 h) is explained due to easier packing of large agglomerates (50 nm) rather than individual smaller particles (14 nm) (Ref 17).

The removal of large interagglomerate porosity based on vacancy diffusion requires high temperature and long sintering times. Mayo et al. (Ref 5) compiled evidence for three TiO₂ powders showing that sintering temperature scales with agglomerate size, rather than with size of the individual powder particle (Fig. 16). The agglomerate size scales inversely with particle size. Nonagglomerated powders sinter at the lowest temperature, despite their largest nanoparticle size.

Fig. 16 Effect of agglomerate size on pressureless sintering of nanocrystalline TiO_2 . Bold type indicates agglomerate size and the number in parentheses is the particle size. "N/A" indicates that the powder was not agglomerated. Source: Ref 5

In TiO_2 , the quantitative agreement between observed and calculated grain growth (Eq 7) is better when grain boundary diffusion is considered the sintering mechanism (Ref 39). The fitting value for the activation energy used (139 kJ/mol) is about half of the activation energy for lattice diffusion (251 kJ/mol). Activation energies as low as 96 kJ/mol have been reported for 11.5 nm TiO_2 (Ref 82).

A grain growth exponent (Eq 3) for nanocrystalline TiO_2 of about 3 has been reported (Ref 5, 15, 99). Solute additions, such as yttrium (Fig. 5), calcium, or tin, inhibit grain growth in near-full density nanocrystalline TiO_2 (Ref 100). Alternatively, sintering temperatures up to 600 K lower than conventional minimize or even eliminate the need for sintering additives or grain growth inhibitors (Ref 101).

The curvature part of the total sintering pressure during hot pressing (Eq 2) increases when the particle size is reduced and can reach high values as the particles become increasingly small. The applied pressure must be higher than this curvature driven pressure to be effective. Consistent with this threshold effect, no external pressure effect is observed in TiO_2 unless a certain pressure level is achieved (Ref 20, 21, 102, and 103). Hot pressing gives distinct advantages in comparison to pressureless sintering in achieving full densities and minimal grain growth (Ref 17, 104, 105). Generally, the pressures used in hot pressing span a large range from low (<100 MPa) (Ref 80, 106), to moderate (100 to 500 MPa) (Ref 31, 105, 107) to high levels (>0.5 GPa) (Ref 17, 18, 70, and 108). Final grain size is inversely proportional to the applied pressure. Nanocrystalline TiO_2 is sintered to theoretical density at 725 to 825 K ($\sim 0.35 T_m$) using 1 GPa with minimal grain growth (Ref 18). Application of high pressure (>1 GPa) resulted in grain size less than 60 nm in TiO_2 sintered to 95% density at 675 K (Ref 109).

Sinter forging has been extensively applied to consolidation of nanocrystalline titania (Ref 20, 103, 110, and 111). As an illustration, TiO_2 has been sinter forged with a final grain size of 87 nm, compared to pressureless sintering which gave a 400 nm grain size for the same final density (91%) (Ref 20, 21). Grain sizes less than 50 nm have been retained in TiO_2 densified at $0.43 T_m$ (Ref 103).

Processing time in microwave sintering is reduced as compared to conventional heating from external sources due to the direct energy coupling with electric dipoles within the heating body (Ref 91, 92). These shorter times produce energy and final property benefits. Temperature gradients are reduced and an overall short sintering time minimizes grain growth. Because grain boundaries are the primary sites for electric dipoles, microwave sintering appears particularly attractive for the densification of nanocrystalline powders. The method has been applied to nanocrystalline TiO_2 (Ref 93, 112, 113). Densities no greater than 95% have been achieved for grain size less than 100 nm.

Zirconia. The pressureless sintering onset of 8 to 9 nm zirconia is 870 to 920 K ($0.3 T_m$) as compared to 1370 K ($0.5 T_m$) for 70 nm powder (Ref 18, 31). Commercial powders sinter above 1945 K (Ref 18). Rhodes sintered centrifugally cast ZrO_2 -6.5 mol Y_2O_3 to 99.5% density at 1375 K with a final grain size of 200 nm (Ref 29). Similar attempts to sinter ZrO_2 achieved greater than 98% density at 1493 K when Y_2O_3 was added and 93% at 1208 K when the additive was Bi_2O_3 (Ref 116), as shown in Table 1. In both cases, the final grain size was 600 to 700 nm. Pressureless sintering of yttria-stabilized zirconia resulted in grain growth independent of heating rate (Fig. 17) (Ref 117). Surface diffusion is the dominant mechanism initially (Ref 15, 114, 115). Thuenissen et al. (Ref 15) found an atypically low activation energy (100 kJ/mol) in the early sintering of 15 nm yttria-stabilized tetragonal zirconia. In contrast, when aggregate size is 50 nm, the activation energy has the usual value of 275 kJ/mol. Intensified efforts on sintering nanocrystalline ZrO_2 have resulted in fully dense ceramics with restrained grain growth. The sinterability of ceramic nanopowders has been greatly enhanced by improvements in nanopowder synthesis, particularly the control of nanopowder agglomeration (Ref 5, 96, and 97). Examples of dense zirconia ceramics that have retained nanosized grains by pressureless sintering are provided in Table 1. As seen in this table, full densification without grain coarsening has been achieved predominantly in the ZrO_2 system. The explanation for this behavior has been found to be twofold (Ref 5, 15, 18, 29, and 118). First, ZrO_2 has the slowest coarsening tendency among ceramics. Second, the pore size does not seem to affect grain coarsening (Ref 5).

Table 1 Pressureless sintering of metastable nanocrystalline ceramics

Material	Sintering parameters				Final properties		Reference
	Initial grain size, nm	Temperature, K	Time, h	Atmosphere	Density, %	Grain size, nm	
ZrO_2	6-9	1400	1.3	Air	Full	80	31

Fig. 17 Grain growth in pressureless sintered 15 nm zirconia, showing the independence of heating rate. Source: Ref 117

In HIP under identical conditions, a change in the sintering mechanism from creep and volume diffusion in coarse-grained zirconia to grain boundary diffusion in nanocrystalline zirconia occurs (Ref 51), as seen in Fig. 11. Full density processing is also possible by hot pressing (Ref 31, 51).

Wet processing provides significantly improved packing uniformity of nanocrystalline zirconia (Ref 5). For instance, a green density close to the ideal value for monosize spheres (74%) is achieved in 12.5 nm Y_2O_3 -doped ZrO_2 by centrifugation from a slip suspension (Ref 29).

Pressure-assisted consolidation of nanocrystalline zirconia synthesized by precipitation routes is hampered by formation of strong agglomerates. Upon cold pressing, they do not break, and consequently, no transition point is observed as seen for metals (Fig. 9). This is the case for agglomerates in calcined water-washed, yttria-stabilized zirconia that survive a cold isostatic pressing at 400 MPa (Ref 119). Particle rearrangement is hindered and lower green densities are likely to be achieved as compared to conventional micron size powders. Bourell et al. (Ref 51) achieved 45% density for 70 nm yttria-partially stabilized zirconia and only 29% for 40 nm particle size. Conversely, when particle sliding is facilitated, high green densities are obtained. This can be accomplished by using lubricants or coatings. Deagglomeration of a commercial ZrO_2 reduced sintering from 4 h at 1775 K to 1 h at 1375 K (Ref 29). Efforts to produce nonagglomerated powders have intensified; Mayo (Ref 5) produced a good summary of the progress. The benefits of a small pore size and narrow size distribution in reaching high densities and reduced grain coarsening have been shown by several researchers for nonagglomerated ZrO_2 (Ref 18, 31, 32).

Sinter forging has been applied to nanocrystalline zirconia, producing materials with grain size less than 50 nm at $0.4 T_m$ (~ 1200 K) (Ref 31, 86, 120, 121, 122, 123, 124) (see Fig. 18). Precautions should be considered to avoid ceramic specimen fracture at high strain rates and low temperatures.

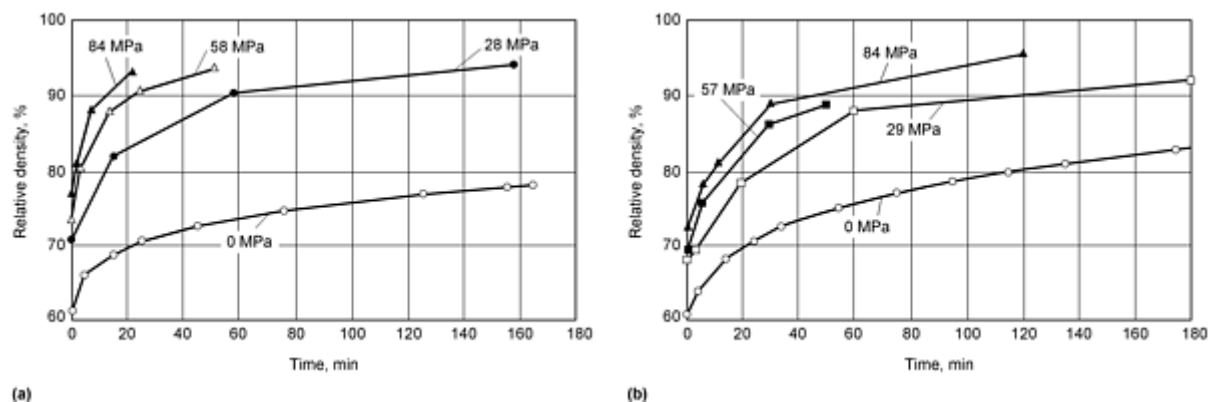

Fig. 18 Increase in relative density with time at 1370 K during pressureless sintering and sinter forging of (a) $95ZrO_2-5Y_2O_3$, and (b) $92ZrO_2-4Y_2O_3-4CeO_2$. Source: Ref 124

Other Ceramics and Intermetallics. The benefits of fine grain size in ceramic sintering were reported almost 30 years ago when the sintering onset for very fine grained MgO was found to be as low as 625 K (Ref 125). Examples of dense ceramics and intermetallics with retained nanocrystalline grains up to 100 nm by conventional sintering are provided in Table 1.

Low sintering temperatures during conventional sintering are common. The sintering onset for 4 nm Y_2O_3 is 600 K ($<0.25 T_m$) (Ref 18). Si_3N_4 has been fully sintered 700 K lower than coarse-grained material after cold pressing (Ref 40, 126), as seen in Fig. 8. TiC powder of 140 to 170 nm particle size sintered to 91% density at 1900 K as compared to 5 μm powder with the same density at 3070 K (Ref 127). Densification of nanocrystalline TiN starts at 1170 K and is completed below 1823 K, whereas microcrystalline powder is only 63% dense at 1823 K (Ref 34). Macroscopically, stabilization of particle surfaces (i.e., lower surface energy values when oxides are formed) results in a decrease of the driving force for sintering. This has been observed in nanocrystalline TiN at higher oxygen contents (Ref 34). TiAl was pressureless sintered to greater than 95% density by conventional sintering at low temperatures ($0.4 T_m$) with grain size less than 15 to 20 nm (Ref 128, 129).

Green densities up to 65% can be reached by conventional cold compaction of 70 to 80 nm TiN. At very high pressures (7 GPa) the density obtained was approximately 80% (Ref 130). Subsequent warm compaction at 675 K resulted in densities exceeding 90%. High pressure compaction (1 GPa) at 525 K also resulted in high densities for the intermetallics TiAl (Ref 110), Fe₃Al, and Ni₃Al (Ref 70).

HIP has been applied to nanoceramic densification in only a few cases where densities of 91 to 92% have been reached, such as in SiC at 2175 K (Ref 131) and Si₃N₄ at 1925 K (Ref 132). The final grain size exceeded the nanometer range. Generally, the final grain size in dense materials obtained by HIP of nanocrystalline powders falls in the micron size range (Ref 131, 132, 133). However, by careful control of HIP parameters, particularly temperature, it is possible to produce dense products with grain size less than about 100 nm (Fig. 19). This has been demonstrated for ball-milled TiAl, and Ti₃Al (Ref 134, 135), and FeAl (Ref 136). Another limitation in using HIP for ceramic/intermetallic densification is the lack of adequate encapsulation materials with softening temperatures close to ceramic sintering temperatures (Ref 5).

Fig. 19 Microstructures of ball-milled and HIPed (a) Ti-24Al-11Nb, and (b) Ti-55Al. Initial particle size was 10-15nm. HIP was performed at the temperature shown for 2 h with 207 MPa pressure. Source: Ref 134

Theoretical or near-theoretical densities and grain sizes less than 100 nm have been achieved by hot pressing of mechanically alloyed Al-10Ti (Ref 137), Fe₃Al, Ni₃Al (Ref 70, 138) and TiAl (Ref 140).

In cold isostatic pressing at very high pressures (up to 5.6 GPa), densities in excess of 80% have been achieved for SiO₂ (Ref 42). A factor in high pressure approaches in ceramic powders is the high level of residual stress that can result in fracture upon subsequent handling (Ref 5).

Sinter forging has been effectively applied (Fig. 18) in full or near full density processing of ceramics (Ref 25, 31, 32, 87, and 104). Generally, the stress levels required for densification by sinter forging are lower than in hot pressing or HIP. This method received substantial attention both theoretically and experimentally as applied to ceramic densification (Ref 84, 120, 140, 141, 142). The most attractive benefit of sinter forging is the capability to densify green compacts with large interglomerate pores.

In the Ti-Si system, shock consolidation yielded 30 to 40 nm grain size of crystalline TiSi₂ and Ti₅Si₃ phases (Ref 143). Only limited grain coarsening took place upon subsequent annealing at 1070 K for 1 h. Full densification was also reported in mechanically alloyed TiAl specimens with a final grain size of 15 nm (Ref 144). These results are compared with HIP, in which full consolidation was achieved at 1075 K (207 MPa for 2 h) but with a grain size of about 100 nm.

Consolidation of Ultrafine and Nanocrystalline Powder

David L. Bourell, The University of Texas at Austin; Joanna R. Groza, University of California at Davis

Composites and Cermets

Handwerker et al. (Ref 83) summarized the sintering behavior of ceramic composites. Hot pressing gives distinct advantages in comparison to pressureless sintering in achieving full densities and minimal grain growth as shown, for example, in nanograined Fe-(Fe, Mo)₆C (Ref 145, 146) and ZrO₂-Al₂O₃ (Ref 87). A grain size of only 16 nm has been retained in cryomilled Fe-10Al which was hot pressed at 823 K and heat treated for 1 h at 1223 K (Ref 107). This unusual

stability is attributed to nanometer dispersoids of γ -Al₂O₃ and AlN particles. Similar densification results with final nanocrystalline structures have been reported by hot pressing of tungsten-titanium and metal-nitride composites (Ref 147, 148). Hot pressing of nanoceramic composites, such as ZrO₂/Al₂O₃ (Ref 149), Si₃N₄/SiC (Ref 150), and Al₂O₃/Ni (Ref 151), achieved full densities and grain sizes below 100 nm. Mechanically alloyed Al-10.7Ti powder was densified to 98% under 2 GPa at 573 K with virtually no grain growth and retention of the initial aluminum supersaturation (Ref 109).

Nanograined WC-Co powders have been fully consolidated with minimal grain growth by conventional sintering, but the final grain size is approximately 100 to 200 nm (Ref 152, 153, 154). This final grain size is mainly attributed to the liquid phase mechanism that typically promotes grain growth. One approach in restricting grain growth in WC-Co is to use inhibitors (Ref 152).

Consolidation of Ultrafine and Nanocrystalline Powder

David L. Bourell, The University of Texas at Austin; Joanna R. Groza, University of California at Davis

Computational Studies

Molecular dynamics simulations have been performed for two to nine nanocrystalline metallic particles: copper composed of 4,688 atoms sintered at 700 K (Ref 16, 155, 156, 157), nickel composed of 767 atoms sintered between 50 K and 945 K (Ref 158), and 3 nm palladium clusters (Ref 159). In all cases, two-particle interactions were typified by particle rotation to a low-energy orientation accompanied by neck growth. The time required for these processes to occur was 10 to 500 picoseconds. Rapid neck formation has been attributed to dislocation activity driven by contact Hertzian stresses that exceed the ideal shear strength (Ref 156). Dislocations are generated in the neck and move along the usual slip systems in the fcc crystals. Particle rotation during sintering has been observed experimentally (Ref 114, 160, and 161). Further, particle rotation at least partially explains twin formation in nanocrystalline metallic particle pairs (Ref 115, 162, 163).

Reactive Sintering

David E. Alman, Albany Research Center, U.S. Department of Energy

Introduction

COMBUSTION SYNTHESIS (also termed variously in the literature as self-propagating, high-temperature synthesis (SHS) and reactive synthesis) has been used to produce advanced ceramic and intermetallic compounds, such as MoSi_2 and WC, in particulate form (Ref 1, 2, 3) since the late 1940s and early 1950s. Quite simply, combustion synthesis consists of forming compounds or composites from elemental or subcompound components:

or

The driving force for the reaction is the negative heat of mixing of the forming compound. This results in a release of energy (as heat), which sustains and propagates the reaction through the body of the reactants. A complete description of the thermodynamics, wave propagation, and phenomenological aspects of combustion synthesis can be found in the article "Combustion Synthesis of Advanced Materials" in this Volume. Commonly, the product of a combustion synthesis reaction is porous and therefore easily milled into powder.

Evolution of Porosity During Combustion Synthesis. Porosity is induced during combustion synthesis from several factors (Ref 4, 5, 6, 7, 8, 9, 10, and 11):

- *Kirkendall and Frenkel effects.* The diffusivity of the elements is unbalanced (i.e., element A diffuses more rapidly into element B than B diffuses into A; as a consequence, after the reaction propagates through the reactants a pore forms at prior particle A powder sites).
- *Gas evolution.* The heat generated by the initiation of the combustion synthesis reaction may be great enough to volatilize residual impurities attached to the surfaces of the starting powders. The evolution of gaseous species may be violent enough to prevent densification of the product or can be entrapped within the product resulting in porosity.
- *Molar volume changes.* The product phase has a different molar volume than the reactants. Typically, the product phase is denser than the reactants. For aluminides, the density increase is typically less than 12%, while for ceramics, the increase is quite substantial, ranging from 15 to 30% (see Table 1, Ref 8). The resulting volumetric change is intrinsic, as it is a direct result of the inherent atomic structure and bonding of the resultant product versus those of the starting constituents. Unless the change in the dimensions of the product (e.g., shrinkage due to sintering) is equal to the intrinsic volume change resulting from the reaction, porosity will be generated in the product.
- *Initial porosity.* The starting green compact of pressed powders contains 20 to 50 vol% porosity. This must be eliminated during the sintering operation for product densification to occur.

The aim of reactive sintering is to form dense intermetallic and ceramic compounds, alloys, or composites directly from elemental powders. As discussed below, during combustion synthesis of certain compounds, the formation of porosity can be eliminated by careful control over the reaction and/or through the application of external pressure during reactive sintering by reactive hot pressing (RHP) or reactive hot isostatic pressing (RHIP).

Table 1 Intrinsic volume and density changes during formation of ceramic and intermetallic products from

elemental powders

Product	Volume change (ΔV), %	$\rho_p/\rho_r^{(a)}$
MoSi ₂	-40.6	1.39
SiC	-28.4	1.39
TiSi ₂	-27.5	...
TiC	-24.4	1.32
WC	-23.8	1.31
TiB ₂	-23.3	1.29
NiAl	-12.6	...
TiAl	-5.3	...
Ni ₃ Al	-5.2	...
ReHf	-2.2	...
3TiC + 2Al ₂ O ₃	-22 to -28	1.28 to 1.39
3TiB ₂ + 5Al ₂ O ₃	-27 to -28	1.37 to 1.39
9Fe + 4Al ₂ O ₃	-22	1.28
3Fe + Al ₂ O ₃	-19	1.23

Source: After Ref 8

(a) ρ_p/ρ_r is theoretical density of product(s)/theoretical density of reactants (i.e., density of nonporous compact of reactants).

Reactive Sintering. Coble (Ref 12) defines seven classes of reactions that can occur during sintering:

$A_1 \rightarrow A_2$ (1)
Crystallographic phase change
$A + B \rightarrow \alpha$ (2)
Solid-solution formation
$A + B \rightarrow \alpha + \beta$ (3)
Solid-solution formation
$A + B \rightarrow \alpha + \text{liquid}$ (4)
Liquid phase sintering
$A + B \rightarrow AB$ (5)
Compound formation
$A_1 + \text{liquid} \rightarrow A_2 + \text{liquid}$ (6)
$\beta \rightarrow \alpha \text{Si}_3\text{N}_4, \text{ with liquid}$
$A_{\text{solid}} + B_{\text{liquid}} \rightarrow AB_{\text{solid}}$ (7)
Disappearing liquid phase, reactive infiltration

Reactions 2 and 3 are simple eutectic systems at temperatures below the eutectic temperature. The final product is either single phase (α) or two phase ($\alpha + \beta$). The fourth reaction is analogous to the third reaction, except at temperatures above the eutectic temperature. The sixth reaction is for phase transformation via solution in a liquid. An example of this is $B \rightarrow \alpha \text{Si}_3\text{N}_4$ transformation in magnesium silicate liquid. This article is concerned with sintering when reactions of type 5 occur and both starting constituents are in solid form. Reactive liquid infiltration of powder preforms is not within the scope of this article.

In many instances, the combustion synthesis reaction is accompanied by the formation of a transient liquid phase (Ref 13, 14). As with any liquid phase sintering operation, densification occurs due to capillary effects associated with the formation of the liquid. Figure 1 illustrates the reactive sintering process for forming the compound AB from a mixture of A and B powders (Ref 13). The initial compact is composed of mixed elemental powders, which diffusively interact during heating. When the lowest liquidus temperature is reached (e.g., a eutectic or the melting point of one of the constituents), partial melting of the compact occurs. The liquid flows into pores between the solid particles resulting in densification. Also, the liquid is a rapid diffusion path between the elements, which facilitates compound formation. The final product is single phase and dense AB.

Fig. 1 A binary phase diagram and the typical sequence of events expected in reactive sintering of compound AB from a mixture of A and B powders. Source: Ref 13

Formation of the transient liquid phase during processing does not guarantee a dense product. Shrinkage porosity may develop during the solidification of the liquid phase (Ref 8). Control over the formation of the liquid phase, hence the reaction, through judicious selection of the characteristics of the starting powders and the process parameters is paramount for producing dense articles with useful microstructures by reactive sintering. Further difficulties can arise during reactive sintering when the adiabatic flame temperature of the reaction exceeds the melting point of the forming compound. Nevertheless, monolithic aluminides, ceramics, and composites have been fabricated by reactive sintering and its variants, as discussed in detail below.

Densification during Reactive Sintering

Figure 2 shows a microstructure of Ni₃Al produced by reactive sintering nickel and aluminum powders at 750 °C for 15 min in vacuum. The elemental powder mixture was die pressed at room temperature to a green density of about 70% and heated at a rate of 20 K/min to the sintering temperature. As is evident, near-fully dense (>97% theoretical) Ni₃Al can be produced utilizing processing cycles consisting of short sintering times and low homologous sintering temperatures ($T_H = 0.60$ and is defined as the sintering temperature, 1023 K, divided by the melting temperature of compound, 1660 K). Densification coincides with the initiation of the reaction, as shown by the dilatometer and differential thermal analysis scans illustrated in Fig. 3. The high final density is a result of:

- The relatively small volume change (-5.2%, see Table 1) that occurs when the nickel and aluminum powders transform to Ni₃Al
- The presence of a transient liquid phase during the sintering cycle

The processing parameters that influence the reaction between the constituent powders and alter the amount, distribution, and duration of the liquid phase impact the density of the final product. These processing parameters include: powder particle sizes, composition, green density, heating rate, and sintering atmosphere. Proper manipulation of these parameters can enhance the density of the reactively sintered product.

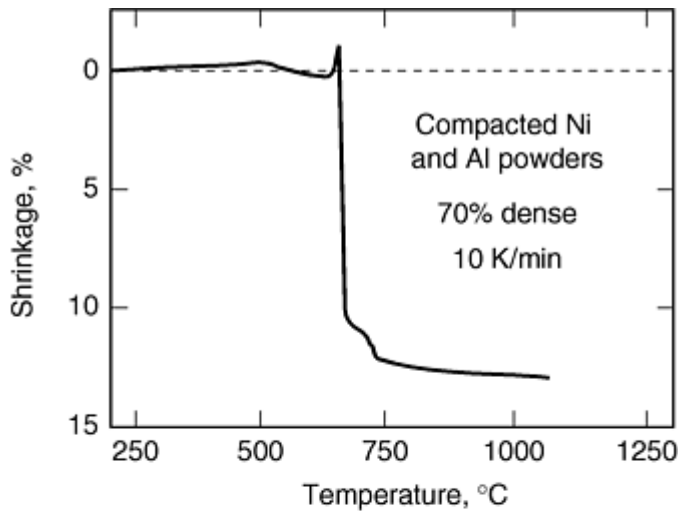

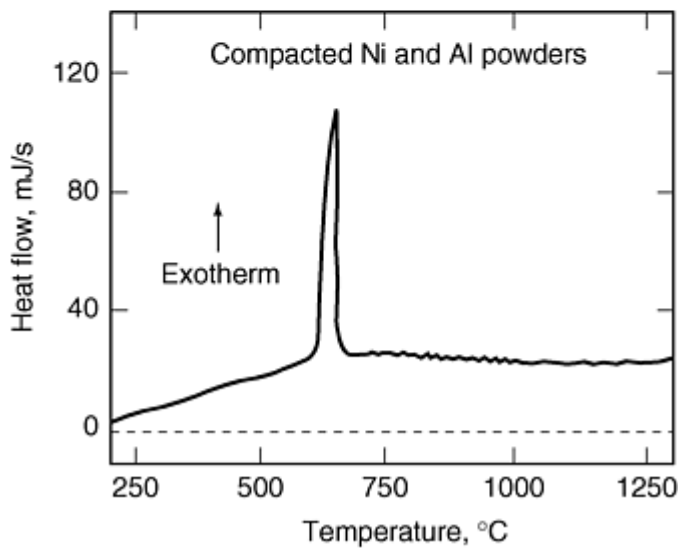

Fig. 2 Microstructure of reactive sintered Ni₃Al (750 °C, 15 min). (a) As-polished. (b) Etched with Kallings solution

(a)

(b)

Fig. 3 Dilatometry (a) and differential thermal analysis (b) of compacted nickel and aluminum powders mixed at the Ni_3Al stoichiometry. Densification (shrinkage on the dilatometry scan) corresponds with the reaction (as indicated by the exothermic reaction on the DTA scans). Source: Ref 14

Manipulation of the Liquid Phase with Process Parameters. The size ratio of the reactant powder particles plays an important role in the distribution of the liquid phase and therefore impacts the final density of several reactive sintered compounds (Ref 15, 16, 17, 18, 19, 20, 21, and 22), as illustrated in Fig. 4 for Ni_3Al . By selecting appropriate nickel and aluminum powder particle sizes, the initial green microstructure will consist of two interpenetrating and interconnected nickel and aluminum powder networks. In this configuration, the contact surface between the nickel and aluminum will be maximized, which mitigates pore formation when the transient liquid reacts and flows into the solid phase. Interconnectivity of the particulate phases is necessary for long-range densification by means of capillary action. If the aluminum particles exist in an isolated configuration, pools or pockets of liquid form upon melting and porosity will form at the prior aluminum sites when the liquid flows from the pockets into the solid phase during the reaction.

Fig. 4 A schematic diagram depicting the effect of particle size on reactive sintering of Ni₃Al. Source: Ref 15

Aluminum constitutes 34 vol% of the solid powder mixture in stoichiometric Ni₃Al, and at this volume fraction interconnectivity requires a nickel-to-aluminum powder size ratio of 2.4 to 1. German and coworkers (Ref 15, 17, 18, 19, and 20), reactively sintered Ni₃Al to 97% of its theoretical density, using 45 μm agglomerated Ni and 15 μm Al powders (i.e., a nickel-to-aluminum particle size ratio of 3 to 1). Nishimura and Liu (Ref 21), using similar powders (agglomerated 45 μm Ni and 15 μm Al), obtained 98% dense Ni₃Al by reactive sintering at 620 °C for 15 min in a vacuum. Experiments using other nickel-to-aluminum particle size ratios produced Ni₃Al microstructures with substantially more porosity (Ref 15, 16, 17, 18, 19, and 20), as shown in Fig. 5(a). Powder size ratio also influenced the density of reactive sintered NbAl₃, as shown in Fig. 5(b) (Ref 22). In this case, aluminum constitutes 74 vol% of NbAl₃, and interconnectivity requires a niobium-to-aluminum particle size ratio of 1 to 3. Dense NbAl₃ (95%) was reactively sintered using a niobium-to-aluminum particle size ratio of 1 to 3 (10 μm Nb and 30 μm Al powders). The pores in this specimen were less than 10 μm in diameter, indicating that capillary action caused densification of the structure. Specimens produced using other niobium and aluminum particle size ratios (3 to 1, 1 to 1.5, and 1 to 9.5) swelled upon sintering. The microstructure of these specimens contained large pores. The large pores formed when the disconnected liquid aluminum pools were consumed by the reaction (the liquid aluminum diffuses into the niobium powders, leaving pores). Unfortunately, similar particle size adjustments did not mitigate swelling during reactive sintering of TiAl, Al₃Ta, and Fe₃Al (Ref 18, 23, 24).

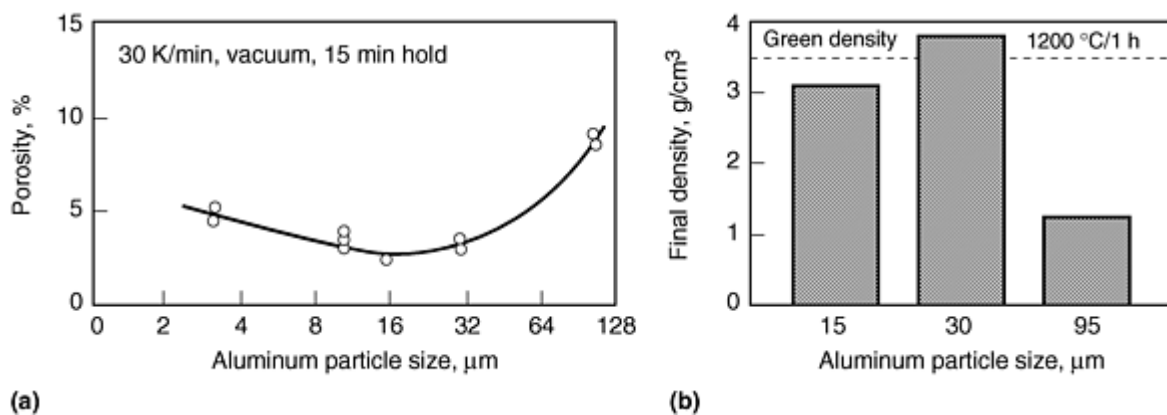

Fig. 5 Influence of aluminum particle size on the density of: (a) reactive sintered Ni₃Al, using 45 μm Ni

powders. Source: Ref 17 and (b) NbAl₃, using 10 μm Nb powders. Source: Ref 22

The influence of heating rate and sintering atmosphere on the density of reactive sintered Ni₃Al is shown in Fig. 6 (Ref 15, 17, 18, 19, and 20). The role of sintering atmosphere is explained by heat conduction and entrapped gas effects. Heat is carried away from the compact during reaction by the higher thermal conductivity of gas versus vacuum. This lowers the maximum temperature obtained during the reaction, which impedes densification. Furthermore, because of the speed of the reaction there is no time for absorbed vapors and atmosphere captured in the pores to escape. Therefore, the gas becomes entrapped in pores and prevents densification. Heating rate effects on transient liquid phase sintering have been explained based on solid-state interdiffusion prior to liquid formation. With slow heating rates, there is more solid-state diffusion and intermediate compound formation prior to the reaction initiation. This inhibits liquid formation and results in low sintered densities.

Fig. 6 Density of reactive sintered Ni₃Al for two heating rates and three sintering atmospheres. Source: Ref 17

Control over Excessive Liquid Formation by Adding a Diluent. Shape retention is lost if too much liquid forms during reactive sintering. This can occur when the adiabatic flame temperature of the reaction exceeds the melting point of the forming compound. This situation occurs during combustion synthesis of NiAl ($T_m = 1640$ °C), as illustrated in Fig. 7(a) (Ref 25). Control over the reaction can be gained by adding a high melting phase to act as a ballast and dilute the reaction. This phase can be a ceramic reinforcement phase, such as TiB₂ or Al₂O₃, or prealloyed NiAl, as is shown in Fig. 7(b). The addition of the high-melting and inert diluent phase absorbs some of the heat generated by the reaction and lowers the adiabatic flame temperature (Ref 26).

Fig. 7 Macrophotographs of pressed and reactive sintered NiAl (700 °C, 15 min, vacuum). (a) Loss of shape retention in undiluted reaction (i.e., $\text{Ni} + \text{Al} \rightarrow \text{NiAl}$). (b) Shape retention using NiAl as diluent (i.e., $x\text{Ni} + x\text{Al} + (1-x)\text{NiAl}_{\text{prealloyed}} \rightarrow x\text{NiAl}_{\text{reaction}} + (1-x)\text{NiAl}_{\text{prealloyed}} \rightarrow \text{NiAl}$)

The diluted combustion synthesis reaction is as follows:

The amount of diluent $(1-x)$ required to prevent slumping, due to the adiabatic flame temperature (T_{ab}) of the reaction exceeding the melting point of the compound (T_{m}), can be determined from a simple energy balance:

$$x \left[\Delta H_f^T \right]_{\text{AB}} = x \left[\int_T^{T_{\text{m}}} C_{\text{pAB}} dT \right] + (1-x) \left[\int_T^{T_{\text{m}}} C_{\text{pD}} dT \right] \quad (\text{Eq 3})$$

where ΔH_f^T is the heat of formation for the compound at a reference temperature, T , such as the reaction initiation temperature or 298 K. C_{pAB} and C_{pD} are the heat capacity of the compound, AB, and the diluent, D, phase, respectively. The values for ΔH_f^T , C_{pAB} , and C_{pD} are obtained from thermodynamic handbooks. From Eq 3, the mole fraction of the product phase AB, (x) , can be determined using numerical integration techniques. The reaction utilizing prealloyed NiAl powder as the diluent for the combustion synthesis of nickel and aluminum powders is as follows:

The subsequent energy balance is:

$$x \left[\Delta H_f^{298} \right]_{\text{NiAl}} = \left[\int_{298}^{1913} C_{\text{PNiAl}} dT \right] \quad (\text{Eq 4b})$$

Using Eq 4b, x was determined to be 78 mol%, which corresponds to 22% NiAl prealloyed powder required to prevent slumping during combustion synthesis of NiAl. This is consistent with experimental results (Fig. 7, Ref 25). In practice, it is important not to overdilute the reaction as this will inhibit liquid formation and impede densification.

Augmenting Liquid Phase Formation by Alloying. The addition of alloying elements that melt during combustion synthesis prolongs the duration, distribution, and amount of the liquid phase during processing. These elements may or may not participate in the actual reaction. An example of the former is the reactive synthesis of aluminum-modified MoSi_2 , from the following reaction:

The aluminum melts (or forms an aluminum-silicon eutectic) prior to the initiation of the combustion synthesis reaction (Ref 27), as illustrated in the differential thermal analysis (DTA) scans of Fig. 8. The presence of this "extra" liquid acts as a rapid diffusion path, and as a consequence the initiation of reaction associated with the formation of the ternary compounds occurs at a lower temperature than the reaction to form binary MoSi_2 . The "extra" liquid phase can also be used to enhance densification during RHP. Similar results have been observed for silicon-modified aluminide compounds, such as $\text{Ti}(\text{Al},\text{Si})$ (Ref 28).

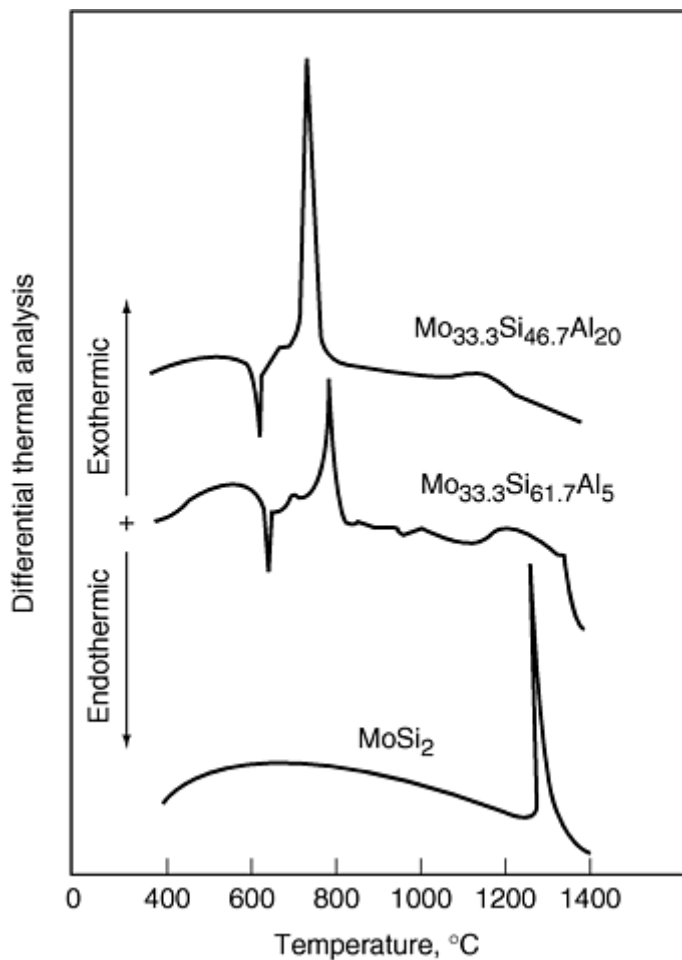

Fig. 8 Differential thermal analysis scans for reactive synthesis of $\text{Mo}(\text{Si},\text{Al})_2$ from elemental molybdenum, silicon, and aluminum powders. Source: Ref 27. The addition of aluminum augments the liquid phase formation during reactive sintering.

Another example of the use of alloying to augment the liquid phase is the combustion synthesis of cermets. The reaction to form the TiC-Ni cermet is:

and a temperature-time profile for this reaction is shown in Fig. 9 (Ref 29). The reaction temperature exceeds the melting point of nickel (1453 °C) for about 20 s. Liquid nickel is present during this time period, and in fact the slight shoulder observed on the profile upon cooling at 1450 °C corresponds to the solidification of the nickel phase. Similar behavior is also noted for the simultaneous reaction of TiC and NiAl and TiC and Ni₃Al from titanium, carbon, nickel, and aluminum powder mixtures (Ref 30).

Fig. 9 Time-temperature profiles for the reactive synthesis of $\text{Ti} + \text{C} + 25 \text{ wt\% Ni} \rightarrow \text{TiC-Ni}$. Source: Ref 29

Alloying additions can also influence the diffusion rates between the reacting elements and minimize Kirkendall porosity. An example of this is the reactive sintering of nickel-modified iron aluminides (Ref 31). Without nickel additions, iron aluminide swells upon reactive sintering. The addition of nickel (substituting for iron) results in a high-density reactively sintered product (Fig. 10). The nickel inhibits the rate of aluminum diffusion in the iron, thus eliminating the pores that develop at the prior aluminum particle sites (Ref 31). However, this only occurs in Fe-Al-Ni powder billets rolled to an 80% reduction prior to reactive sintering at 650 °C for 15 min. This effect does not occur in similar material that was die pressed. This is due to differences in the green structure that develop during rolling compared to die pressing, as discussed below.

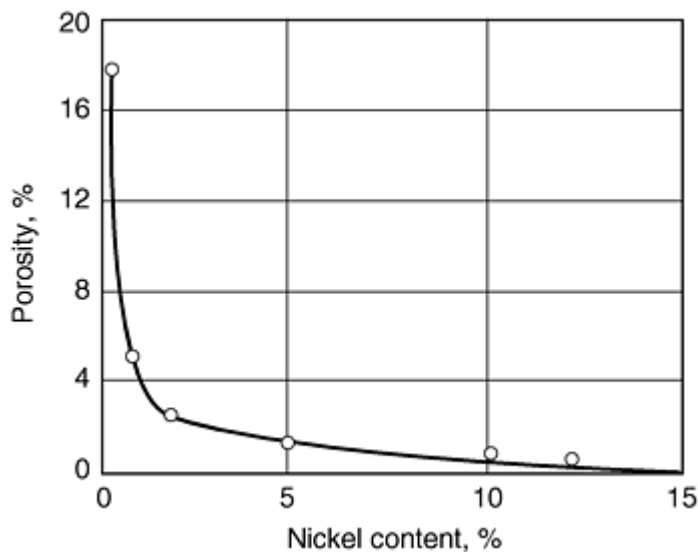

Fig. 10 Effect of nickel content on the porosity of reactive sintered (650 °C, 15 min) iron-aluminides (elemental powder mixtures corresponding (in wt%) to 86.4(Fe + Ni) + 13.6Al. Source: Ref 31. Compacts of elemental powder mixtures were rolled to 80% reduction prior to sintering.

Influence of Green Compaction. As mentioned previously, Fe-Al-Ni powder billets rolled to an 80% reduction prior to reactive sintering at 650 °C for 15 min were dense; however, similar composition of elemental powders, die pressed at more than 550 MPa, swelled upon sintering (Ref 31). Similar behavior is observed during reactive sintering of TiAl. Die-pressed titanium and aluminum powders swell upon reactive sintering. However, Dahms and coworkers (Ref 5, 6, 32, and 33) were able to produce 97% dense TiAl by reactive sintering extruded billets of titanium and aluminum powders, as illustrated in Fig. 11. The extrusion ratio played an important role in the densification of TiAl, with higher extrusion ratios resulting in denser (less porous) pressureless sintered billets.

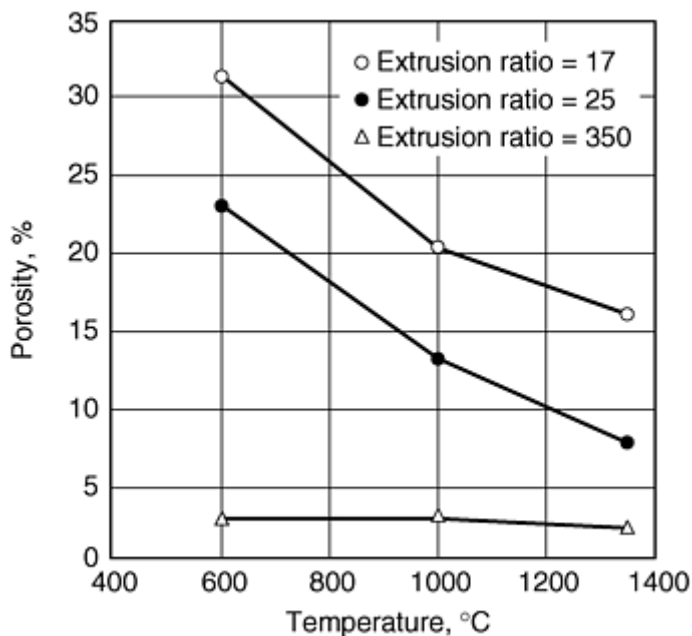

Fig. 11 Porosity of reactive sintered TiAl specimens as a function of sintering temperature and extrusion ratio. Source: Ref 33. Compacts of elemental titanium and aluminum were extruded prior to sintering.

It is evident that the high pressures that can be generated during rolling and extrusion influence the green structure in a beneficial manner. The deformation of the elemental powders that occurs during extrusion and rolling results in increased surface contact area, decreased initial pore size, and improved aluminum distributions in the green microstructure. This results in minimal pore formation during reactive sintering.

Reactive Sintering

David E. Alman, Albany Research Center, U.S. Department of Energy

Pressure-Assisted Reactive Sintering

Even though many of the examples discussed above can be reactively sintered to densities greater than 97% theoretical, this small amount of porosity can be detrimental to the mechanical properties--specifically tensile and fracture behavior--of these compounds. Commonly, a postreactive sintering routine, such as hot isostatic pressing (HIP), is used to fully densify these materials.

Alternatively, the powders can be sintered under pressure by RHP or RHIP. Greater densities can be achieved in the final product if the reaction is initiated under pressure (i.e., RHP), as opposed to applying pressure subsequent to the reaction (i.e., RS + HP), under identical hot pressing conditions. This is illustrated in Fig. 12(a) (Ref 28) for a variety of RHP in situ TiAl-boride composites. The composites that were reacted under pressure were considerably more dense than similar composites in which the pressure was applied subsequent to the reaction (e.g., after the hold temperature was reached). During RHP, compaction of the powders (as indicated by ram travel, Fig. 12b) occurs as the hot-press temperature nears the reaction initiation temperature and the transient liquid phase forms (Ref 34). The applied pressure forces the transient liquid phase into the voids between the solid powder particles, and as a consequence the compact densifies. Further, the heat liberated by the reaction raises the temperature of powder compact. At this temperature, the product may be soft and deform under the applied pressure, resulting in densification (Ref 35).

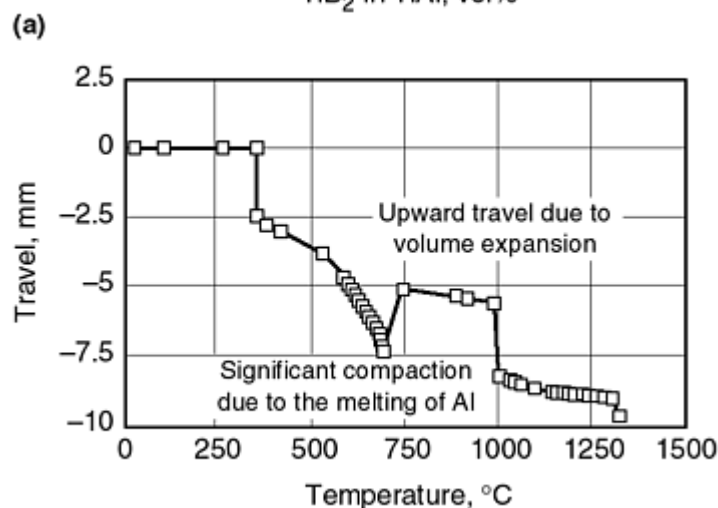

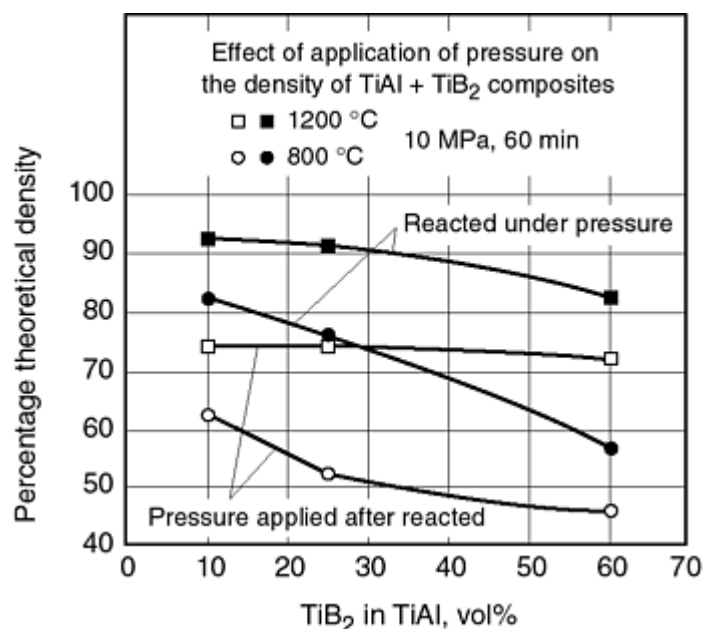

Fig. 12 Influence of the application of pressure on reactive sintering. (a) Densities of TiAl-boride in situ composites fabricated by reactive hot pressing (RHP) and reactive sintering followed by hot pressing (RS + HP). Source: Ref 28. (b) Hot press ram travel during RHP of Ni₃Al. Source: Ref 34

While the simultaneous application of pressure to the reacting powders promotes densification, it can result in inhomogeneous microstructures. This is particularly true for RHP aluminides. Alman and coworkers (Ref 25, 27, 28) noted that microstructures of RHIP-NiAl and RHP-TiAl contained "hot" spots of aluminum-rich intermetallic phases. However, the microstructure of similar aluminides, produced by RS + HIP or RS + HP, were homogeneous. The microstructural inhomogeneities that developed during RHP were attributed to the same mechanism for the enhancement in density. The transient liquid phase is forced into the voids between the solid particles (presumably nickel or titanium).

The liquid is presumably aluminum rich and, upon solidification, results in the microstructural inhomogeneity. Liu and coworkers (Ref 21, 36) found that the application of pressure has a negative impact on the density and microstructure of reactive sintered Ni₃Al. In their studies, single-phase and dense (98%) Ni₃Al was produced by RS + HP. However, porous (70% dense) and multiphase (Al₃Ni, Al₃Ni₂, and nickel) microstructures resulted when the nickel and aluminum powders were RHP under stresses of 5 and 50 MPa. The low densities and inhomogeneity were attributed to the heat transfer associated with the contact of the ram and the powder compact, quenching the reaction. This was further supported by a size effect of the powder compact: the thinner the powder compact hot pressed, the more inhomogeneous was the resultant microstructure.

Reactive Sintering

David E. Alman, Albany Research Center, U.S. Department of Energy

Conclusions

Reactive sintering (RHP and RHIP) have been utilized to produce a variety of ceramics, intermetallics, and composite materials. Table 2 summarizes the processing conditions and tensile properties of select materials produced by reactive powder processing. This is not intended to be an all-inclusive list, but representative of materials produced by these methods.

Table 2 Conditions and tensile properties of select compounds, alloys, and composites fabricated by RS, RHP, and RHIP

Materials	Process	Microstructure	Room-temperature tensile properties			Ref
			Yield strength (σ_{ys}), MPa	Ultimate tensile strength (σ_{UTS}), MPa	Elongation to fracture (ϵ_f), %	
Nickel aluminides						
Ni ₃ Al	Ni + 3Al; RS: 700 °C, vacuum	Ni ₃ Al 97% dense	270	270	1	18

The microstructure that develops during reactive sintering is influenced by a variety of process parameters, including the green structure, the sintering conditions, and product composition. An interconnected configuration of the reactant powders minimizes pore formation during reactive sintering. The distribution of the reactants in the green structure can be adjusted by altering the powder particle characteristics (e.g., particle size ratio) or the green processing method (e.g., extrusion, rolling versus compaction). The parameters of the sintering cycle that influence reactive sintering, include heating rate, sintering atmosphere, and application of pressure. Heating rates and sintering atmospheres that limit interdiffusion and intermediate compound formation prior to the reaction between the powders are preferred. Application of pressure during combustion synthesis results in dense products, but the microstructure of these products may be inhomogeneous, particularly if large amounts of transient liquid form during processing. Both the densification and inhomogeneity can be attributed to the applied pressure forcing the transient liquid into pores between solid powders. Finally, composition of the product can affect the reaction, by the addition of alloying elements and diluent phases (inert, high melting, reinforcement phases). These can affect the amount, duration, and distribution of the transient liquid phase and can also affect the diffusion rates between the reacting elements. With the judicious selection of all these parameters, dense and useful components can be produced by reactive sintering.

Combustion Synthesis of Advanced Materials*

A. Varma and A.S. Mukasyan, University of Notre Dame

Introduction

COMBUSTION SYNTHESIS (CS) is an attractive technique for synthesizing a wide variety of advanced materials, including powders and near-net-shape products of ceramics, intermetallics, composites, and functionally graded materials. This method was discovered in the late 1960s in the former Soviet Union (Ref 1), and its development has led to a new scientific endeavor that incorporates aspects of both combustion and materials science. At about the same time, some work concerning the combustion aspects of this method was done in the United States (Ref 2, 3, 4), although the full potential of CS in the production of advanced materials was not utilized. The scientific and technological activity in the field increased during the 1980s. The significant results of combustion synthesis have been described in a number of review articles (Ref 5, 6, 7, 8, 9, 10, 11, 12).

There are two modes by which combustion synthesis can occur: *self-propagating high-temperature synthesis* (SHS) and *volume combustion synthesis* (VCS). A schematic diagram of these modes is shown in Fig. 1. In both cases, reactants may be pressed into a pellet, typically cylindrical in shape. The samples are then heated by an external source (e.g., tungsten coil, laser) either locally (SHS) or uniformly (VCS) to initiate an exothermic reaction.

Fig. 1 The modes of combustion synthesis. (a) Self-propagating high-temperature synthesis. (b) Volume combustion synthesis

The characteristic feature of the SHS mode is, after initiation locally, the self-sustained propagation of a reaction wave through the heterogeneous mixture of reactants. The temperature of the wave front can reach quite high values (2000 to 4000 K). In principle, if the physicochemical parameters of the medium are known, along with the instantaneous spatial distributions of temperature and concentration, then the combustion velocity and reaction rate throughout the mixture can be calculated. Thus, the SHS mode of reaction can be considered a well-organized wave-like propagation of the exothermic chemical reaction through a heterogeneous medium, followed by the synthesis of desired condensed products.

During VCS, the entire sample is heated uniformly in a controlled manner until the reaction occurs essentially simultaneously throughout the volume. This mode of synthesis is more appropriate for weakly exothermic reactions that require preheating prior to ignition, and it is sometimes referred to as the *thermal explosion* mode. However, the term "explosion" used in this context refers to the rapid rise in temperature after the reaction has been initiated, not to the destructive process usually associated with detonation or shock waves. For this reason, volume combustion synthesis is perhaps a more appropriate name for this mode of synthesis.

From the viewpoint of chemical nature, three main types of CS processes can be distinguished. The first, *gasless combustion synthesis from elements*, is described by:

$$\sum_{i=1}^n X_i^{(s)} = \sum_{j=1}^m P_j^{(s,l)} + Q \quad (\text{Eq 1})$$

where $X_i^{(s)}$ are elemental reactant powders (metals or nonmetals), $P_j^{(s,l)}$ are products, Q is the heat of reaction, and the superscripts (s) and (l) indicate solid and liquid states, respectively. Perhaps the most popular example of this type of reaction is carbidization of titanium:

The second type of CS, called *gas-solid combustion synthesis*, involves at least one gaseous reagent in the main combustion reaction:

$$\sum_{i=1}^{n-p} X_i^{(s)} + \sum_{i=1}^p Y_i^{(g)} = \sum_{j=1}^m P_j^{(s,l)} + Q \quad (\text{Eq 2})$$

where $Y_i^{(g)}$ are the gaseous reactants (e.g., N_2 , O_2 , H_2 , CO) that, in some cases, penetrate the sample by infiltration through its pores. This type of CS is also called *infiltration* (or *filtration*) *combustion synthesis*. Nitridation of titanium and silicon are common examples:

The third main type of CS is *reduction combustion synthesis*, described by:

$$\begin{aligned} \sum_{i=1}^{n-q-r} (\text{MO}_x)_i^{(s)} + \sum_{i=1}^r Z_i^{(s)} + \sum_{i=1}^q X_i^{(s)} \\ = \sum_{j=1}^{m-k} P_j^{(s,l)} + \sum_{j=1}^k (\text{ZO}_y)_j^{(s,l)} + Q \end{aligned} \quad (\text{Eq 3})$$

where $(\text{MO}_x)_i^{(s)}$ is an oxide that reacts with a reducing metal $Z_i^{(s)}$ (e.g., Al, Mg, Zr, Ti), resulting in the appearance of another, more stable oxide $(\text{ZO}_y)_j^{(s,l)}$, and reduced metal $M_i^{(s,l)}$. This reaction may be followed by the interaction of $M_i^{(s,l)}$ with other elemental reactants $X_i^{(s)}$ to produce desired products $P_j^{(s,l)}$. Thus, in general, the reduction combustion synthesis may be considered a two-step process, where the first step is a *thermite* reaction:

$$\begin{aligned} \sum_{i=1}^{n-q-r} (\text{MO}_x)_i^{(s)} + \sum_{i=1}^r Z_i^{(s)} \\ = \sum_{j=1}^k (\text{ZO}_y)_j^{(s,l)} + \sum_{j=1}^l M_j^{(s,l)} + Q_1 \end{aligned} \quad (\text{Eq 4a})$$

and the second step is the synthesis from elements similar to Eq 1:

with the total heat release $Q = Q_1 + Q_2$. An example of this type of CS is:

where TiB_2 is the desired product and Al_2O_3 can be removed (e.g., by centrifugal separation) and used separately, or a ceramic composite material ($\text{Al}_2\text{O}_3 + \text{TiB}_2$) can be produced. In some cases, the reducing reactant (Z_i) is the same as that used for the synthesis (X_i), for example:

The number of products synthesized by CS increased rapidly during the 1970s and 1980s, and currently there are more than 400 different compounds. Specifically, these materials include carbides (TiC , ZrC , SiC , B_4C , etc.), borides (TiB_2 , ZrB_2 , MoB_2 , etc.), silicides (Ti_5Si_3 , TiSi_2 , MoSi_2 , etc.), nitrides (TiN , ZrN , Si_3N_4 , BN , AlN), and intermetallics (NiAl , Ni_3Al , TiNi , TiAl , CoAl , etc.).

Throughout this work, a greater emphasis is placed on the SHS mode of synthesis, because more information is available for it than for the VCS mode. Also, the production of powders by gas-phase combustion synthesis processes (Ref 13, 14) is not considered in this article.

Theoretical Considerations and Phenomenology

Thermodynamics

For any reaction system, the chemical and phase composition of the final product depends on the *green mixture composition*, gas pressure, reactive volume, and initial temperature. CS reactions can be represented in the following general form:

where $X_i^{(s)}$ are the metal or nonmetal solid reactants, $Y_i^{(g)}$ are the gas-phase reactants, $(MO_x)_i^{(s)}$ are the oxide reactants, $Z_i^{(s)}$ are the reducing metal reactants, $P_i^{(s)}$ are the solid products (e.g., carbides, borides, nitrides), and $M_i^{(s)}$ are the reduced metal products. In limiting cases, Eq 5 leads to the three main classes of CS reactions:

- Gasless combustion (Eq 1): $N_Y = 0$, $N_{MO_x} = 0$, and $N_M = 0$
- Gas-solid combustion (Eq 2): $N_{MO_x} = 0$, and $N_Z = 0$, and $N_M = 0$
- Reduction-type combustion (Eq 3): $N_{MO_x} \neq 0$, and $N_Z \neq 0$

Thermodynamic calculations can identify the adiabatic combustion temperature, as well as the equilibrium phases and compounds present at that temperature. The composition of the equilibrium final products is determined by minimizing the thermodynamic potential. For a system with $N^{(g)}$ gas and $N^{(s)}$ solid number of components, at constant pressure, this may be expressed as:

$$F(\{n_k\}, \{n_i\}) = \sum_{k=1}^{N^{(g)}} n_k \left(\ln \frac{p_k}{p} + G_k \right) + \sum_{l=1}^{N^{(s)}} n_l G_l \quad (\text{Eq 6})$$

where p_k is the partial pressure of the k -th gas-phase component, n_i is the number of moles of component i , and G_l is the molar Gibbs free energy of component l (Ref 15). The adiabatic combustion temperature, T_c , is determined by total energy balance:

$$\sum_{i=1}^{N_0} H_i(T_0) = \sum_{k=1}^{N(g)} n_k H_k(T_c^{ad}) + \sum_{l=1}^{N(s)} n_l H_l(T_c^{ad}) \quad (\text{Eq 7})$$

where the enthalpy of each component is:

$$H_i(T) = \Delta H_{f,i}^0 + \int_{T_0}^T C_{p,i} dT + \sum \Delta H_{s,i} \quad (\text{Eq 8})$$

and $\Delta H_{f,i}^0$ is the heat of formation at 1 atm and reference temperature T_0 , $C_{p,i}$ is the heat capacity, and $\Delta H_{s,i}$ is the heat of s -th phase transition for component i .

Thermodynamic calculations of adiabatic combustion temperatures have been made for a variety of systems and compared with experimentally measured values (Ref 16, 17). Under conditions that lead to full conversion, good agreement between theoretical and experimental values has generally been obtained (Table 1).

Table 1 Adiabatic and measured combustion temperatures for various reaction systems

System	Adiabatic combustion temperature, K	Measured combustion temperature, K	Lowest melting point on the phase diagram, K
Carbides			
Ta + C	2700	2650	3295 (Ta)

Combustion Wave Propagation Theory

The application of combustion theory to combustion synthesis processes is based on a comparison of the mass and thermal diffusivities in the solid reactant mixture. In these types of systems, the Lewis number is very small:

$$Le = \frac{D}{\alpha} \ll 1 \quad (\text{Eq 9})$$

where D and α are the mass and thermal diffusivities, respectively, indicating that heat conduction occurs much faster than mass diffusion. As a result, mass transfer by diffusion at the *macroscopic* scale may be neglected, and an average concentration of the reactants in any local region of the heterogeneous mixture may be used. Thus, the physical and thermal properties (e.g., density, thermal conductivity, heat capacity) are the average of reactant and product values. In this case, the combustion synthesis process is controlled only by heat evolution from the exothermic reaction and heat transfer from the reaction zone to the unreacted mixture

Propagation of combustion wave through the reactant mixture with a velocity U can be described by the set of energy continuity and chemical kinetic equations (Ref 18):

$$\begin{aligned} \rho C_p \frac{dT}{dt} + \rho C_p U \frac{dT}{dx} &= \frac{d}{dx} \left(\lambda \frac{dT}{dx} \right) + Q \rho \phi(\eta, T) \\ \frac{d\eta}{dt} + U \frac{d\eta}{dx} &= \phi(\eta, T) \end{aligned} \quad (\text{Eq 10})$$

where ρ , C_p , and λ are respectively the density, heat capacity, and thermal conductivity of the reaction mixture. The term $\phi(\eta, T)$ represents the reaction rate, and x is the spatial coordinate moving with the reaction front. Assuming that the temperature (T) and conversion (η) profiles do not change with time (t), i.e. *constant-pattern propagation*, then the time derivatives can be set equal to zero. Then Eq 10 takes the form:

$$\rho C_p U \frac{dT}{dx} = \frac{d}{dx} \left(\lambda \frac{dT}{dx} \right) + Q \rho \phi(\eta, T) \quad (\text{Eq 11a})$$

$$U \frac{d\eta}{dx} = \phi(\eta, T) \quad (\text{Eq 11b})$$

along with the boundary conditions:

$$T = T_0, \frac{dT}{dx} = 0, \eta = 0 \text{ at } x \rightarrow -\infty \quad (\text{Eq 12a})$$

$$T = T_c, \frac{dT}{dx} = 0, \eta = 1 \text{ at } x \rightarrow +\infty \quad (\text{Eq 12b})$$

The solution of Eq 11a, 11b, 12a, and 12b was first obtained in the context of gas flames (Ref 19) and was later adapted for solid mixtures (Ref 20, 21) to yield the following formula for reaction wave velocity:

$$U^2 = \frac{\lambda}{\rho Q} \frac{RT_c^2}{E} k_0 \exp\left(\frac{-E}{RT_c}\right) \int_0^1 \frac{1-\eta}{\varphi(\eta)} d\eta \quad (\text{Eq 13})$$

where E is activation energy and R is a gas constant. This expression can be solved for various types of kinetics. For example, for zero-order reaction, then:

$$U^2 = \frac{2\lambda}{\rho Q} \frac{RT_c^2}{E} k_0 \exp\left(\frac{-E}{RT_c}\right) \quad (\text{Eq 14})$$

This formula is widely used to determine effective kinetic constants from experimental data, because:

$$\ln\left(\frac{U}{T_c}\right) = -\frac{E}{2RT_c} + \text{constant} \quad (\text{Eq 15})$$

Thus by varying T_c (by dilution or by changing initial temperature, T_0) and plotting $\ln(U/T_c)$ vs. $1/T_c$, the activation energy can be obtained readily. In this manner, the effective values of E have been measured for various SHS systems (Ref 5).

While providing a simple method for analyzing the redistribution of energy in the combustion wave, the model discussed above does not account for the local structural features of the reaction medium. *Microstructural models* account for details such as reactant particle size (d) and distribution, product layer thickness, and so on, and correlate them with the characteristics of combustion to give expressions of the form:

$$U = f(d) F(T) \quad (\text{Eq 16})$$

The first microstructural models were developed independently and essentially simultaneously (Ref 18, 21, 22, 23). For these models, the elementary reaction cell, which accounts for the details of the microstructure, consists of alternating lamellae of the two reactants (A and B), which diffuse through a product layer (C), to react (see Fig. 2a). Assuming that the particles are flat allows one to neglect the change in reaction surface area during synthesis. The characteristic particle size, d , is equivalent to the layer thickness, and the relative thicknesses of the initial reactant layers are determined by stoichiometry.

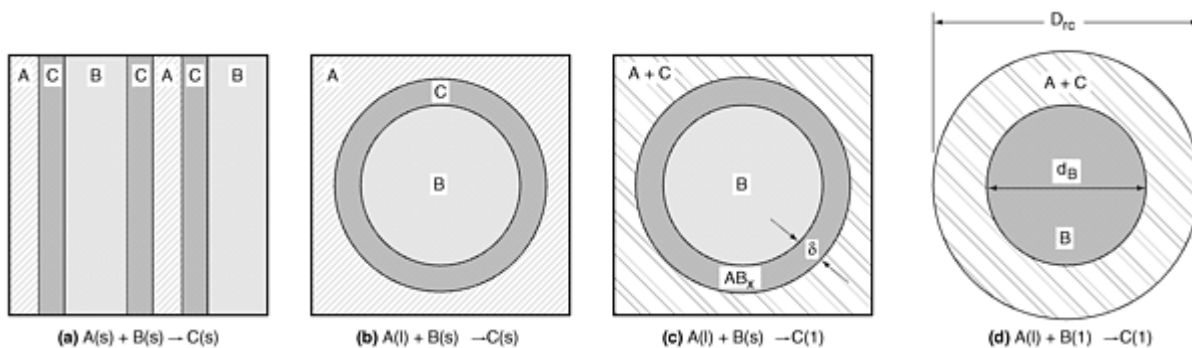

Fig. 2 Geometry of the reaction cells considered in the theoretical models

A simple analytical solution for the case of diffusion-controlled kinetics has been developed, and yields $f(d) \propto 1/d$ (Ref 21). A more accurate expression, based on the same physical geometry, was developed using the following kinetic function (Ref 22, 23):

$$\phi(\eta, T) = k_0 \exp\left(\frac{-E}{RT}\right) e^{-m\eta} \eta^{-n} \quad (\text{Eq 17})$$

which describes linear ($m = 0, n = 0$), parabolic ($m = 0, n = 1$), cubic ($m = 0, n = 2$), and exponential ($m > 0, n = 0$) kinetic dependencies. For example, the solution of Eq 11a, 11b, 12a, and 12b for power-law kinetics (i.e., $m = 0, n \geq 0$) can be written as:

$$U = \frac{(n+1)(n+2)}{d^{(n+1)/2}} F(T) \quad (\text{Eq 18})$$

For the next two types of theoretical models, the elementary reaction cell consists of a spherical particle of one reactant surrounded by a melt of the other reactant. In the first case, the product layers (C) grow on the surface of the more refractory particles (B) due to diffusion of atoms from the melt phase (A) through the product layer (see Fig. 2b). At a given temperature, the concentrations at the interphase boundaries are determined from the phase diagram of the system (Ref 24, 25). The second model (Fig. 2c) assumes that upon melting of reactant A, a layer of initial product forms on the solid reactant surface. The reaction proceeds by diffusion of reactant B through this layer, whose thickness is assumed to remain constant during the reaction (Ref 26, 27). The final product (C) crystallizes in the volume of the melt after saturation. Based on this model, an analytical expression for the combustion wave velocity has been reported (Ref 28):

$$U = \left[\frac{1}{d} \left(2 + \frac{1}{\delta} \right) \right]^{1/2} F(T) \quad (\text{Eq 19})$$

where δ is the thickness of the initial product layer.

For the case where both reactants melt in the preheating zone and the liquid product forms in the reaction zone, a simple combustion model using the reaction cell geometry presented in Fig. 2(d) has been developed (Ref 29). After both reactants melt, their interdiffusion and the formation of a liquid product occur simultaneously. Numerical and analytical solutions were obtained for both kinetic- and diffusion-controlled reactions. In the kinetic-limiting case, for a stoichiometric mixture of reactants (A and B), the propagation velocity does not depend on the initial reactant particle sizes. For diffusion-controlled reactions, the velocity may be written as:

$$U = \frac{\bar{b}}{d} \cdot F(T) \quad (\text{Eq 20})$$

where \bar{b} is a constant that depends on the mixture composition.

The microstructural models described above represent theoretical milestones in gasless combustion. Using similar approaches, other models have also been developed. For example, in Ref 30 the solid-liquid model (Fig. 2c) was used to determine the combustion velocity as a function of stoichiometry, degree of dilution, and initial particle size. Calculations for a variety of systems compared favorably with experimental data. In addition, an analytical solution was developed for diffusion-controlled reactions, which accounted for changes in λ , ρ , and C_p within the combustion wave, and led to the conclusion that $U \propto 1/d$ (Ref 31).

Phenomenological Aspects

As stated above, the characteristic feature of combustion synthesis, as compared to conventional powder metallurgy, is that the process variables, such as combustion wave velocity, U , and temperature, T_c , are strongly related. For example, a small change in T_c may result in a large change in U (see, e.g., Eq 13) and hence the characteristic time of synthesis. The

process parameters (e.g., green mixture composition, dilution, initial density, gas pressure, reactant particle characteristics) influence the combustion velocity and the temperature-time profile, and in turn can be used to control the synthesis process.

Based on the analysis of literature data and incorporation of additional details, some general relationships for gasless combustion synthesis of materials from elements have been outlined as shown schematically in Fig. 3. Both characteristic features of the process, U and T_c , have maximum values when the composition of the green mixture corresponds to the most exothermic reaction for a given system (Fig. 3a). In general, U and T_c decrease with increasing initial reactant particle size and with addition of an inert (nonreactive) diluent to the green mixture (Fig. 3b, c), while increasing significantly with increasing initial sample temperature (Fig. 3d). Different trends have been observed when the initial sample density is varied. With increasing ρ_0 , the combustion front velocity either increases monotonically or goes through a maximum, while the combustion temperature generally remains constant (Fig. 3e). A decrease in the sample size (e.g., sample diameter, D) does not influence U and T_c when the size is larger than a critical value D^* , because heat losses are negligible as compared to heat release from the chemical reaction. Below the critical sample size, both the combustion velocity and temperature decrease due to significant heat losses (Fig. 3f). Many exceptions to the dependencies discussed above have been observed, however, even for the simplest case of gasless combustion synthesis from elements. The combustion wave behavior becomes more complicated in gas-solid and reduction-type reactions. All of these effects are discussed in greater detail in Ref 8, 10, and 12.

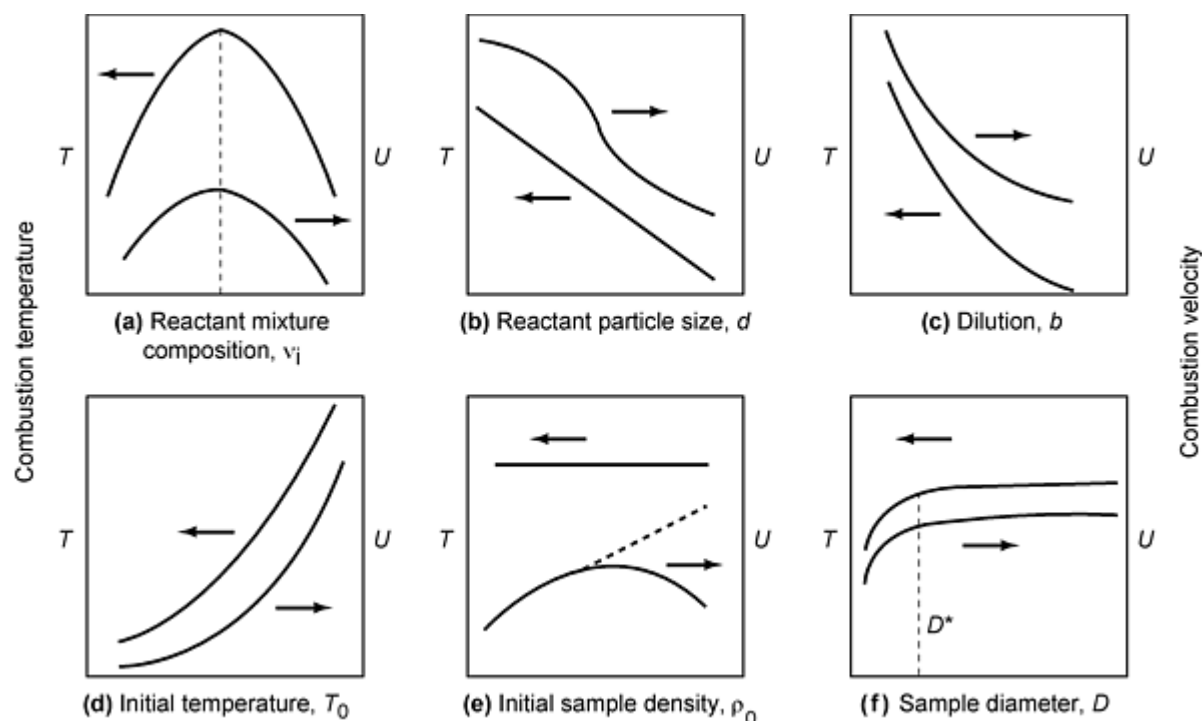

Fig. 3 Dependencies of combustion velocity, U , and maximum combustion temperature, T_c , on various combustion synthesis parameters

Within the region of optimal experimental parameters, the combustion wave velocity remains constant and the temperature profile $T(t)$ has the same form at each point of the reaction medium. This regime is called *steady propagation* of the combustion synthesis wave, or *steady SHS process*. As the reaction conditions move away from the optimum, where the heat evolution decreases and/or heat losses increase, different types of *unsteady propagation* regimes have been observed. These include the appearance of an *oscillating combustion synthesis* regime, where macroscopic oscillations of the combustion velocity and temperature occur. The reaction may also propagate in the form of a hot spot that, for example, may move along a spiral pattern in cylindrical samples, and is called the *spin combustion* regime of CS. The combustion regime has great importance in the production of materials, because it influences the product microstructure and properties.

Combustion Synthesis of Advanced Materials*

A. Varma and A.S. Mukasyan, University of Notre Dame

Methods for Large-Scale Synthesis

In general, methods for the large-scale production of advanced materials by combustion synthesis consist of three main steps: (a) preparation of the green mixture, (b) high-temperature synthesis, and (c) post-synthesis treatment. A schematic diagram of these steps is presented in Fig. 4. The first step is similar to the procedures commonly used in powder metallurgy, where the reactant powders are dried (e.g., under vacuum at 80 to 100 °C), weighed into the appropriate amounts, and mixed (e.g., by ball mixing). For some applications, cold pressing of the green mixture is necessary, especially for the production of low-porosity or poreless materials. Typically, no plasticizer is used, and the density of the cold-pressed compacts varies from 40 to 80% of the theoretical density. The final procedure in sample preparation determines the type of product to be synthesized: a powder product results from loose powder reactants, while sintered products are yielded from cold-pressed compacts. Pressing the green mixture into special molds or machining pressed initial compacts yields complex-shaped articles.

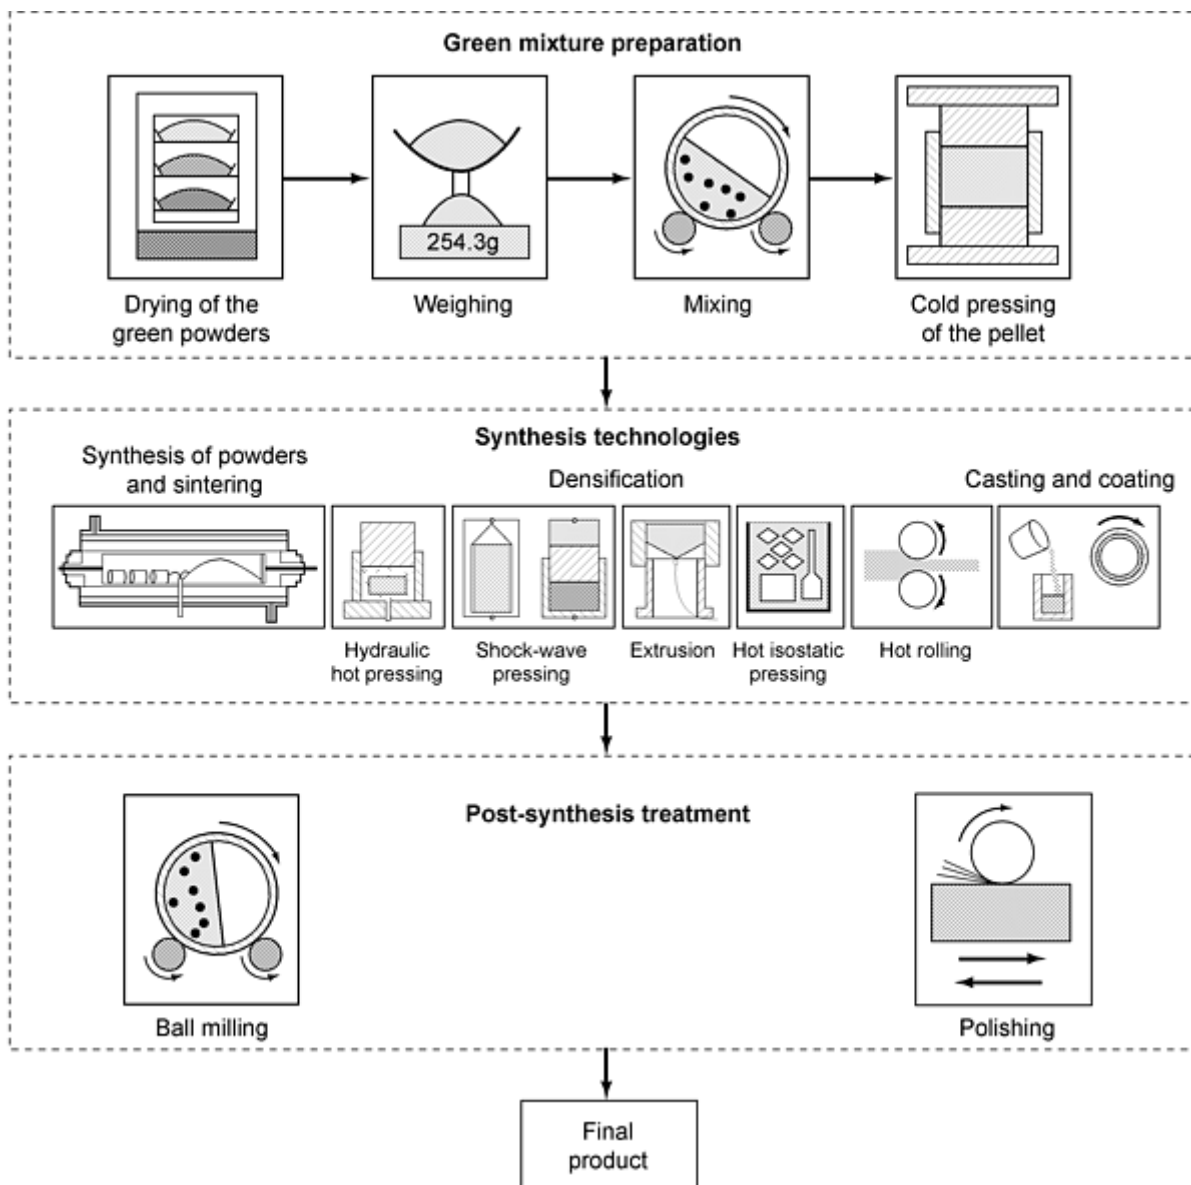

Fig. 4 Generalized schematic diagram of combustion synthesis technologies

The main production technologies of combustion synthesis by the SHS mode are presented in the second block of Fig. 4. They may be classified into several major types: powder production and sintering, densification, casting, and coating.

The third main step of combustion synthesis technologies is post-synthesis treatment. Not all products require this step. Powder milling and sieving are used to yield powders with a desired particle size distribution. Annealing at elevated temperatures (800 to 1200 °C) removes residual thermal stress in brittle products. The synthesized materials and articles may also be machined into specified shapes and surface finish.

The VCS mode is used primarily for the synthesis of weakly exothermic systems. Various types of heaters, mostly commercially available furnaces but also spiral coil and foil heaters, are used to preheat the sample to the ignition point. To date, VCS materials have been produced only in laboratories.

Powder Production and Sintering

The design of a commercial reactor for large-scale production of materials is shown in Fig. 5. Typically it is a thick-walled stainless steel cylinder, with volume up to 30 L, that can be water cooled. The inner surface of the reactor is lined with an inert material to protect the vessel from extreme reaction temperatures. Graphite is generally used for lining during carbide, boride, or silicide synthesis, while boron nitride and silicon nitride provide protection during nitride

synthesis. The green mixture or pressed compacts are loaded inside the vessel, which is then sealed and evacuated by a vacuum pump. After this, the reactor is filled with inert or reactive gas (Ar, He, N₂, O₂, CO, CO₂). Alternatively, a constant flow of gas can be supplied at a rate such that it permeates the porous reactant mixture. Two different types of reactors are used, depending on the product synthesized. The first type can maintain pressures up to 150 atm and is widely used for production of powders in gasless and gas-solid systems. Carbides, borides, silicides, intermetallics, chalcogenides, phosphides, and nitrides are usually produced in this type of reactor. The second type, a high-pressure reactor (up to 2000 atm), is used for the production of nitride-based articles and materials, because higher initial sample densities require elevated reactant gas pressures for full conversion. For example, well-sintered pure BN ceramic with a porosity about 20 to 35% was synthesized in 100 to 5000 atm N₂ (Ref 32).

Fig. 5 Schematic diagram of self-propagating high-temperature synthesis reactor

SHS with Densification

The application of an external force during or after combustion is generally required to produce a fully dense (i.e., poreless) material. A variety of techniques have been investigated for applying the external force, such as static, dynamic, and shock-wave loading (see Fig. 6).

Fig. 6 Schemes of self-propagating high-temperature synthesis densification. 1, sample; 2, press die; 3, pressure-transmitting medium; 4, pressing body; 5, ignitor; 6, metal container; 7, massive piston; 8, explosive; 9, electric fuse; 10, glass containers; 11, "chemical furnace" mixture

The oldest method uses a relatively slow static loading provided by a hydraulic press along with a specially designed die (Ref 33, 34, 35, 36, 37). Owing to the high temperature of the combustion products being densified, several approaches have been used to isolate the reacting sample from the die. One possible solution is the use of steel dies lined with graphite or BN ceramics (Ref 38). Another possibility is to use a pressure-transmitting medium such as SiO_2 (sand) or Al_2O_3 , as shown in Fig. 6(a) (Ref 39). Essentially poreless (porosity less than 1%) and large-scale (up to 1 m in diameter) ceramic and metal-ceramic composite materials (Fig. 7) can be produced by SHS using the static pressing method (Ref 40).

Fig. 7 Commercially produced hard-alloy articles. Reprinted with permission. Source: Ref 6

Another method of SHS densification involves high-speed loading by an explosion shock. Two possible schemes of *high-speed shock-wave pressing* are presented in Fig. 6(b). The first method provides axial densification; the other, radial densification. The dynamic axial densification method has been used to synthesize dense materials including TiC, TiB₂, and HfC (Ref 41, 42, 43, 44). The radial shock-wave densification technique has been applied to produce several materials, including dense high-temperature ceramic superconductor, YBa₂Cu₃O_{7-x} (Ref 45, 46).

In the techniques described above, combustion synthesis was first initiated, and then dynamic loading was applied to the hot product immediately after the combustion front propagated through the sample. Alternatively, shock compression applied to the reaction mixture may result in a rapid increase in temperature, initiating the chemical reaction with supersonic propagation rates. This approach, called *shock-induced synthesis*, has recently been developed (Ref 47, 48, 49). A variety of dense silicides (e.g., MoSi₂, NbSi₂, Ti₃Si₃, TiSi₂) and aluminides (NiAl, NiAl₃) have been synthesized using this method. Although the boundary between combustion and shock-induced synthesis is not well defined, the difference between them is addressed in a review article that describes different shock-induced methods to synthesize materials (Ref 50).

Another method used for the production of fully dense materials by combustion synthesis is SHS with *extrusion*, shown schematically in Fig. 6(c) (Ref 51). In this case, a powder compact of the reaction mixture is placed in the mold, and the process is initiated locally by a heated tungsten wire. After the combustion wave has propagated through the sample, appropriate pressure is applied to the plunger, extruding the products through the hole of the conic die. A high plasticity at the elevated reaction temperature allows the formation of long rods of refractory materials. The form and size of the die hole determine the extruded product configuration. The best developed application of SHS extrusion to date is the production of TiC-based cermet electrodes used for electric spark alloying (Ref 52).

A promising method for densification of combustion-synthesized products is a combination of SHS with *hot isostatic pressing* (HIP). This idea was first applied to the synthesis of TiB₂ ceramics under a pressure of 3 GPa, provided by cubic anvil press, resulting in 95% dense material (Ref 34, 53). The relatively low exothermic reaction of SiC from elemental powders was also carried out under these conditions (Ref 54), and 96% conversion to β-SiC was achieved as compared to 36% conversion when the reaction was initiated locally.

Another approach is to use high gas pressure for densification of the product simultaneously with combustion synthesis. The method of SHS + HIP with pressing by gas has been developed by using a so-called "chemical furnace." A schematic drawing of this *gas pressure combustion sintering* method is shown in Fig. 6(d) (Ref 34, 35). The green mixture is placed in evacuated glass containers, which are surrounded by a highly combustible mixture (e.g., Ti + C) that is enveloped by high-pressure gas (e.g., argon at 100 MPa). After ignition, the combustible mixture acts as a chemical furnace that heats the samples in the containers to their ignition point. The heat evolved from the chemical furnace also heats the glass to its softening temperature, where it becomes plastic and easily deformable. The material synthesized inside the containers is

then pressed isostatically by the surrounding high gas pressure to zero porosity. A variety of ceramics, cermets, and functionally graded materials have been produced using this method, such as TiC, TiB₂, TiB₂-Ni FGM (Ref 56, 57), MoSi₂-SiC/TiAl FGM (Ref 58), and Cr₃C₂-Ni (Ref 59).

Along with the various methods of combustion product densification, the *hot rolling* technique has been investigated (Ref 60, 61). It has been shown that simultaneous synthesis and hot rolling of intermetallic and ceramic materials (e.g., TiAl, TiC_{0.47}) under vacuum yields articles with porosity in the range of 5 to 50% (Ref 61).

SHS with Casting

Combustion synthesis of highly exothermic reactions (typically reduction-type) often results in completely molten products, which may be processed using common metallurgical methods. Casting of CS products under inert gas pressure or centrifugal casting has been used to synthesize cermet ingots, corrosion- and wear-resistant coatings, and ceramic-lined pipes.

Casting under gas pressure is similar to conventional SHS production. The reduction-type initial mixture (e.g., CrO₃ + Al + C, WO₃ + Al + C) is placed in a casting die and the reaction is initiated under an inert gas pressure (0.1 to 5 MPa) to prevent product sputtering by gas evolution from the thermite reaction (Ref 62, 63). Also, the molten product may consist of two immiscible phases, either molten oxides (e.g., Al₂O₃, MgO) with dispersed non-oxides (e.g., metals carbides or borides) or molten metals with dispersed ceramic droplets. Owing to the difference in densities, the two phases may separate. By controlling the characteristic times of cooling (t_{cool}) and phase separation (t_{ps}), different distributions of phases may result. Thus, it is possible to obtain cermets with uniform ($t_{cool} \ll t_{ps}$), gradient ($t_{cool} \sim t_{ps}$), and layered ($t_{cool} \gg t_{ps}$) products.

Centrifugal casting allows for greater control of the distribution of phases by controlling the time of separation. The two types of centrifugal casting equipment are shown in Fig. 8 (Ref 64). For *radial centrifuges* (Fig. 8a), the sample is placed at a fixed radial position from the axis of rotation, and the applied centrifugal force is parallel to the direction of propagation. The influence of centrifugal acceleration on the degree of phase separation, η_{ps} , is shown in Fig. 9. This parameter characterizes the phase distribution in the final product:

$$\eta_{ps} = m_s/m_t$$

where m_s is the mass of the non-oxide phase (e.g., metal, carbide, boride) fully separated from the oxide matrix, and m_t is the total mass of this phase produced by the reaction. Thus, $\eta_{ps} = 0$ for the cermet product with uniformly distributed oxide and non-oxide phases, while $\eta_{ps} = 1$ for multilayer materials or cases in which the metal-type ingot is totally separated from the oxide slag layer. Finally, the ingots have a gradient distribution of phases when $0 < \eta_{ps} < 1$.

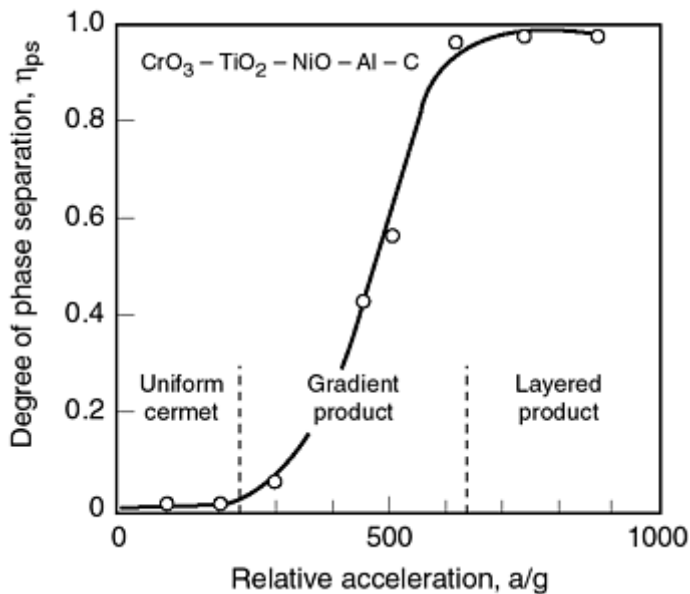

Fig. 9 The degree of phase separation as a function of centrifugal acceleration, a , where g is acceleration due to gravity. Source: Ref 64

The second type of centrifugal casting apparatus, called an *axial centrifuge* (Fig. 8b), is used for production of ceramic, cermet, or ceramic-lined pipes. The axial centrifuge casting method was developed further for production of long pipes with multilayer ceramic inner coatings (Ref 65, 66). In this process, a thermite mixture (e.g., $Fe_2O_3/2Al$) is placed inside a rotating pipe and ignited locally. A reduction-type combustion reaction propagates through the mixture, and the centrifugal force results in separate layers of metal and ceramic oxide, with the latter forming the innermost layer (Fig. 10). The process is carried out in air under normal pressure, and pipes with diameters up to 30 cm and 5.5 m long have been obtained.

Combustion Synthesis of Advanced Materials*

A. Varma and A.S. Mukasyan, University of Notre Dame

Classes and Properties of Synthesized Materials

The synthesis of several hundred materials, by both the SHS and VCS modes, has been reported in the literature. The types of compounds produced include carbides, borides, intermetallics, silicides, aluminides, composites, nitrides, hydrides, and oxides. This section describes the synthesized compounds, as well as the materials (i.e., powders, poreless materials, and functionally graded materials) and articles produced.

Gasless Combustion Synthesis from Elements

Group IV Metal Carbides. Group IVa transition metal carbides (TiC, ZrC, HfC) were among the first compounds synthesized by the SHS method (Ref 67). With high melting points, high hardness, and good chemical stability, these materials can be used as abrasives (economical substitutes for diamond powders and pastes) or as components of cermet and ceramic materials (Ref 68).

These compounds have relatively high heats of formation (e.g., -185 kJ/mol for TiC and -198 kJ/mol for ZrC). The heat evolved upon initiation of the reaction allows the materials to be synthesized in the SHS mode, with a high degree of conversion. For example, the amount of unreacted carbon has been reported to be as low as 0.09 wt% for TiC and 0.01 wt% for ZrC and HfC (Ref 67). Emission spectrochemical analysis of the powders (Ref 16) has confirmed the high purity of the combustion-synthesized TiC, where the largest impurity constituents were Al (up to 2000 ppm), Ar (300 ppm), Si (100 ppm), Fe (100 ppm), B (80 ppm), and Ca (30 ppm). The impurities in the product were typically 2 to 7 times lower than in the initial mixture. Owing to the high temperature of combustion, the material self-purifies by purging any volatile impurities from the reaction mixture. Some properties of SHS powders are presented in Table 2.

Table 2 Some characteristics of self-propagating high-temperature synthesis powders

Powder	Chemical composition, wt%	Main impurities, wt%	Average particle size, μm or specific surface area, m^2/g
TiC	$C_{\text{fixed}} = 19.2-19.5$	$C_{\text{free}} < 0.8$	3-5 μm
TiC (titanium carbide abrasive)	Ti = 77.0-79.5 $C_{\text{fixed}} = 18.0-19.8$	$C_{\text{free}} < 0.2-2.0$ Mg = 0.06 Fe = 0.1	Polydispersed 1-200 μm
NbC	$C_{\text{total}} = 11.0$	$C_{\text{free}} < 0.1$ O < 0.2	Polydispersed 1-100 μm
SiC (β - phase)	$C_{\text{total}} = 27.0-27.8$	$C_{\text{free}} < 0.3-0.8$ O < 1.0 Fe < 0.2	8-10 m^2/g
BC₄	$B_{\text{total}} = 74$ $C_{\text{total}} = 20.0$	$B_2O_3 < 0.5$ Mg < 0.5	3.9 m^2/g
TiB₂ (polydispersed)	Ti = 69.6 $B_{\text{total}} = 29.2$	O < 0.5	1-200 μm
TiB₂ (finely dispersed)	Ti = 66.7 $B_{\text{total}} = 30.5$	$B_2O_3 < 0.2$ Mg < 0.3	1-10 μm
MoSi₂	Mo = 61.9-62.5 $Si_{\text{total}} = 35.5-36.5$	$Si_{\text{free}} < 0.3$ O < 0.3 Fe < 0.1	1-50 μm
TiSi₂	Ti = 44.3 $Si_{\text{total}} = 52.0$	O < 0.1 Fe < 0.1	1-100 μm

Source: Ref 32, 163

The high heat of formation of TiC and specific features of the Ti-C phase diagram make it possible to produce, by CS, non-stoichiometric carbides, TiC_x ($x = 0.38$ to 1.0) (Ref 69), self-binding materials that consist of non-stoichiometric TiC and titanium located along the carbide grain boundaries, and cemented carbides (Ref 70). A wide variety of metal additives have been also used to produce dense cermets, where combustion-synthesized TiC grains are joined by metal (e.g., up to 60 wt% Ni or Fe) or intermetallic binders. Static pressing of hot TiC_x immediately after synthesis yields dense ceramic or cermet (self-binded carbide) materials, with product densities as high as 99% of theoretical (Ref 16, 39, 70). Dense self-binded TiC_x -Ti cermets with residual porosity $\sim 1\%$ have also been produced by pseudo-HIP (Ref 71, 72). By applying SHS with isostatic pressing to a $Ti + 0.42C$ green mixture, dense (4.54 g/cm^3) cermets with high hardness (86 to 87 HRA) and bending strength (652 MPa) have been synthesized.

The production of TiC-based materials with different binders has been reported: TiC + Ni (Ref 73, 74), TiC + (Ni-Al) (Ref 75, 76), TiC + (Ni-Mo) (Ref 70, 77), TiC + (Ni-Mo-Cu) and $(TiC-Cr_3C_2) + Ni$ (Ref 70), $(TiC-Cr_3C_2) + steel$ and $(TiC-TiN) + (Ni-Mo)$ (Ref 32), TiC + (Ti-Al) (Ref 78), and TiC-Al (without pressing) (Ref 79). Some properties of combustion-synthesized and static-pressed cemented carbides are listed in Table 3, and characteristic microstructures of TiC-Ni cermets are shown in Fig. 11.

Table 3 Some properties of self-propagating high-temperature synthesis cermet alloys

Cemented carbide alloy	Basic composition	Density, g/cm^3	Average grain size, μm	Hardness, HRA	Ultimate flex strength, kg/mm^2	Application
STIM-1B/3	TiC/TiB ₂ + Cu	4.94	5-7	93.5	70-80	Cutting edges, targets
STIM-2	TiC + Ni	5.50	5-7	90.0	100-120	Wear-resistant coatings
STIM-2A	TiC + (Ni-Mo)	6.40	1-2	87.0	160-180	Press tools
STIM 3B/3	TiC-Cr ₃ C ₂ + Ni	5.37	3-4	92.5	80-100	Cutting edges
STIM-3B	TiC-Cr ₃ C ₂ + steel	5.40	2-4	92.5	100-120	Corrosion-resistant articles

Group Va Carbides. To a lesser extent, combustion synthesis from elements of transition (Group Va) metal carbides has also been investigated, especially for TaC (Ref 80, 81) and NbC (Ref 82). Some properties of reaction-synthesized NbC powders are presented in Table 2.

Nonmetal Carbides. Among non-metallic carbides, SiC synthesized from elemental silicon and carbon powders has attracted the most attention. Silicon carbide has a relatively low heat of formation (69 kJ/mol), and additional heat input is required for combustion to occur. For example, locally igniting pressed Si + C samples, placed on a ribbon heater, yielded ~64% conversion to β -SiC, while increasing the area of ignition with a specially designed carbon-sleeve heater improved the conversion to ~99% (Ref 83). Dense SiC ceramics have been produced by combining the carbon-sleeve heater with hot pressing (Ref 54). Another method of heating and ignition is to pass an electric current through the sample, yielding fine stoichiometric SiC powders (Ref 53). Fine-grained powders (0.2 to 0.5 μ m) with high specific surface area (6.2 m²/g) have been synthesized in the VCS mode by inductively preheating the Si + C mixture 1300 °C (Ref 84, 85). Solid SiC and SiC-C blocks have also been produced by infiltration of arc-melted silicon into porous carbon, during which the SHS reaction occurred (Ref 86). A characteristic microstructure of SiC powder synthesized by the SHS method is shown in Fig. 12.

Fig. 12 Characteristic microstructure of self-propagating high-temperature synthesis β -SiC powder conglomerate (16,000 \times)

An alternative method of activating the reaction between silicon and carbon without preheating has been reported (Ref 87), which involves using potassium nitrate (KNO_3) as an activating agent. With this method, fine SiC powders containing 28 to 29 wt% bound carbon and 0.5 wt% free carbon have been produced.

Borides. Most of the transition metal borides can be synthesized in the SHS mode (Ref 88, 89). Early works reported synthesis of relatively pure (with residual unreacted boron less than 0.3 wt%) ZrB_2 , TiB_2 , HfB_2 , and MoB (Ref 4, 67). Combustion-synthesized borides also include TiB , TaB_2 , LaB_6 , and NbB_2 (Ref 7). Similar to TiC for carbides, the combustion synthesis of transition metals borides from elements has focused primarily on TiB_2 .

The high heat of formation for these borides (e.g., -279 kJ/mol for TiB_2 , -160 kJ/mol for TiB) makes it possible to add chemically inert metals and alloys (or weakly exothermic mixtures) to the metal-boron system. The subsequent plasticity of the products at the combustion temperature allows for various methods of densification to be applied, yielding poreless boride ceramics or boride-based cermets. For example, dense TiB -Ti self-binding borides (Ref 90) and TiB_2 ceramics with 95% theoretical densities (Ref 36) have been formed by hydraulic pseudo-isostatic pressing and uniaxial pressing in a graphite-lined die, respectively. The hydrostatic pressing method has also been applied to synthesize TiB_2 -TiNi composites with 93% relative density and molar content of TiNi ranging from 0 to 95% (Ref 91). Dense TiB_2 ceramic materials have been formed by high-pressure combustion sintering under 3 GPa in a cubic anvil press (Ref 34), as well as by gas HIP at 100 MPa using a chemical furnace (Ref 92). Synthesis of composite products, such as TiB_2 -Al (Ref 93) and TiB_2 -Fe (Ref 94), has also been reported.

TiC-TiB₂ Composite Ceramics. In some cases, several refractory compounds can result from two or more parallel reactions occurring simultaneously in the combustion wave. A typical example is the Ti-C-B system, where both the $\text{Ti} + \text{C}$ and $\text{Ti} + 2\text{B}$ reactions affect the combustion synthesis and structure formation processes (Ref 95). By adjusting the contents of carbon and boron powders in the reactant mixture, either carbide- or boride-based ceramics may be obtained.

The Ti-C-B system has been used for a series of ceramic poreless composites produced by the SHS + HIP method (Ref 70). Near-eutectic 40TiC-60TiB₂ (wt%) compositions were primarily investigated, while various metal additives were tested (e.g., Co, Cu) as the binder phase, with contents varying from 0 to 12 wt%. The materials demonstrated good mechanical properties (Table 3) and may be used for cutting tools. Materials with higher TiC content (80 wt%) possess higher bending strength.

Silicides. Compounds of metals with silicon were synthesized from elements by both the SHS (Ref 96, 97, 98, 99) and VCS modes (Ref 100). Powders and sintered samples of various chemical compositions were obtained, including Ti_5Si_3 , $TiSi$, $TiSi_2$, Mo_3Si , Mo_5Si_3 , $MoSi_2$, Zr_2Si , Zr_5Si_3 , $ZrSi$, and $ZrSi_2$. Among them, titanium and molybdenum silicides have received the most attention due to their high melting points, excellent oxidation resistance, relatively low density and high electrical and thermal conductivities (Ref 101, 102). The properties of some silicide powders are shown in Table 2.

Combustion-synthesized $MoSi_2$ powders have been used to produce high-temperature heating elements (Ref 6). The application of the SHS + extrusion method for one-step production of $MoSi_2$ heaters has been reported (Ref 51). Combustion synthesis of molybdenum aluminosilicide (Mo-Al-Si) has also been demonstrated (Ref 103).

Aluminides. Combustion synthesis of nickel aluminides in the VCS mode was first demonstrated during sintering of a Ni-Al mixture (Ref 104). Shortly thereafter, the SHS mode of combustion synthesis was reported for a variety of aluminides, including those of Zr, Ti, Cr, Co, Mo, Cu, Fe, Nb, etc. (Ref 105, 106, 107, 108, 109, 110). However, most attention has been paid to nickel aluminides (Ref 111, 112, 113) and titanium aluminides (Ref 114, 115, 116).

As discussed above, aluminides have been used as binders for carbide- and boride-based cermets, for example by adding nickel and aluminum powders to exothermic mixtures of titanium with carbon or boron. On the other hand, some intermetallic compounds (e.g., NiAl, Ni_3Al , TiAl) possess high enough heats of formation that composites with intermetallic matrices can be produced either in the VCS or SHS regimes. The ceramic components are either added in the green mixture or synthesized in situ during the reaction.

For example, Ni_3Al -matrix composites reinforced by Al_2O_3 , SiC, or B_4C whiskers have been formed in the SHS mode (Ref 117, 118). A typical microstructure of Ni_3Al/Al_2O_3 composite is shown in Fig. 13. $Ni_3Al-TiB_2$ composites have been synthesized in situ under microgravity conditions ($a = 10^{-4} m/s^2$). The kinetics of growth of TiB_2 particles in the Ni_3Al matrix, for both normal and microgravity environments, are shown in Fig. 14, indicating that finer microstructure results in reduced gravity synthesis (Ref 119). NiAl-matrix composites reinforced with TiB_2 particles (10 and 30 wt%) have been synthesized using SHS + HIP hot pressing (Ref 120). The TiAl matrix was formed in the SHS mode, while reinforcing SiC particles were added in the initial Ti + Al mixture (Ref 121). Also, aluminum and TiAl₃ matrix composites, reinforced by TiC, TiB_2 , and TiC + TiB_2 particles synthesized in situ, were fabricated recently in the SHS regime (Ref 122).

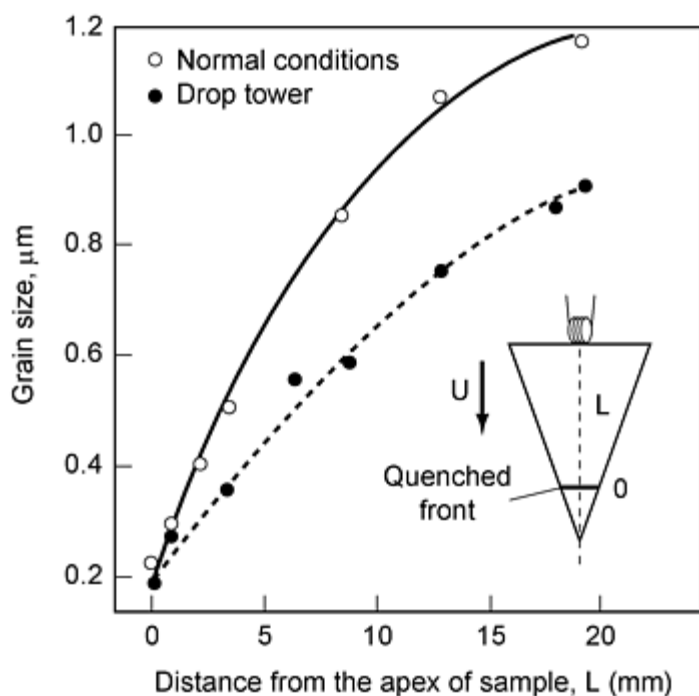

Fig. 14 Evolution of TiB_2 grain size in $(3Ni + Al)/(Ti + 2B)$ quenched sample. Source: Ref 119

Owing to their high plasticity at the combustion temperature, poreless aluminides can be produced using various methods of densification. Dense titanium materials have been obtained in the VCS regime with pseudo-HIP (Ref 123), while hydraulic hot pressing combined with SHS has been used to form NiAl-matrix composites with porosities of 1% or less (Ref 119). Hot rolling under vacuum has been applied to form combustion-synthesized TiAl (Ref 61). Other materials have been synthesized by the extrusion of nickel-rich NiAl (Ref 109). Shock-induced synthesis with dynamic densification has been reported for titanium, niobium, and nickel aluminides (Ref 47, 124, 125). Densification of iron aluminides and Fe_3Al -matrix composites reinforced with Al_2O_3 particles has been performed by pressing in graphite-lined dies at 10 to 70 MPa (Ref 113), as well as by HIP and pseudo-HIP (Ref 126). It has been shown that a 99.7% dense Fe_3Al -Nb alloy billet can be prepared by SHS followed by superplastic consolidation (Ref 127).

Compounds of Titanium. While intermetallic Ti-(Ni, Co, Fe) compounds cannot be synthesized from elemental powders without preheating, a relatively low increase above room temperature is generally sufficient to initiate a self-sustained reaction. Almost all compounds of the Ti-Ni, Ti-Co, and Ti-Fe systems have been produced by this method (Ref 128, 129, 130). Intermetallic TiNi compounds are especially attractive for their shape memory characteristics. Combustion-synthesized Ti-Ni powders and materials have been used in the industrial production of sheets, tubes, and wires with shape memory in Russia (Ref 131) and in Japan (Ref 132). Cold-deformed binary alloys have retained up to 90% of their original shape, while 99.5% of the original shape may be restored for ternary alloys (e.g., Ti-Ni-Fe and Ti-Ni-Al). A 70 kg coil of hot-rolled TiNi wire produced by the CS + HIP technique is shown in Fig. 15 (Ref 132).

Fig. 15 Hot-rolled coil (70 kg) of NiTi wire (9.5 mm diameter) after forging. Reprinted with permission. Source: Ref 132

Diamond Composites. At normal pressures, diamond is a metastable phase of carbon. At temperatures higher than 1300 K (either in vacuum or inert gas), it converts to graphite. The rate of conversion is extremely rapid at temperatures higher than 2000 K (Ref 133). Thus, graphitization during sintering of diamond composites makes it difficult (if not impossible) to produce refractory-matrix composites with diamond particles. Due to the short time of interaction, SHS is an attractive method for producing diamond-containing composite materials with refractory and wear-resistant matrices. SHS combined with pressing (pseudo-HIP) has been used to obtain TiB-diamond composites from elemental Ti + B with up to 20 wt% synthetic diamond (Ref 134). By decreasing the combustion temperature from 2200 to 1900 K, the extent of graphitization was reported to decrease from 6 to 0.5% (Ref 135). Further investigation of the combustion synthesis of TiB- and NiAl-matrix diamond-containing materials has shown that under certain conditions, diamond particles retain their shape, surface quality, and mechanical properties after synthesis (Ref 136, 137). The characteristic microstructure of the diamond-containing portion of an Ni-Al/diamond composite synthesized by SHS is shown in Fig. 16.

Fig. 16 Characteristic microstructure of the diamond-containing region in a Ni-Al diamond composite produced by self-propagating high-temperature synthesis. Reprinted with permission. Source: Ref 137

Functionally Graded Materials. The concept of functionally graded materials (FGMs) to tailor nonuniform distribution of components and phases in materials, and hence combine mechanical, thermal, electrical, chemical, and other properties that cannot be realized in uniform materials. For example, the material structure may have a smooth transition from a metal phase with good mechanical strength on one side, to a ceramic phase with high thermal resistance on the other side (see Fig. 17). With a gradual variation in composition, FGMs do not have the intermaterial boundaries found in multilayer materials, and hence they exhibit better resistance to thermal stress.

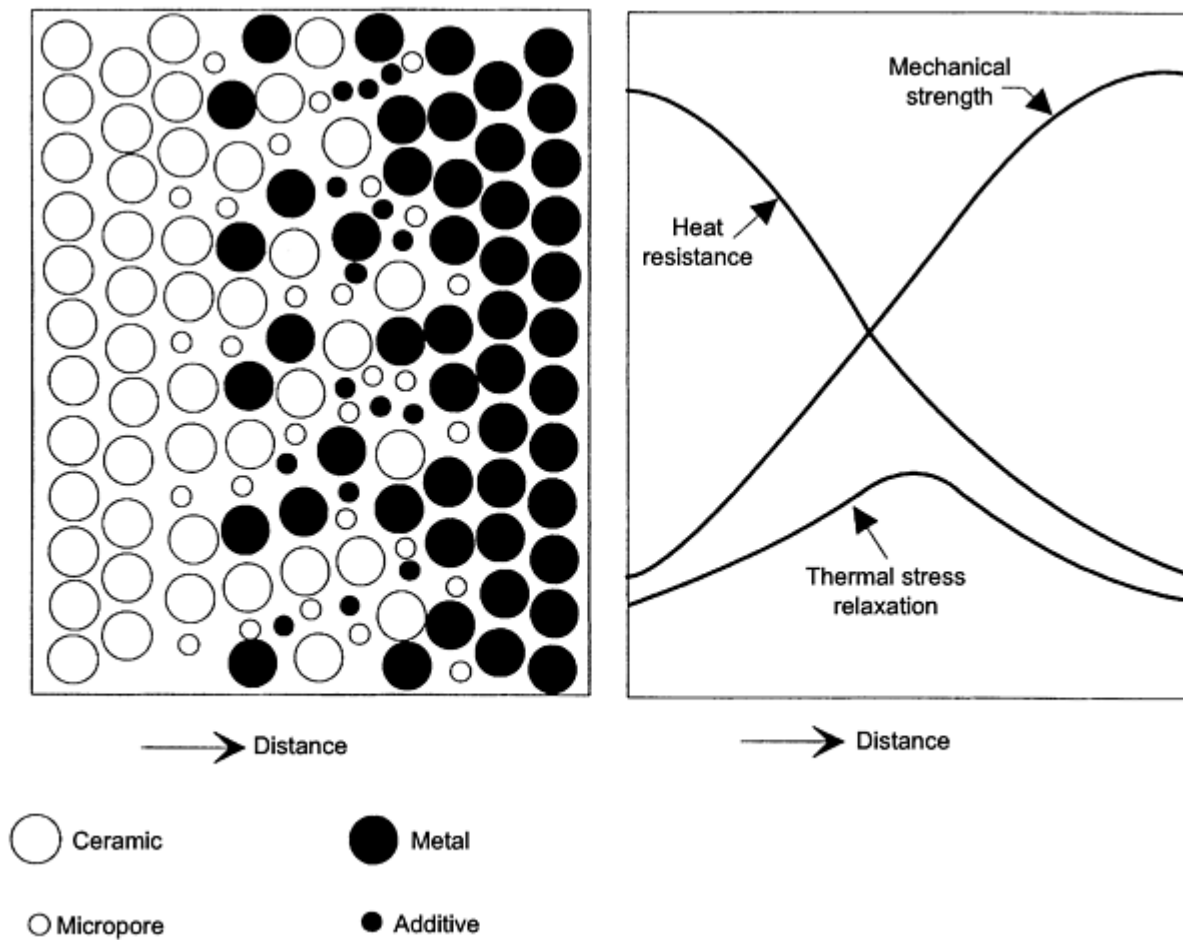

Fig. 17 The concept of functionally graded materials. Source: Ref 138

Combustion synthesis has been applied successfully in the production of $\text{TiB}_2\text{-Cu}$ FGM, with the amount of TiB_2 varying from 0 (metal side) to 100% (ceramic side) for cylindrical samples, 30 mm in diameter and 5 mm thick (Ref 138). A predetermined distribution of elements in the green mixture was created using an automatic powder stacking apparatus. During synthesis, simultaneous densification by hydrostatic pressing was also applied. Similar methods were used to produce $\text{TiB}_2\text{-Cu}$ FGM samples from cylindrical green compacts, 17 mm in diameter and 10 mm in height (Ref 140).

The method of gas-pressure combustion sintering was applied to produce a TiC-Ni FGM (Ref 56). The Vickers microhardness of this material gradually changed from 2 GPa at the nickel side to 23 GPa at the TiC side, where the TiC grain size decreased with increasing local nickel content. Figure 18 shows the microstructure of a $\text{Cr}_3\text{C}_2/\text{Ni}$ FGM, consolidated by the SHS + HIP method from a green compact consisting of powder layers with different Cr-C-Ni compositions.

Fig. 18 SEM image of $\text{Cr}_3\text{C}_2/\text{Ni}$ functionally graded material microstructure. Reprinted with permission. Source: Ref 139

Another approach is to prepare a green mixture with relatively few (typically two or three) layers, but so that desired gradients in the product appear during the SHS process due to infiltration and migration of melts, diffusion, and other transport phenomena (Ref 141). This approach has been used to produce poreless functionally gradient cermets, including TiC-Ni and (Ti,Cr)C-Ni, by combining SHS with pseudo-HIP. An example of a multilayer material synthesized by CS + hot pressing is the $\text{TiB}_2\text{-Al}_2\text{O}_3\text{-ZTA}$ (zirconia toughened aluminum) composite. The microstructure of this layered material is shown in Fig. 19 (Ref 142). The layers can have different thicknesses and are well bonded to one another. The production of diamond-containing FGMs has also been reported (Ref 143), where properties of materials are determined by the gradient distribution of diamond in the combustion-synthesized matrix.

Fig. 19 SEM photomicrograph of multilayer $\text{TiB}_2/\text{Al}_2\text{O}_3$ with zirconia-toughened alumina. Reprinted with permission. Source: Ref 142

Other Classes of Products. Chalcogenides, including sulfides and selenides of Mg, Ti, Zr, Mo, and W represent another group of compounds that can be synthesized from elements during the combustion process. Experimental synthesis of luminescent ZnS samples was also carried out (Ref 144). Combustion reactions between chalcogenides and alkali metal compounds have been applied to produce GaAs and GaP from solid-state precursors (Ref 145). In addition, compounds of metals (Ni, Cu, Zr, etc.) with phosphorus were obtained (Ref 146, 147). Also, phosphides of Al, Ga, and In were formed by direct combustion synthesis from elemental powders (Ref 148). An interesting example of the combustion synthesis of aluminum iodide Al_2I_6 from a mixture of aluminum powder with crystalline iodine has been reported (Ref 149). It should be noted, however, that synthesis of chalcogenides, phosphide, and iodides represents a process intermediate between gasless and solid-gas processes due to intense vaporization of the nonmetal reactant during combustion.

Among intermetallic compounds not mentioned previously, Mg_2Ni is a promising material for storing hydrogen. It has been shown that the combustion synthesis of this material is feasible, in spite of a relatively low heat of reaction. For example, high-purity Mg_2Ni has been obtained in the SHS mode (Ref 150).

Combustion Synthesis in Solid-Gas Systems

Nitrides and nitride-based ceramics produced by combustion synthesis in solid-gas systems are described below.

Metallic Nitrides. A wide variety of metallic nitrides, including TiN, ZrN, NbN, HfN, TaN, and VN, have been produced by combustion synthesis. Among these, titanium and zirconium nitrides have been investigated most thoroughly. These nitride powders can be used to form refractory corrosion-resistant coatings and conducting materials in electronic applications. Depending on the nitrogen pressure, titanium and zirconium nitrides with a wide range of nitrogen compositions have been synthesized, ranging from solid solutions with a minimum amount of nitrogen ($\text{MeN}_{0.1}$) to single-phase supersaturated solutions ($\text{MeN}_{0.34}$ to $\text{MeN}_{0.45}$), as well as stoichiometric MeN. Full conversion to the stoichiometric compound can be achieved by dilution of the initial metal powder with the corresponding nitride product (Ref 151, 152).

Other metallic nitrides have been synthesized by combustion synthesis. SHS-vanadium nitride (Ref 153) is the basis of ferrovanadium ($\text{VN} + \text{Fe}$), a commonly used alloying agent for the manufacture of steels with low-temperature applications (Ref 154). A unique cubic structure of TaN, which has the highest microhardness among all transition metal nitrides (3200 kg/mm^2) and can be used as a hard alloy component, has been formed during combustion of tantalum powder in liquid nitrogen (Ref 155). Niobium nitride powders, with a transition temperature to superconductivity at 14.3 K, have been synthesized by SHS. In addition to powders, thin superconducting plates and wires of NbN have been obtained using $\text{Nb} + \text{NbN} + \text{N}_2$ mixture as a chemical furnace (Ref 156). Both SHS and VCS modes have been used for the synthesis of magnesium nitride, Mg_3N_2 (Ref 157). The characteristics and properties of some combustion-synthesized transition metal nitrides are presented in Table 4.

Table 4 Some characteristics and properties of metallic self-propagating high-temperature synthesis nitride powders

Products	Chemical composition, wt%	Impurities, wt%	Particle size and specific, surface area	Other properties
Titanium nitride (cubic, $a = 4.24$)	Ti = 77.0-78.5, N = 2.03-21.5	O = 0.3-0.5, Fe < 0.2	1-200 μm , easily grindable	$H = 1800 \text{ kg/mm}^2$
Hafnium nitride (cubic, $a = 4.510$)	Hf = 92.0-94.0, N = 5.9-6.0	O = 0.3-0.5	1-50 μm	$T_{\text{sc}} = 6.6 \text{ K}$
Tantalum nitride (cubic, $a = 4.323$)	Ta = 91.7-92.2, N = 7.3-7.6	O = 0.1-0.3, C = 0.05-0.1	1-10 μm , 0.6 m^2/g	$H = 3200 \text{ kg/mm}^2$
Zirconium nitride (cubic, $a = 4.576$)	Zr = 87.3, N = 12.6	O = 0.3-0.5, Fe < 0.2	1-200 μm	$H = 1570 \text{ kg/mm}^2$, $T_{\text{sc}} = 9.6 \text{ K}$
Niobium nitride (cubic, $a = 4.385$)	Nb = 86.9, N = 6.1	O = 0.1-0.3, C = 0.05-0.1	1-50 μm	$H = 1670 \text{ kg/mm}^2$, $T_{\text{sc}} = 14.3 \text{ K}$

H, Microhardness; T_{sc} , transition temperature to superconducting state. Source: Ref 67, 163

Nonmetallic nitrides including Si_3N_4 , BN, and AlN, have important applications as high-temperature structural ceramics. As discussed above, two methods may be used to produce nitrides by CS: elemental reactions ($\text{Si} + \text{N}_2$, $\text{B} + \text{N}_2$, $\text{Al} + \text{N}_2$) and reduction reactions (e.g., $\text{B}_2\text{O}_3 + \text{Mg} + \text{N}_2$). Tables 5, 6, and 7 compare the chemical composition and specific surface area of powders produced by CS and by conventional method. Powders synthesized by SHS (see Fig. 20) have nitrogen contents that are comparable to, if not higher than, those of powders produced by conventional methods. The metal impurities (mainly iron) are the consequence of either inappropriate mixing/grinding equipment or impure raw materials, both of which may be remedied. The mechanism of combustion SHS nitrides synthesized from elements has also been investigated (Ref 158).

Table 5 Some characteristics and properties of Si₃N₄ powders

Parameter	SHS	SHS
	β -phase	$\alpha + \beta$ -phase, ($\alpha \geq 80\%$)

Fig. 20 Characteristic microstructure of self-propagating high-temperature synthesis Si_3N_4 powders. (a) α - Si_3N_4 . 8,625 \times . (b) β - Si_3N_4 . 15,000 \times

The industrial ceramics produced by conventional sintering of β -phase Si_3N_4 powders synthesized by SHS (Ref 159) can be used as high-temperature articles with attractive dielectric properties ($\tan \delta = 4.4 \cdot 10^{-3}$ at $f = 10^6$ Hz, and dielectric strength of 9.2 kV/mm). Also, silicon nitride powders with a relatively high α -phase content ($\geq 80\%$) have been used for the production of advanced structural ceramics with good mechanical properties ($\sigma_b = 900$ MPa, $K_{Ic} = 6.7$ to 7.2 $\text{mN/M}^{3/2}$, and $\text{HV} = 13.3$ to 14.2 GPa). Because their mechanical properties are maintained at high temperatures (up to 1700 K), silicon nitride materials are attractive for use in high-temperature structural applications in chemically aggressive environments. For example, Table 8 shows some properties of a Si_3N_4 -based SHS ceramic ($\text{Si}_3\text{N}_4 + \text{SiC} + \text{TiN}$, Ref 160) that is suitable for ceramic engines.

Table 8 Some properties of self-propagating high-temperature synthesis silicon nitride ceramics

Source: Ref 160

The dielectric materials produced by hot pressing SHS AlN powders have about the same thermal conductivities, but higher bending strength, compared to those produced in conventional furnaces (Ref 161). For this reason, they are suitable for fabrication of panels in the microelectronics industry. A poreless composite material, TiAl-TiB₂-AlN, has been obtained by reacting a Ti + (0.7-0.95)Al + (0.05-0.50)B mixture under 30 to 100 atm N₂ pressure (Ref 162). The use of high-pressure nitrogen gas was found to be effective for simultaneous synthesis and consolidation of nitride ceramics with dispersed intermetallic compounds (e.g., TiAl). Dense, crack-free products with uniform grains (approximately 10 μm in size) were obtained. Also, aluminum nitride powders synthesized by SHS have been used as a heat-conducting

component in silicon-organic adhesive sealants. This glue has a thermal conductivity about twice that of alternative adhesives (Ref 32).

Combustion synthesis of boron nitride powder, BN, was reported in one of the earliest works on SHS. More recently, finely dispersed hexagonal BN powder has been obtained from reduction-type reactions (Ref 163). The main applications for BN materials take advantage of their dielectric properties, which are maintained at high temperatures (even above 2000 K) in nonoxidizing atmospheres. Some properties of BN materials are listed in Table 9 (Ref 160). The high temperatures present in the CS process make it possible not only to produce powders, but also to sinter materials and form net-shape articles (see Fig. 21) in the combustion wave.

Table 9 Some properties of self-propagating high-temperature synthesis BN ceramics

Properties	BN	BN + SiO ₂
Chemical composition, wt%	N=55; O <0.5; B _{free} < 0.5; B ₂ O ₃ < 0.3; C < 0.5	BN = 74 SiO ₂ = 26

Hydrides. The heats of formation for transition metal hydrides are much lower than those for nitrides or oxides. However, the high diffusivity of hydrogen within the reaction medium makes it possible to organize self-sustained combustion (Ref 165). More than thirty hydrides and deuterides of scandium, titanium, vanadium, and the major lanthanide metals have been obtained by gas-solid combustion synthesis (Ref 166). Hydrides of the transition metal alloys and intermetallic compounds (e.g., ZrNiH₃, Ti₂COH₃) have also been obtained (Ref 167). The production of complex hydrocarbides and hydronitrides is of special interest (Ref 168). For example, multicomponent single-phase hydronitrides of the following compositions may be synthesized: Zr_{0.9}-Nb_{0.1}-C_x-N_{1-x}-H_{0.19} to Zr_{0.4}-Nb_{0.6}-C_x-N_{1-x}-H_{0.26}.

Oxides. Combustion synthesis has been used to produce complex oxide materials, such as ferrites and ferroelectric piezoelectric, and superconducting materials. In these systems, the heat required for SHS is supplied by the heat released from the reaction between oxygen and metal. Oxygen can be supplied to the reaction by either an external source (oxygen gas) or an internal source (e.g., reduction of oxides in the starting reaction mixture) or by a combination of the two.

High-Temperature Superconductors. One of the promising oxide materials produced by SHS is the YBa₂Cu₃O_{7-x} (Y₁₂₃) ceramic superconductor (Ref 6). This material has a number of applications, including targets for magnetron spraying, superconducting shields, wires and cables. The compound is produced by SHS using the following reaction:

The effects of processing conditions, including green density, oxygen pressure, particles sizes of copper, BaO₂, and Y₂O₃ and the use of Cu₂O and CuO as starting materials have been investigated (Ref 169, 170, 171, 172).

Table 10 compares Y₁₂₃ powders produced by SHS (SHS-J1 and SHS-J2) with those produced by furnace synthesis. The oxygen content, transition temperature, orthorhombic phase Y₁₂₃ content, basic impurities, and mean particle sizes of SHS powders compare favorably with those produced by furnace synthesis. However, the time of Y₁₂₃ production for a conventional furnace is an order of magnitude longer than that for SHS. Items of relatively high density (~90%) with superconducting transition temperature, T_{sc} of 92 K have been fabricated by SuperConco Company (U.S.) by sintering SHS-J2 powders (Ref 173). Thick films (1 mm) made from this powder exhibit a critical current density up to 10⁶ A/cm². Materials of Bi₂Sr₂CaCu₂O_y and Tl₂Ba₂Ca₂Cu₃O_y compositions with T_{sc} = 125 and 131 K, respectively, have also been synthesized by SHS (Ref 169).

Table 10 Some characteristics and properties of superconductive powders (YBa₂Cu₃O_{7-x}) produced by conventional methods and self-propagating high-temperature synthesis

Powder	Oxygen contents (7-x)	TSC, K	Orthorhombic (Y ₁₂₃) phase, %	Basic impurities	Average particle size, μm
SC5-S ^(a)	6.92	93.5	98	CuO	40.0
SC5-P ^(a)	6.87	93.5	~99	CuO	8.2
SC5-6.5 ^(a)	6.88	90.5	97	BaCuO ₂	6.8
SC5-7 ^(a)	6.85	92.5	~99	CuO	5.7
CPS A-1203 ^(a)	6.85	92.0	~99	BaCuO ₂	3.0
SSC 03-0065 ^(a)	6.89	92.0	~99	...	6.5
SHS-J1 ^(b)	6.90	92.0	97	CuO	9.0
SHS-J2 ^(b)	6.92	93.5	~99	...	8.0

 (b) Combustion synthesis.

Ferroelectric Materials. The properties of electronic ceramics produced by SHS, including chemical and phase compositions as well as electromagnetic properties, are strongly affected by the maximum combustion temperature (Ref 173). This feature suggests that the properties of the final product can be tailored for a specific application by changing the combustion temperature, which can be achieved by adjusting the processing conditions.

Ferroelectric laminated bismuth compounds, which have applications as high-temperature piezoelectrics and semiconductors, can be synthesized by SHS. Table 11 presents the properties of several ferroelectric materials along with their potential applications. In addition, LiNbO₃ and LiTaO₃ can be obtained by SHS with densities two times higher than those produced by conventional methods, by varying the Li₂O/Me₂O₅ ratio in the product (Me is Nb or Ta). The formation of rare-earth (lithium and terbium) molybdate materials can also be achieved by SHS. All of the above materials have electronic applications. During conventional synthesis, difficulties arise when forming single crystals of lithium and terbium molybdates due to the high volatility of molybdenum oxide. This difficulty has been overcome by using SHS-produced stoichiometric powders, which are characterized by minimal losses during heating, melting, and crystallization.

Table 11 Some characteristics and properties of ferroelectric materials produced by self-propagating high-temperature synthesis

Composites	Resistivity, ρ , ($\Omega \cdot \text{cm}$)	Dielectric constant, ϵ	Dielectric dispersion, $\tan \delta$	Applications
Bi₄V₂O₁₁	4.7×10^9	63	0.089	Gas sensor (ethanol, acetone)
BiFeO₃	4.2×10^9	46	0.169	Gas sensor (ethanol, acetone, gasoline)
Bi₂Fe₄O₉	6.0×10^9	10	0.004	Gas sensor (ethanol, acetone)
Bi₄Fe₂O₉	2.8×10^9	40	0.109	Temperature-sensitive resistance, gas sensor (ethanol, acetone, gasoline)
BaBi₂Ta₂O₉	4.0×10^{11}	49	0.0022	Gas sensor (ethanol, acetone, natural gas, H ₂ O)
Bi₃TiNbO₉	1.9×10^{10}	70	0.0047	Moisture sensor
BaBi₂Ni₂O₉	3.5×10^{11}	92	0.0081	Moisture sensor
Na_{0.5}Bi_{4.5}Ti₄O₁₅	1.45×10^9	82	0.0059	Moisture sensor

Products of Thermite-Type SHS

It is impossible to describe, even briefly, all of the products obtained by thermite-type self-propagating reactions. Some examples involving magnesium metal are presented in Table 1. The use of magnesium leads to MgO product, which can be easily leached, leaving behind the desired product composition in powder form. In this section, some selected products reported in the literature are considered, specifically those whose phase distribution and properties are controlled by gravitational or centrifugal forces. Owing to high heats of formation, the products are completely molten at the combustion temperature. As a result, gravity-induced processes of convection and buoyancy may affect phase separation and crystallization, as well as combustion wave propagation.

Centrifugal SHS casting has been used to produce oxide-carbide ceramics by the following reaction: $\text{MO}_x + \text{Al} + \text{C} \rightarrow \text{M}_x\text{C}_y + \text{Al}_2\text{O}_3$ (Ref 174). In general, titanium, chromium, molybdenum, and tungsten carbides are synthesized with an alumina melt in the combustion wave (e.g., $\text{Cr}_3\text{C}_2\text{-Al}_2\text{O}_3$, $\text{WC-Al}_2\text{O}_3$, $(\text{Ti,Cr})\text{C-Al}_2\text{O}_3$, $\text{MoC-Al}_2\text{O}_3$). Also, addition of metal (iron group) oxides (NiO , CoO , Fe_2O_3) results in formation of cermet composites containing a metal binder (e.g., $(\text{Ti,Cr})\text{C-Ni}$), in addition to the carbide phase. The lighter oxide phase can be fully separated from the cermet by centrifugal acceleration. A centrifugal overload of 150 g is sufficient to separate MoC from Al_2O_3 , while 300 and 1000 g are required to separate WC-Co cermet and WC, respectively, from the alumina melt (Ref 64). Lower centrifugal overloads result in incomplete separation and the formation of graded materials. This phenomenon has been used to obtain refractory and chemically stable protective coatings on various substrates (see, e.g., Fig. 22) that possess relatively complex compositions and structures (Ref 62, 175).

Fig. 22 Characteristic microstructures of protective coatings on steel produced by combustion synthesis (400×). (a) Titanium-chromium carbide coating. (b) Chromium-nickel carbide coating

An interesting application of thermite-type SHS reaction with centrifugal overload is the fabrication of multilayered composite pipes (Ref 176, 177, 178). The simple and well-known composition $\text{Fe}_2\text{O}_3 + \text{Al}$ was used to produce a two-layer lining inside the steel pipe; see Fig. 10 (Ref 65). The iron outer layer provides good adhesion of the coating to the inner surface of the steel pipe, while the inner layer (Al_2O_3) provides protection from corrosion and abrasion. Separation of the layers was achieved by rotating the pipe (centrifugal acceleration between 50 and 200 g). Some properties of the ceramic layer are presented in Table 12. The effects on the structure of the pipe lining layer of adding SiO_2 and Al_2O_3 to the $\text{Fe}_2\text{O}_3 + 2\text{Al}$ mixture have been investigated (Ref 179). More complex structures have been formed using multicomponent mixtures (Ref 64). For example, the Ti-C-Ni-Al-O reaction system yielded multiphase gradient layers, where the composition gradually changed from TiC-Ni cermet to the $\text{Al}_2\text{O}_3 + \text{TiO}_2$ ceramic. The local density changed from 6.8 g/cm^3 at the cermet side to 3.9 g/cm^3 at the ceramic side. The production of steel pipes lined with a porous alumina-zirconia ceramic layer by reaction of $\text{Fe}_2\text{O}_3 + \text{Al} + \text{Zr} + \text{additives}$ has also been described (Ref 180).

Table 12 Properties of the alumina-based ceramic layer produced by the centrifugal-thermite process

Property	Value
Porosity	5.6%
Bulk density	3.86 g/cm^3
Linear expansion (at 293-1273 K)	$8.57 \times 10^{-6} \text{ K}^{-1}$
Thermal conductivity (at 293 K)	$13.9 \text{ W/m} \cdot \text{K}$
Resistivity (at 293 K)	$2 \times 10^7 \Omega$
Vickers hardness	1200 MPa
Compressive strength	> 850 MPa
Bending strength	150 MPa
Bulk modulus	$2.2 \times 10^3 \text{ MPa}$

Infiltration

Claus G. Goetzel, Stanford University, and Joanna Groza, University of California, Davis

Introduction

DURING INFILTRATION, a liquid, metal mass or front moves through or penetrates the pore system of a solid-phase powder compact. This process is similar to liquid-phase sintering, in which one of the constituent powders of a compact melts and disperses throughout the compact in situ. Voids are filled by shrinkage and particle rearrangement. During infiltration, liquid externally contacts the porous solid, and capillary forces draw it inward. Reduction of total surface-free energy of the system is a prerequisite during infiltration and determines whether a particular solid-liquid phase system is suitable for infiltration.

A variation of capillary-action infiltration at ambient pressure consists of penetration of pores by liquid assisted by external force. Impregnation treatment of this type is widely used to fill pores of sintered products with hydrocarbons, organics, and nonmetallic fillers. For a solid-liquid phase system with suitable surface free energy, infiltration can be used to attain:

- Full density without high compacting or re-pressing pressures or subsequent forging, rolling or extrusion, or hot pressing
- Precise and complex shapes, including large sizes, using conventional P/M operations, tooling, and equipment
- Layered P/M products of different composition, or of one P/M section and a cast or forged element
- Surface characteristics that permit standard joining and coating methods
- Improved machinability due to uninterrupted chip forming, facilitated by minimization of pores or due to favorable chip-breaking caused by a duplex microstructure
- Reasonable control of phase distribution that may result in a uniform or a purposely graded microstructure
- Good mechanical properties due to a minimum of angular stress-raising pores
- Increased strength through subsequent effective heat treatment

Infiltration

Mechanism of Infiltration

The principles of infiltration mechanisms are discussed in Ref 1, 2, 3, 4, 5, and 6. Infiltration rate is related to Poiseuille's law defining the rate of flow or rise of a liquid in a glass capillary (Ref 2, 3). The parabolic rate law was confirmed for the early penetration stages of infiltration for a number of systems. However, bent and twisted channels in powder compacts made comparison with the straight capillaries of the model almost impossible. Furthermore, in many systems involving metals, penetration is followed by a second infiltration stage when the pore filling liquid reacts with the solid.

Successful infiltration of a porous, skeletal solid with a liquid phase requires that the total surface-free energy of the system after infiltration be lower than the total surface-free energy before infiltration. The total includes the surface-free energies of the solid and the liquid phases, as well as the interfacial energy between the solid and liquid. This relationship is expressed by:

$$\gamma_{s/l} = \gamma_s - \gamma_l \cos \theta$$

Where $\gamma_{s/l}$ is the specific surface-free energy of the solid-liquid interface, γ_s and γ_l are the respective surface-free energies of the solid and liquid, and θ is the liquid-solid contact or wetting angle. A low contact angle is essential for infiltration. The rate and depth or height of infiltrant penetration of the compact pore system can be enhanced by lowering the contact angle with the use of detergents (Ref 7). Solid, liquid, or vapor-forming surfactants mixed with the powder or passed through the compact prior to infiltration are suitable additives.

With a sufficiently low contact angle, surface tension forces in many systems cause the liquid metal to spread on the outside faces of the skeleton body. Because of diminished resistance, complete envelopes may form before capillary forces draw the liquid into the interior.

A number of conditions other than a low liquid-solid contact angle must be fulfilled to ensure successful infiltration and useful end products. These conditions have been discussed by many investigators (Ref 8, 9, 10) and are reviewed below.

The Skeleton. The compacted powder matrix, or skeleton, should consist of a network of solid particles or grains throughout the infiltration process. It should provide a system of interconnected pores and channels of a size range that permits unimpeded capillary force action. Closed-off pores must be avoided; they cannot be penetrated by the liquid infiltrant under normal circumstances. An attempt should be made to remove oxide or nitride films prior to infiltration.

Infiltrant must have a melting temperature below that of the skeleton. High fluidity in the liquid state is desirable because it aids the driving force of the surface tension. Thermal expansion characteristics of the infiltrant affect ultimate strength of the infiltrated body. If the infiltrant skin surrounding the infiltrated skeleton expands during rapid solidification, the strength of the finished part may be decreased; however, the opposite reaction occurs if the skin contracts on cooling from the liquid state. This phenomenon was found for iron infiltrated with copper and bismuth, respectively (Ref 11).

System Compatibility. The ideal liquid infiltrant should have a contact angle with a solid that is near zero, and reaction between solid and liquid should be kept to a minimum. Some refractory metal-conductor metal systems fulfill this condition. If the reaction products formed during infiltration (intermetallic compounds, eutectics, or solid solutions) have a specific volume equal to or greater than the combined initial specific volumes of the skeleton and infiltrant, penetration of the liquid is halted before completion, or it is blocked completely. A similar effect is obtained if the reaction products are dissolved in the liquid phase and the infiltrant becomes less fluid. In either case, external infiltrant residue and unfilled pore space remain.

Solubility. When solid solution formation between components is minimal at low temperatures and when equilibrium conditions at infiltration temperature produce minimal dissolution of the skeleton in the liquid infiltrant, the effects of solubility generally are beneficial. Maximum operating temperature may be lower and kept at only slightly above the liquidus of the infiltrant alloy. Strong bonds at the interface between the two phases are formed, and nearly full density of the product is obtainable.

If the infiltrant dissolves more than traces of the skeleton material, the infiltration rate may be lowered, requiring longer times for complete penetration. Also, at the point of contact with the liquid infiltrant mass, the exterior surface of the skeleton body can erode. Presaturation of the infiltrant with the skeleton metal or alloying with a solubility-inhibiting element eliminates this problem. Prealloying of copper with iron for infiltration into iron skeletons is a typical example.

The stability of the compact becomes impaired as the solubility of the solid in the liquid increases. Consequently, wide pore channels and short infiltration times should be utilized. Diffusion barriers deposited on the pore walls of the skeleton can cause sufficient delay in dissolving the solid surfaces to permit penetration of the liquid phase through the entire pore system.

In applying copper films on the inner surfaces of iron skeletons by precipitation from a copper sulfate solution, carbon diffusion through the resulting copper-base solid solution can be slowed sufficiently to prevent solidification of a cast iron infiltrant before the entire compact is penetrated. Unless these precautions are taken, excessive solubility of the solid in the liquid rapidly leads to the collapse of the skeleton and to a meltdown of the partly or fully penetrated compact.

Microstructure. Structural integrity of the infiltrated body is closely associated with the microstructure. If the dihedral angle at the intersection of the boundary between two solid grains or particles and a liquid phase approaches zero, the liquid metal tends to penetrate along the grain boundary. An example of this is the W-Ni-Cu heavy alloy system. During the penetration stage of infiltration of the nickel-copper alloy, closed-off pores can become filled. This mechanism can lead to a loosening of the contacts between the solid tungsten grains and a loss of coherence of the skeleton. Consequently, volume expansion can occur during infiltration, while some of the original pores remain unfilled. New pores also can be generated by particle rearrangement (Ref 12), or as a result of liquid-solid phase reactions.

Control of dimensional changes of the compact during infiltration is difficult in systems where the dihedral angle is zero and may even require the confinement of the skeleton in a mold. Also, the ultimate properties of the infiltrated body can be affected by the cohesive strength level of the skeleton that remains after boundary penetration by the liquid phase.

Vacuum. Capillary infiltration can be enhanced by subjecting the system to a vacuum. Volatile impurities are more readily removed from the infiltrant melt and the free surface of the solid under vacuum. For alloy infiltrants, the solidus temperature may be raised, and premature freezing in the skeleton channels can occur if the composition is changed as a result of a high vapor pressure of one of the elements. In that event, vacuum operations should be avoided, and pressure should be applied in a sealed vessel during infiltrant melting and melt penetration of the skeleton.

Pressure Gradient. If a vacuum is applied to a confined skeleton on the side opposite the face contacting the infiltrant, penetration of the liquid is enhanced. By increasing the pressure gradient further with the aid of an external force acting on the liquid, compacts with a less controlled pore structure or wider pore spectrum can be penetrated. Infiltration becomes progressively less dependent on capillary action and good wetting as the pressure gradient becomes larger.

Systems in which the liquid forms high contact angles with the solid can be infiltrated if the pressure differential is sufficient, but the liquid cannot be retained by the skeleton and may be exuded partially or completely. In that case, the skeleton functions as a filter.

Infiltration

Claus G. Goetzel, Stanford University, and Joanna Groza, University of California, Davis

Infiltration Techniques

Throughout the development of metal infiltration technology, numerous methods have been employed. All acceptable methods for production work utilize, at least in part, procedures, tooling, and equipment common to the P/M industry. However, depending on the system involved and the quality specifications of the product, specific tools, devices, fixtures, supports, or molds generally are required. For example, the shape complexity of a component or its potential for reaction with either the skeleton or liquid metal can determine whether a carbon base or ceramic container or mold is used during infiltration.

The type of furnace used must permit control of time and temperature for both stages of infiltration--penetration of the liquid through the pore system and reaction of the liquid with the skeleton after filling of the pores. The particle size distribution of the powder must be selected or custom blended, and the compacting pressure must be adjusted to produce a large number of interlocking pores, as well as free paths between them, required to receive and pass the liquid metal.

Capillary-Dip Infiltration. The skeleton body is partly immersed into a molten metal bath contained in a crucible, where it acts as a wick (Fig. 1a). Liquid is drawn in by capillary forces and rises, expelling the gas volume contained in the pores. The bath may be metered to fill exactly the available pore volume of the solid.

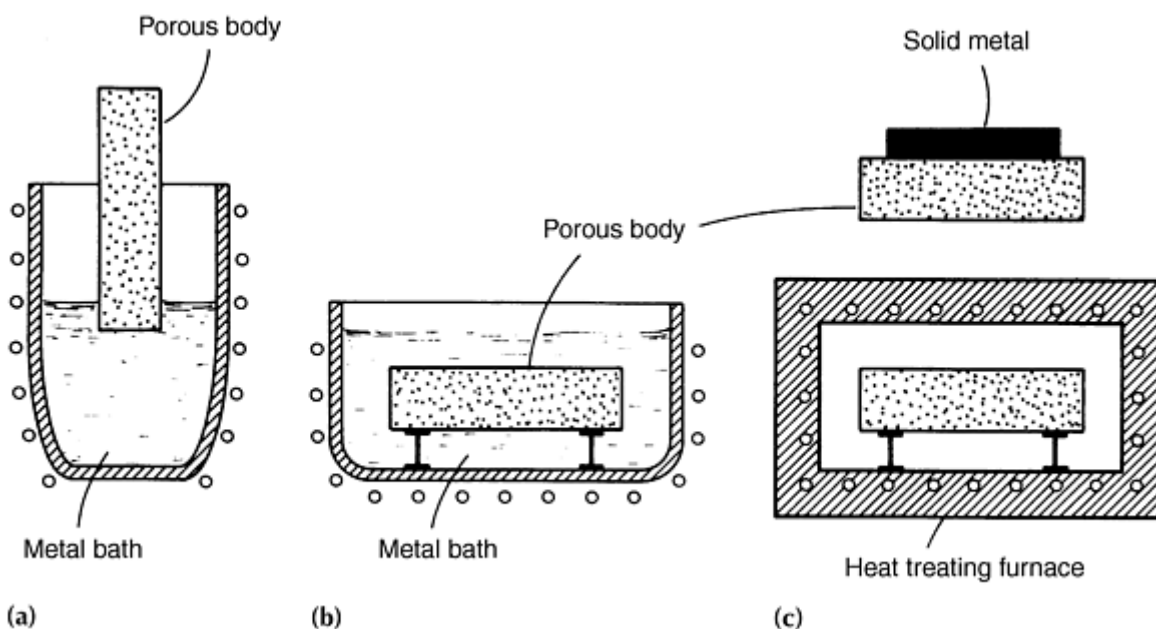

Fig. 1 Capillary infiltration methods. (a) Dip of a small part of a skeleton body into a melt. (b) Complete submersion of a skeleton body into a melt. (c) Positioning of solid infiltrant on top of a skeleton, followed by pore penetration on melting. Source: Ref 8

Full-Dip Infiltration. The skeleton is completely submerged in the melt (Fig. 1b). Penetration occurs from all sides toward the core; therefore, the gas volume can be displaced only by diffusion through the liquid. To avoid gas entrapment, immersion of the skeleton must proceed slowly or in stages. The melt may be poured onto the porous body from one side with a tilting bath container. Application of a vacuum facilitates degassing. Excess molten metal is unavoidable, but can be used as a cast metal extension of the infiltrated compact.

Contact Infiltration. The infiltrant is initially placed in juxtaposition with the free-standing skeleton. After melting, a liquid film is formed that penetrates the pores. If the infiltrant is placed on top of the skeleton (Fig. 1c), surface tension can spread the film over all faces of the skeleton before penetration into the core occurs. Gas displacement from the pores is aided by placing the infiltrant beneath the skeleton or by applying a vacuum. Exact allotment of the metal required to fill the pore volume is possible, thus eliminating the need for liquid metal containers. This method is an adaptation of conventional sintering and elevates infiltration to a production process.

Gravity-Feed Infiltration. In this method, capillary forces are augmented by external pressure exerted by the high head of an infiltrant melt reservoir above the skeleton, which in turn is contained in an investment-casting inert mold. Auxiliary force is a function of the height of the liquid metal head; if the mass of the head is large enough, more than one skeleton can be fed, and cluster arrangements similar to those of the investment-casting process are possible.

Separation of the infiltrated product from excess infiltrant of the head or sprues is aided by suitable gating, made of coarse powder compacts or fiber felts to facilitate passage of the molten metal. If gate and skeleton materials are the same composition, the liquid can dissolve some of the gate and become partially saturated with the alloying element, thus preventing surface erosion of the infiltrated product. This process is suitable for producing precision-shaped and graded cermet turbine blades. Figure 2 shows the infiltration mold assembly used in this technique.

Fig. 2 Cermet turbine blade infiltration mold assembly. Source: Ref 13

External Pressure Impregnation. When capillary forces are ineffective because of poor wetting, unsuitable pore size and distribution, or high viscosity of the liquid, the solid body can be impregnated by the molten metal only with the help of a substantial external force. This force can be supplied by a pressurized gas or liquid, a dead load, or a piston inside a cylinder, and must exert pressure on the melt. The infiltrant mass may be limited to the exact amount required for filling the pores, providing a continuous film surrounding the end product, thereby eliminating the need for cropping excess material.

Molten infiltrant can make contact with the skeleton at any desired face, although the top or bottom usually is the most practical contact surface. The liquid metal must be contained in a suitable pressure vessel before and during impregnation. This method is applicable to systems in which the molten infiltrant tends to solidify before penetration is completed, due to diffusion-induced changes in composition.

An example of such diffusion-solidification can be found in iron/cast iron systems. High-speed steel has been produced by impregnating molten high-carbon iron into porous low-carbon steel compacts made from shotted granules or wire clippings with 0.5 MPa (75 psi) pressure (Ref 14). Figure 3 shows the closed mold arrangement used for this process.

Fig. 3 Mold arrangement for pressure impregnation of low-carbon steel compacts with a high-carbon steel melt (experimental process). Compact dimensions: 6.3 mm (0.25 in.) diam, 80 mm (3 in.) in length. Source: Ref 14

Centrifugal pressure impregnation is an adaptation of external pressure-aided impregnation of liquid metal into pores of a solid. This process uses the centrifugal investment casting method, but requires special features such as more refractory, chemically inert, and tight-fitting ceramic molds and atmospheric control. The centrifugal force on the molten infiltrant can cause segregation due to exudation of a heavy liquid from the skeleton. This phenomenon may require special mold adapters or inserts.

Vacuum Infiltration. Two methods can be employed to create a vacuum in metal infiltration. One method creates a pressure gradient by applying suction to the liquid phase through the interconnected pore system of the skeleton, allowing atmospheric pressure on the molten infiltrant to be the driving force. A closed-mold system that contains the molten infiltrant and the skeleton is required. The vacuum then is applied to the end of the skeleton, away from contact with the melt.

The second method simply provides for placement of the entire infiltration arrangement in a vacuum furnace. This method is useful for systems with strong outgassing components, but can cause difficulties in controlling the infiltration cycle of monitoring skeleton and infiltrant temperatures.

Infiltration Systems

Even if essential infiltration conditions are strictly met, the possible binary systems in which a high-melting single metal or compound can be infiltrated by a lower melting single metal are many. Table 1 lists systems that are partially or fully immiscible in the liquid state (Ref 8), but also includes workable systems that form terminal or even complete solid solutions (e.g., iron-copper and nickel-copper). Systems for which infiltration has gained acceptance for past production tasks or where infiltration is presently in use by industry are shown by closed circles, open circles indicate systems capable of infiltration in the laboratory or systems possessing infiltration potential on the basis of established criteria.

Source: Ref 8

The material combinations listed in Table 1 are incomplete, because the possibilities for infiltration combinations are expanded if binary or more complex alloys are used for the skeleton and/or infiltrant. It is possible to produce nonequilibrium alloys of a final composition that cannot be made by melting and casting; if the respective phase diagram indicates some solubility relationships in the liquid or solid state, diffusion heat treatments just below or above the

melting temperature of the infiltrant can result in truly equilibrated alloys, usually distinguished in their microstructure by rounded grains embedded in a matrix (Ref 8).

In principle, homogeneous alloys can be produced by infiltration if solubility of the skeleton in the infiltrant (or vice versa) is unlimited in the liquid or solid state. The nickel-copper system is an example; Monel compositions were successfully produced with 63 to 67% Ni by complete penetration of nickel skeletons with copper and binary alloys of copper with 10% Al or 10% Si.

Another example is the capillary infiltration of iron or low-carbon steel powder compacts of predetermined porosity with molten cast iron under conditions of close time, temperature, and carbon-diffusion control. When a homogeneous alloy is produced, process variables such as pore and capillary channel, size of the powder compact, time for melting the infiltrant and its complete penetration of the skeleton, and type of diffusion inhibitor must be carefully controlled to ensure homogeneity.

After the penetration stage has been successfully completed, sintering with the liquid phase in place can proceed at the infiltration temperature, and full homogenization of the alloy can be accomplished by subsequent heat treatment in the solid state. The principal advantage of this procedure lies in the potential for obtaining alloys of nearly full density without mechanical working. Unfortunately, process control problems have made this approach impractical.

Refractory metal-based composite structures of tungsten-copper, tungsten-silver, molybdenum-copper, and molybdenum-silver systems are among the oldest P/M products produced by infiltration. The solubility of refractory metals in molten silver is minimal, and solubility in molten copper is practically nil. Along with excellent wetting characteristics, these properties constitute ideal conditions for infiltration.

The ratio of the two phases that can be combined by this method can vary considerably (from about 35 to 40 vol% up to 85 to 90 vol% of the refractory metal). The upper limit is set by the requirement of an interconnected pore structure in the compacted and sintered refractory metal, while the lower limit can be controlled by selection and treatment of the powder, which is piled loosely in a suitable container (e.g., graphite).

Generally, refractory metal powder is reduced oxide type with particle sizes ranging from about 1 to 50 μm . However, coarser powders ranging from 50 to about 400 μm with a more sharp-edged crystalline particle shape, such as that obtained by mechanical comminution of sintered or swaged scrap metal, have produced sintered skeleton structures with improved erosion and wear resistance (Ref 15). The desired porosity in the loose pile is obtained by tapping, vibration, jolting, or ramming, whereas porosity of compacted powders is controlled by the static pressure of the press tools.

The refractory metal skeleton usually is sintered prior to infiltration to improve strength and cohesion. Sintering temperature must be selected in conformity with powder particle size and shape, compacting pressure, and specific final composition; it is usually about 100 °C (180 °F) above the melting point of the infiltrant metal. Higher temperatures tend to produce severe grain growth and shrinkage and can even destroy the interconnected pore system needed for successful infiltration, especially in very fine starting powders. Figure 4 schematically presents the growth of tungsten grains with rising sintering temperature and the change in the distribution of a subsequently infiltrated copper phase, especially above 1600 °C (2900 °F).

Fig. 4 Schematic drawing of microstructure of tungsten sintered at different temperatures before being immersed into molten copper. (a) 1100 °C (2010 °F). (b) 1350 °C (2460 °F). (c) 1600 °C (2910 °F). (d) 2800 °C (5070 °F). 500×. Source: Ref 16

Infiltrated bodies that have a continuous skeleton phase above approximately 65 vol% can be shaped only by machining, while those having a smaller proportion of refractory metal dispersed as loose grains in the ductile metal matrix are plastically deformable at elevated temperatures (Ref 8). Soldering, brazing, or plating of the infiltrated product is aided by generally smooth surface films or high contents of infiltrant metal.

The preceding binary systems illustrate combinations of two metals of widely differing melting temperatures that can be advantageously produced to near-net shape and full density by infiltration. Nickel also can be infiltrated into tungsten, but equilibrium at liquid-phase temperature causes severe attack of the refractory metal and requires careful process control to prevent incomplete penetration due to diffusion solidification. Coarse tungsten powder helps to produce compacts with larger capillary channels for better penetration. High heating rates, especially after about 90% of the absolute melting temperature of nickel is reached, improve infiltration conditions.

If nickel is alloyed with copper, the solubility of tungsten in the liquid phase decreases as the copper percentage is increased. Infiltration is more practical (Ref 8) for heavy alloy systems because tungsten powder and process control requirements are less stringent. If nickel is alloyed with iron, however, the solid-liquid phase interaction is similar to the binary tungsten-nickel system, and infiltration again is more difficult.

The same principle applies to the more complex refractory metal systems with nickel-chromium and cobalt-chromium alloys. Nevertheless, skeleton bodies of tungsten and molybdenum, as well as bodies of binary 85W-15Cr and 75W-25Cr alloys, can be successfully infiltrated with superalloys of the Nichrome-V, Hastelloy-C, Stellite, and Vitallium compositions into shapes simulating mechanical and engine test specimens (Ref 17).

Several other refractory metal-based composite structures can be readily produced by infiltration. These include the high-density tungsten-lead system to produce materials suitable for shielding against radiation and the chromium-copper system to produce compositions for welding electrodes (Ref 8). To retain the low liquid-solid contact angles in these systems, a strong reducing atmosphere is necessary to prevent oxide films on the molten lead or on the solid chromium. A free metallic surface requires sintering of the skeleton above 1250 °C (2280 °F) to reduce any oxide film on the solid chromium.

Carbide-Based Systems. Liquid-phase sintering of tungsten carbide/cobalt or titanium carbide/nickel systems capitalizes on the eutectics of the two phases. A limited solubility of the carbide in the matrix metal facilitates bonding; carbon and metal diffusion through the liquid are less important in densification than reactions at the carbide-metal phase boundaries. It is unknown whether the carbide particles in these systems form a rigid skeleton, but the interfacial tension between crystals of the carbide and the liquid metal appears to be anisotropic (Ref 18).

During cooling from the sintering temperature, some or most of the carbon and metal dissolved in the liquid precipitates on grains that remained solid during the process. This mechanism can be altered somewhat if the rigid skeleton is formed first and the liquid phase subsequently infiltrates into the pore system. By first saturating the matrix metal with carbon and skeleton metal, the liquid phase dissolves less skeleton materials, and shape distortion is diminished. Carbide coalescence and grain growth also are decreased.

The earliest attempts to produce cemented carbides were made by infiltrating carbide skeletons with unalloyed binder metals (Ref 19). Later, binder metal prealloyed with elements of the skeleton to inhibit contact face erosion was used in a broad investigation of infiltrating single and double carbides with many cobalt and nickel alloys (Ref 20). Table 2 lists some of the alloys used. The large number of feasible combinations includes several noteworthy successes, especially for titanium carbide-based stems with Nichrome and Vitallium infiltrants. A feasibility study (Ref 17) produced similar results for the same infiltration systems and laid the foundation for an extensive development program to utilize these materials for heat-resistant applications.

The structure of infiltrated carbides reflects infiltration mechanics on a macroscale. In zones penetrated by the infiltrant, fully dense regions and slight expansion of the skeleton due to carbide grain separation are observed. Substantial porosity and some shrinkage occur in areas inadequately penetrated by the liquid alloy, such as the side opposite the contact face in unidirectional infiltration, or in the center for infiltration from opposite sides. Subsequent heat treatment is ineffective in eliminating porosity. Erosion at the contact faces is greatly diminished by infiltrating skeletons composed of tungsten-base multcarbides, so that saturating the infiltrant with skeleton elements by prealloys frequently is not required.

The microstructure reflects the crystallographic characteristics of the carbide, and fully infiltrated regions do not differ in grain size and morphology from material whose liquid phase was sintered in situ. Rectangular and triangular grains are retained in infiltrated tungsten carbide, whereas for infiltrated titanium carbide, the cubic lattice is reflected by distinctly rounded grains. Grains of solid-solution carbides of tungsten and titanium or titanium and molybdenum are slightly rounded at the corners. Graphite precipitates accompany porosity in poorly infiltrated regions for tungsten carbide and titanium carbide skeletons, especially if starting powders contain more than a trace of free carbon.

Ferrous-Base Systems. The thermodynamic affinity between solid iron and liquid copper offers the potential for virtually pore-free P/M products by infiltration. Moreover, the excellent wetting characteristics that exist in the brazing of steel can also be utilized for joining disparate bodies during infiltration. A powder compact and a casting or forging, or halves of complex or offset configurations, can be joined. Figure 5 (Ref 10) illustrates this self-brazing capacity without strength degradation. Finally, the generally smooth cupric film surrounding the infiltrated body serves as a base for surface coating or plating.

Fig. 5 Infiltration-brazed butted iron-copper bars. Green bars were clamped together end-to-end, and one free end surface was contacted with molten infiltrant. Rupture of composite bar occurred away from the joint, evidence of the high strength of the brazed bond. (a) Butt joined bars after infiltration. (b) Machined tensile bar. (c) Tested tensile bar

The ability of the infiltration process to combine major proportions of normally unalloyable industrial premier metals (iron and copper) was recognized as early as World War I (Ref 21, 22), but it was only in the late 1940s, through refinements in technique, that sound products could be made (Ref 10, 23, 24, 25). These products, in turn, have culminated in the present advanced state of the art. While copper content must be higher than for most commercially sintered iron-copper alloys because of the need to maintain an interconnected pore system for complete infiltration, good mechanical properties can be realized.

This is apparent from the tensile strength-elongation data given in Fig. 6 for commercial iron powder with and without graphite additions (Ref 24). Strength is enhanced because the infiltrated structure, with a minimal amount of isolated pores, is virtually free of internal notches. The iron-copper system permits a precipitation-strengthening mechanism. If carbon is diffused into the iron to produce a hypoeutectoid structure of the skeleton, hardening by martensite transformation is possible. Where other metals are alloyed with the copper, solid solution strengthening of the matrix can be achieved.

Fig. 6 Mechanical property ranges of copper-infiltrated iron and hypoeutectoid steel compacts before and after heat treatment

In the binary iron-copper system, about 3.8 to 4% Fe is dissolved by the liquid copper under equilibrium conditions at an infiltration temperature of 25 to 50 °C (45 to 90 °F) above the peritectic temperature of 1090 °C (2000 °F) at the copper side of the phase diagram, while the γ -iron dissolves about 8 to 8.5% of the copper. At 900 °C (1650 °F), the solubility of α -iron in copper is about 1.5%; it diminishes to less than 0.04% at room temperature, at which point the solubility of copper in iron is equally low.

These thermodynamic relations form the basis for precipitation hardening. However, macrodispersion of the two phases in the infiltrated alloys causes concentration of precipitates in thin zones at the phase boundaries, as shown in Fig. 7 (Ref 26). Consequently, conventional hardness tests are not precise enough to show a noticeable increase in macrohardness after a precipitation treatment, such as quenching from 900 °C (1650 °F) followed by prolonged tempering at 600 °C (1110 °F). The precipitation mechanism produces increases in strength, elongation, and impact resistance (Ref 8) and also can be traced through changes in the electrical conductivity (Ref 25).

Fig. 7 Microstructure of 25Cu-Fe compact sintered at 1100 °C (2010 °F) for 30 min. Large, rounded, dark areas are α -iron, separated by a diffusion layer from the light copper phase containing the fine, dark, iron-rich precipitate. 1000 \times . Source: Ref 26

If carbon is diffused into the iron skeleton with copper infiltrated afterward, two processes compete with one another during cooling. During quenching, normal martensitic transformation occurs inside the skeleton structure. At the same time, however, precipitation of the dissolved iron in the copper and copper in iron, respectively, is suppressed in the phase boundary zones. During reheating, martensite decomposition causes a decrease in hardness of the steel skeleton structure, with simultaneous increases in hardness and strength of the boundary zones.

Table 3 shows the effect of such a heat treatment on the mechanical properties of a copper-infiltrated 0.3% carbon steel. Water quenching produces an appreciable increase in hardness and brittleness. With increasing reheating temperatures, however, the material becomes softer and tougher, without loss in strength (Ref 8).

Table 3 Effect of heat treatment on the mechanical properties of 0.3% carbon steel infiltrated with 11 vol% Cu

Treatment ^(a)	Hardness, HV	Ultimate tensile strength		Elongation, %	Impact resistance ^(b)	
		MPa	ksi		J	ft · lb
Copper-infiltrated and furnace cooled	262	704	102.1	7.3	22.16	16.35
Reheated to 900 °C (1650 °F) and water quenched	437	790	114.6	5.2	11.76	8.68
Reheated for 2 h at 400 °C (750 °F)	360	14.71	10.85

Reheated for 2 h at 600 °C (1110 °F)	255	750	108.8	13.5	62.75	46.30

- (a) Hametag iron powder pressed to 88% of theoretical density, sintered at 1220 °C (2230 °F) for 1 h in hydrogen, and infiltrated with electrolytic copper at 1100 °C (2010 °F) for 30 min.
- (b) Unnotched test bar of 1 cm² cross section.

When a copper alloy is used as an infiltrant, other benefits can accrue. When precipitates form in the matrix, such as copper alloys with beryllium, chromium, or silicon, the resulting strength increase during heat treating of the infiltrated body reinforces iron-copper precipitation zones at the boundaries. The strengthening effect of precipitates is independent of heat treatment and augments strength increases obtained with unalloyed copper infiltrant in solid-solution alloys. However, some solid-solution alloy infiltrants minimize erosion at the point of initial contact with the iron skeleton, because these alloys melt slowly over a range of temperatures. Brass containing 20% Zn exhibits this phenomenon.

A copper alloy with manganese in amounts up to 5%, especially if it also contains sufficient iron to inhibit a severe attack of the skeleton contact faces, has a different beneficial effect. The manganese oxidizes preferentially in the commercial atmospheres where infiltration takes place. A nonadhering porous crust results that can be removed during finishing more easily than the tenacious residue formed by a binary copper-iron infiltrant (Ref 27, 28).

Many ferrous metal-base infiltration systems have been explored experimentally. Kieffer and Benesovsky (Ref 8) have investigated the iron-gold, iron-bismuth, iron-cadmium, iron-lead, iron-antimony, and iron-tin systems for bearings, and the iron-cobalt-silicon, iron-copper-silicon, and iron-manganese-silicon systems for magnetic or structural parts. Alloys of the iron-zinc system have also been produced by infiltration, but treatment in a pressure vessel is required to overcome the high vapor pressure of the zinc (Ref 29).

Austenitic stainless steel skeletons infiltrated with silver possess excellent corrosion resistance, thus making them suitable for food processing applications. Ferritic stainless steel and high-manganese steel compacts with varying carbon contents also display improved corrosion resistance when infiltrated with cupric alloys. These alloys also exhibit extraordinary hardness and wear resistance, coupled with a considerable toughness. Table 4 lists mechanical and technological properties of several ferrous-base infiltrated materials.

Table 4 Properties of some ferrous metal-based infiltrated alloys

Skeleton composition, %	Infiltrant composition, %	Infiltrant, vol%	Density, g/cm ³		Hardness, HV	Ultimate tensile strength		Elongation, %	Impact resistance ^(a)		Comment

Unnotched test bar of 1 cm² cross section.

Nonferrous-Based Systems. The major nonferrous metals with higher melting points are thermodynamically compatible with many low-melting metals in the liquid state. Consequently, skeleton bodies of cobalt and nickel can be readily infiltrated with gold, as well as with many of the low-melting heavy metals, such as bismuth, lead, or antimony (Ref 8). Copper can also be infiltrated into cobalt and nickel skeletons; however, because of the formation of solid solution in all proportions, infiltration into nickel powder compacts requires a narrow particle size range, wide capillaries within a pore volume not exceeding about 35%, short infiltration time, and a vacuum to assist the capillary forces. Mercury wets nickel well without forming an amalgam and is easily impregnated into skeleton bodies, provided the pore structure prevents exudation of the heavy liquid metal (Ref 30).

Copper is another skeleton metal with pores that can be readily filled with liquid low-melting-point metals, such as lead (Ref 31, 32) or bismuth (Ref 33). Vacuum impregnation is suitable for incorporating lead-base alloys, such as those containing 15% Sb and 5 to 10% Sn, into spongy structures of nickel-copper or nickel-iron supported by steel backing (Ref 34).

Combinations of aluminum or aluminum alloys with low-melting metals such as bismuth, lead, thallium, or thallium-lead by means of infiltration in hydrogen or a vacuum have been proposed (Ref 33, 35). However, strict control of powder characteristics, especially particle shape and surface condition, to maximize wetting appears to put infiltration at a disadvantage over in situ liquid-phase sintering. To overcome this problem, zinc or cadmium can be added to the aluminum of the skeleton, followed by cleaning and activating the free surface of the pores by evaporation of the lower boiling metal before proceeding with the impregnation of a metal such as lead (Ref 36).

Infiltration Products

Electrical Contacts and Electrodes. Composite materials for heavy-duty service contacts consist of (a) a refractory metal component to supply the necessary hardness, wear resistance, burning and material transfer through arcing, and high-temperature strength, and (b) a matrix of an electrically and thermally conducting metal. Tungsten and molybdenum are the principal refractory metals, but tungsten carbide, tungsten-niobium double carbide, and titanium carbide have also been used for this purpose (Ref 8). Conductor metals are copper and silver.

Because the two metal types do not alloy with one another, the rule of mixture can be applied to determine the density of a specific composition. Figure 8 shows the effect of increasing tungsten content on density, hardness, and electrical conductivity for copper-tungsten contact material (Ref 37). The straight-line relationship between volume ratio and conductivity is typical for this system. Figure 9 shows the change in thermal expansion coefficient with tungsten content; principal mechanical properties versus tungsten content are plotted in Fig. 10 (Ref 38). The boldface portions of the curves represent composition ranges of material that can be readily produced by infiltration with a low-melting metal content of approximately 10 to 40 vol% (5 to 25 wt%).

In infiltrated materials, the soft conductor metal matrix is the minor constituent, and extrusion for profile generation is not practical except for nickel-silver composites. All materials are readily machinable into a variety of shapes, especially caps, platelets, and rings. Usually, the heavy-duty contact metal, as a facing, is joined by clamping or brazing onto a support structure. The facing also may be penetrated by an infiltrant with a major portion, that on cooling, solidifies like a casting; an example is copper that is strengthened by small amounts of beryllium, chromium, or nickel and is cast into the form of a backing, arm, or other support structure.

Primary applications for infiltrated tungsten-copper composites are resistance welding electrodes and make-and-break contact facings in oil or air circuit breakers or transformer taps. Tungsten-silver contacts are used in switch gear and low-voltage regulators (Ref 37). Low contact resistance and nonsticking properties of nickel-silver contacts make them suitable for high-voltage disconnect switches (Ref 39). Porous, cup-shaped nickel compacts have been impregnated with mercury as part of a short circuiting safety switch contact in proximity fuses for radio-controlled detonation (Ref 40, 41).

Rocket Nozzles. The manufacture of silver-infiltrated tungsten contacts formed the basis for the development and production of large billets, from which rocket nozzle throat liners have been fabricated. This material has proved successful in actual service in rockets of underwater-launched ballistic missiles (Ref 42) because:

- Extreme stability of the structure (virtually zero change in critical dimensions due to the high-temperature, high-pressure gaseous environment in the nozzle throat)
- High resistance to thermal shock during heating and cooling at the extremely high rates experienced by the throat surface in contact with rocket propulsion gas. This in turn requires high tensile strength and resistance to high hoop stresses at the outer perimeter of the throat liner, as well a good thermal conductivity to provide adequate heat transfer to the backup structure.
- Fabricability, especially machinability, on an economical production scale
- Optimum reliability and reproducibility of the nozzle throats in spite of their relatively large size, compared to similarly produced P/M parts in electrical switch gear

An additional advantage of using silver as the matrix metal is its relatively high vapor pressure. Silver evaporation aids infiltration of large capillaries by forming deposits on the pore walls before the liquid metal enters individual pores. Also,

the exposed surface region of the throat liner is kept at a temperature considerably below that of the propulsion gas due to evaporative transpiration cooling (Ref 43).

Figure 11 shows a typical silver-infiltrated tungsten ring machined from a large billet that weighed nearly 90 kg (200 lb). It contained about 80 vol% W; the conductor metal was uniformly dispersed throughout the entire cross section, filling all interconnected pores (Fig. 12). Processing parameters, production details, and starting material characteristics are described in Ref 44 and 45.

Fig. 12 Microstructure of silver-infiltrated 80W-20Ag billet. Angular microconstituents are silver. 500× Source: Ref 42

Toensing and Zalsman (Ref 44) have also reported on the effect of these parameters on mechanical properties at ambient and elevated temperatures. Figure 13 shows the change in tensile strength with temperature for a tungsten skeleton with 20% pore volume before and after silver infiltration. Data represent average values, but strengths as high as 620 to 700 MPa (90 to 100 ksi) have been reported. As the melting temperature of the silver is approached, the strength of the composite converges with that of the tungsten skeleton. Table 7 summarizes mechanical and physical properties of 20 vol% silver-infiltrated material for different test temperatures within the operating temperature range experienced by the throat liner during rocket propulsion (Ref 42).

Jet Engine Components. The quest for materials to withstand the high temperatures and stresses imposed by combustion gases in the gas turbines of jet engines led to the development of cermets in the late 1940s and early 1950s. Cermets offered increased operating temperatures and engine efficiency when used in rotating blades. Their inherent brittleness prevented the use of cermets for this purpose, however, and their use for stationary gas-conducting nozzle vanes also failed to win acceptance. For more information, see the article "Cermets and Cemented Carbides" in this Volume.

To overcome brittleness, the infiltration process was applied to the production of gas turbine components. Sintered and preformed titanium carbide skeletons were infiltrated with a nickel-or cobalt-base superalloy in a vacuum. Graded products that had the following structural characteristics were produced:

- Ductile and tough roots and airfoil tips containing nearly 100% superalloy that withstood combined tensile and bend stresses at moderately high temperatures
- Ductile and tough superalloy-rich leading and trailing edges that resisted impact from small solid particles at temperatures ranging from ambient to operational
- Strong, creep-resistant airfoil portions containing 60 to 80 vol% titanium carbide that withstood the centrifugal force-induced tensile stresses at the highest temperature zones near the radial centroid of the foil, about midway between the root and tip
- Oxidation-protective, ductile, superalloy-rich airfoil encasements integrally joined with the metallic matrix

Figure 14(a) shows a graded turbine bucket for a J-47 jet engine after infiltration. Figure 14(b) shows the graded turbine bucket after machining of the root configuration. The change in microstructure across the airfoil is shown in Fig. 15 (Ref 43). Table 8 gives stress-rupture for different zones of the graded bucket (Ref 43, 49). Other infiltrated titanium carbide turbine components are shown in Fig. 16.

Table 8 Stress-rupture properties of infiltrated graded cermet bucket

Bucket section	Material	Average service temperature		Average service stress		Stress-rupture life (100 h)			
						Temperature		Stress	
		°C	°F	MPa	ksi	°C	°F	MPa	ksi

Fig. 16 Infiltrated titanium carbide cermet jet engine turbine components. (a) J-35 nozzle vane. (b) Experimental hollow vane. (c) J-57 turbine bucket. (d) J-47 turbine bucket

While these infiltrated carbide turbine components, like their sintered cermet counterparts, did not reach commercial production, blades for several stages of the compressor for a J-33 jet engine were mass produced from copper alloy infiltrated steel compacts (Ref 50). These blades were heat treated to a yield strength of 620 MPa (90 ksi), with an

elongation of 5%, and withstood three to four times as much vibration at an operating temperature of 370 °C (700 °F) as blades for these stages made from martensitic type 403 stainless steel precision forgings.

Tools. In parallel development with turbine blades, titanium carbide skeletons were infiltrated with a variety of liquid steel alloys to manufacture tools and wear-resistant parts. The infiltrant varied from simple low-carbon steel to alloy and high-speed steels (Ref 51). Angular or rounded titanium carbide grains resulted, depending on carbide content and matrix composition. Infiltrated materials can be heat treated to produce specific properties. For instance, hardness ranged from 90.1 to 90.6 HRA after water quenching and from 86.0 to 90.3 HRA after tempering. At temperatures up to 750 °C (1380 °F), hot hardness for the titanium carbide that was infiltrated with type T6 tungsten high-speed steel was equivalent to commercial grades of cemented carbides. This material had better oxidation resistance than cemented carbides up to 870 °C (1600 °F) and room-temperature transverse-rupture strengths up to 1500 MPa (220 ksi). Cutting speeds were twice those of molybdenum high-speed steel, one and one-half times those of Stellite, but only one fourth those of commercial steel-cutting grades of cemented carbides.

Because the solubility of titanium carbide in liquid steel is high, the rate of infiltration is slowed so that penetration of the liquid tends to be confined to the regions near the original contact face. The remaining porosity cannot be filled because of diffusion solidification, regardless of the time allowed for penetration of the liquid. As a result, severe size limitations are required for the infiltrated product to be sound and uniform in structure. This disadvantage has caused the substitution of in situ liquid-phase sintering of titanium carbide and steel powder mixtures in the production of such tool materials. For more information, see the article "Cermets and Cemented Carbides" in this Volume.

Mechanical Parts. Infiltration is widely used in the production of ferrous structural parts requiring densities in excess of 7.4 g/cm³ and mechanical properties superior to those obtained by compacting, sintering, and coining. Depending on the application, porous skeletons of iron or steel can be fully or partially infiltrated with copper alloy.

There are several advantages to infiltration of iron-base structural parts with copper alloys (Ref 52):

- *Increased mechanical properties.* Higher tensile strengths and hardnesses, greater impact energies, and fatigue strengths are obtained through infiltration. Figure 17 shows the effect of infiltration on strength.
- *Uniform density.* Parts that contain non-uniform and/or heavy sections can be infiltrated to obtain more uniform density; infiltration tends to even out density variations.
- *Higher density.* Infiltration is a useful method to increase sintered part weight without increasing the size of the part. Given the press size limitations and restrictions in pressing technique and powder compressibility, it is often easier to obtain high density through infiltration. Certainly, when considering normal P/M operations, it would be difficult to obtain densities in excess of 7.2 g/cm³ without resorting to additional pressing and sintering operations. Infiltration makes densities in excess of 7.2 g/cm³ possible in a single pressing and sintering operation.
- *Removal of porosity for secondary operations.* Infiltration can be used in place of impregnation as a method to seal surface porosity so that secondary operations such as pickling and plating can be performed without damaging the interior of the part and creating subsequent "bleeding" problems. It is also a method of sealing a part used for applications in which no porosity is desired.
- *Selective property variation.* It is possible by infiltrating only selected areas of a part to obtain, within limits, a controlled variation of properties in the part—for example, variations in density, strength, and hardness. This is known as localized infiltration. Infiltration to considerably less than the full density in the part (e.g., 7.1 g/cm³) is known as starve infiltration.
- *Assembly of multiple parts.* Different sections of the final part, pressed separately, can be assembled by sintering the individual pieces together and bonding the pieces into one part through common infiltration.

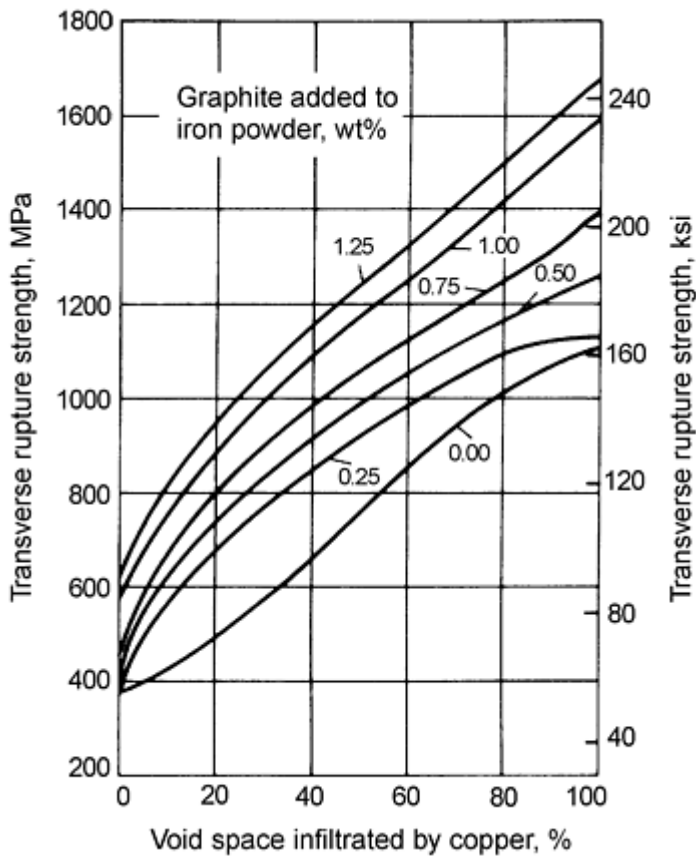

Fig. 17 Effect of infiltration on transverse-rupture strength of iron-carbon alloys sintered to a density of 6.4 g/cm³. Combined carbon in alloys was about 80% of graphite added to iron powder; amount of copper infiltrant was adjusted to fill various fractions of void space. Source: Ref 53

The usual method of infiltrating iron and steel skeletons is to place a compact pressed from the powder of the infiltrant material next to the skeleton. The compact of infiltrant powder can be positioned on top or underneath the skeleton compact, or two infiltrant compacts can be used--one on top, the other underneath the skeleton compact. The exact amount of infiltrant needed can be compacted in the same die in which the powder for the porous skeleton is pressed.

After the skeleton has been sintered, the green compact or compacts of infiltrant powder are positioned next to the skeleton and the assembly heated to the infiltration temperature. Sintering of the skeleton and infiltration can be combined into one operation, in which the green compact or compacts of the infiltrant are positioned next to the green compact of the skeleton. By controlling the rate of heating, the skeleton compact will be adequately sintered by the time the melting point of the infiltrant is reached. This operation is called "sintrating."

If only part of the porous skeleton is to be infiltrated--for example, the teeth of an infiltrated gear--the skeleton can be positioned in a graphite container in which space is provided adjacent to the gear teeth to be preferentially infiltrated. This space is then filled with the appropriate amount of infiltrant in powder form. Because iron has some solubility in copper, the liquid infiltrant will attack the surface of the skeleton when it first comes in contact with it, and severe erosion can take place at this point. One method to minimize erosion is to use a copper alloy (e.g., 80%Cu-20%Zn brass) as infiltrant. Because the brass does not melt at one temperature, but over a range of temperatures, less erosion takes place.

Another method is to use an alloy of copper with iron as an infiltrant. However, it is difficult to specify the exact amount of iron; too little iron can cause erosion, and too much iron can cause an undesirable adherent deposit on the infiltrated part. A third method is to use an alloy of copper, iron, and a third alloying constituent, such as manganese, which oxidizes in the atmosphere in which infiltration takes place. In this case, a crust containing an oxide of the oxidizing alloying ingredient of the infiltrant is formed, which does not adhere to the skeleton but which can be more or less readily removed.

Figure 18 shows a small foot holder that required strength, machinability for tapping a thread, and plateability. These characteristics were achieved by infiltrating a sintered iron-rich skeleton (7% Cu) with a copper-rich alloy containing 5% Mn and 5% Fe. The compacts were infiltrated under furnace conditions similar to those used for sintering, using infiltrating slugs previously pressed. The infiltrated parts were electroplated with chromium to a satin finish. Processing details for the two-step procedure are given in the table that accompanies Fig. 18.

Press and tool details	
Type of press	Mechanical ^(a)
Press capacity	45.4 metric tons (50 tons)
Die material	Tungsten carbide (6% Co)
Punch material	D2 tool steel

Atmosphere for sintering and infiltrating	Endothermic

(a) Two movements above and three below

Fig. 18 Small compact infiltrated with copper alloy to provide machinability, strength, and plateability

The control of dimensions during infiltration can cause problems. It depends on the composition of the steel; carbon-free iron shows the greatest growth during infiltration. It also depends on the exact temperature of infiltration and the time during which the infiltrated compact is above the liquidus temperature of the infiltrant.

Bearings. The best example for the industrial use of infiltration in the bearing field is strip-backed steel, precision-type main, and connecting rod bearings for automobiles. In this application, the anti-friction babbitt alloy is used to infiltrate the pores of a skeletal cupronickel strip that is bonded to the steel backing and produces an extra layer on the surface facing the crankpin (Ref 7, 34).

Infiltration techniques can also be applied to high-temperature bearing materials, such as bearing retainers in gas turbines for supersonic aircraft. To combat the high wear of these cages, an ideal structure consists of a hard, load-bearing phase

intertwined with a liquid metallic lubricant. Structures that closely approach the ideal concept and operate up to 370 °C (700 °F) have been developed (Ref 53).

Materials exhibiting improved anti-friction properties against steel under simulated service conditions involving very high rotational speeds are efficiently fabricated by P/M techniques that include an infiltration step. These materials are characterized by a duplex structure (a soft, metallic phase of about 15 vol%) that is uniformly dispersed throughout the hard matrix. The matrix can be either Monel or a 48Ni-48Cr-4Si alloy, with 10 wt% molybdenum disilicide added in some cases to reduce wear. The soft phase consists of silver that is infiltrated after sintering the hard alloy powder compact.

Infiltration Update

Recently, significant advances have been made into the understanding and control of infiltration processes by developing models for liquid metal flow, heat transfer, wetting and spreading phenomena, and pressure effects. A short summary of such analytical and experimental treatments follows in the section "Mechanism of Infiltration." On the practical side, new ideas concerning infiltration techniques have been developed, the range of infiltration systems has extended, and, most notably, infiltration applications and final products have diversified to cover traditional and new areas. A literature survey on the latter topics is given in "Selected References" at the end of this article.

Mechanism of Infiltration

Analytical treatments to describe fluid flow and heat transfer during infiltration of porous preforms by a liquid metal have been addressed by different groups at MIT (Ref 54, 55, 56, 57, 58, 59, 60, 61) and Colorado School of Mines (Ref 62) in the United States, also in England (Ref 63), France (Ref 64), Japan (Ref 65), China (Ref 66), and Jordan (Ref 67). General expressions have been derived to describe heat, mass, fluid flow, and kinetics during the infiltration process. A review of theoretical factors and mechanisms dealing with infiltration of a porous body by a liquid metal is given in Ref 68. Factors that control the matrix grain size, interfacial reactions, and morphology of the fiber-matrix interface and its stability have been predicted (e.g., initial fiber temperature, preform compressibility, reaction heat, external cooling, or reaction kinetics) (Ref 54, 57, 59, 70). Infiltration kinetics, size of the remelting region, and temperature distributions can be calculated (Ref 54, 58, 61, 62, 65, 70).

Models for pressure effects in conventional or new infiltration processes (squeeze casting or chemical vapor infiltration) have been developed (Ref 54, 57, 60, 61, 67, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80). Based on the analysis of physical phenomena that govern the infiltration process, good practical guidelines to optimize the processing techniques and the materials produced can be found in Ref 75.

The mechanism of wetting and spreading of the liquid metal has been studied (Ref 54, 78, 81, 82). These studies reveal the formation of a precursor film ahead of the bulk liquid front by adsorption, condensation, and surface migration on the solid wall (Ref 82). A model for chemical vapor infiltration is presented in Ref 83 and 84.

Sensors and models apparatuses (e.g., noninvasive capacitance technique), model experiments, and instrumented casting facilities have been developed to confirm theoretical predictions (Ref 55, 56, 58, 60, 64, 78, 81, 85, 86, 87). Modeling of magnetic field assisted and ultrasonic infiltration also has been attempted (Ref 88, 89, 90). A validation of the Lorenz force model has been experimentally obtained (Ref 88).

Infiltration Techniques

- Lorentz-Force-Driven Infiltration by Aluminum, R.M. Andrews and A. Mortensen, *Mater. Sci. Eng. A*, Innovative Inorganic Composites Symp., 8-11 Oct 1990 (Detroit, MI), Vol A144, 1991, p 165-168. A new process for infiltrating fibrous preforms with liquid metal that eliminates the need for pressurization of the metal or preform chemical pretreatment is presented. The molten matrix material and preform are held in a ceramic crucible so that the melt forms an annulus around the preform. The material and preform are then subjected to an intense high frequency magnetic pulse. The eddy currents induced in the melt interact with the magnetic pulse to propel the metal into the preform at a high speed, infiltrating the preform. The infiltration length is governed by the nature and number of discharges. The predicted electromagnetic field is then used together with Ergun's equation to calculate the infiltration distance.
- The Preparation of Oxidation Resistant Silicon Carbide-Silicon Carbide Composites by Chemical Vapor Infiltration (CVI), D. Bashford, *New Materials and Their Applications 1990*, Proc. of the 2nd Int. Symp., 10-12 April 1990 (Warwick, U.K.), D. Holland, Ed., IOP Publishing, Bristol, U.K., 1990, p 239-245. Continuous fiber-reinforced ceramics need to be prepared so that they possess benign fracture characteristics to give a good balance between strength and fracture toughness. CVI is particularly suitable for preparing SiC-SiC composite shapes, provided specific attention is given to preform construction, fiber to matrix interfaces, infiltration techniques, and overall composite microstructure.
- Processing of Carbon Fiber-Reinforced Aluminum Composite Using K_2ZrF_6 Treated Carbon Fibers: A Degradation Study, S.N. Patankar, V. Gopinathan, and P. Ramakrishnan, *J. Mater. Sci. Lett.*, Vol 9 (No. 8), 1990, p 912-913. The infiltration of molten aluminum in an array of carbon fibers by application of K_2ZrF_6 onto the fiber surface is discussed. The presence of K_2ZrF_6 causes instantaneous infiltration of carbon fiber torus; however, fiber degradation occurs if the molten aluminum temperature and time of contact during infiltration are not regularly checked.
- Microstructural Evolution during the Infiltration Treatment of Titanium Carbide-Iron Composite, K.-W. Chae, D.-I. Chun, D.-Y. Kim, and Y.-J. Baik, *J. Am. Ceram. Soc.*, Vol 73 (No. 7), 1990, p 1979-1982. The microstructural evolution of grain-matrix interfaces in TiC-Fe cermet has been observed and explained in terms of equilibration reaction and interfacial energy minimization. The coherency strain energy is assumed to be the driving force for enhanced dissolution of certain specific planes, which results in a very irregular grain shape. The equilibrium shape appears after heat treatment for a long period of time.
- Synthesis of SiC Platelet Reinforced 2014 Aluminum Alloys by a Pressure Infiltration Technique, R. Asthana and P.K. Rohatgi, *J. Mater. Sci. Lett.*, Vol 10 (No. 4), 1991, p 230-234. A technique that employs countergravity pressure is used to infiltrate prepacked columns of SiC platelets. This liquid metallurgy technique is applicable to synthesize aluminum alloy composites containing relatively high (50% or more) volume fractions of platelet-shaped silicon carbide reinforcement.
- Fabrication of Cast Particle Reinforced Metals via Pressure Infiltration, E.M. Klier, A. Mortensen, J.A. Cornies, and M.C. Flemings, *J. Mater. Sci.*, Vol 26 (No. 9), 1991, p 2519-2526. A new casting process for fabrication of particle-reinforced metals whereby a composite of particulate reinforcing phase in metal is first produced by pressure infiltration is presented. This composite is then diluted in additional molten metal to obtain the desired reinforcement volume fraction and metal composition. This process produces a pore-free as-cast particulate metal matrix composite. It was demonstrated for Mg-SiC particles (3, 10, 30 μm) and compared to compocasting (which produces unacceptable porosity).
- Vapor-Phase Fabrication and Properties of Continuous-Filament Ceramic Composites, T.M. Besmann, B.W. Sheldon, R.A. Lowden, and D.P. Stinton, *Science*, Vol 253 (No. 5024), 1991, p 1104-1109. The continuous-filament ceramic composite is becoming recognized as necessary for new high-temperature structural applications. Yet because the filaments are susceptible to damage from traditional methods for the preparation of ceramics, vapor-phase infiltration has become the fabrication method of choice. The chemical vapor infiltration methods for producing these composites are now being studied in earnest, with the complexity of filament weaves and deposition chemistry being merged with standard heat and mass-transport relationships. Two of the most influential effects on the mechanical properties of these materials are adhesion and frictional force between the fibers and the matrix, which can be controlled by a tailored interface coating. A variety of materials are available for producing these composites, including carbide, nitride, boride, and oxide filaments and matrices. SiC-based materials are by far the most advanced and are already being used in aerospace applications.

- Chemical Vapor Infiltration (CVI) of Silicon Carbide Fiber Preforms, R. Lundberg, L. Pejryd, and G. Loof, *J. Phys. (France) IV*, Vol 1 (No. C2), 1991, p 491-495. An alternative fabrication technique for ceramic matrix/ ceramic fiber composites involving filling a fiber fabric preform with an Si/Si₃N₄ slurry and subsequent reaction bonding is presented. For the first processing step, chemical vapor deposition (CVD) is evaluated as a means of both binding together and protecting the fibers. SiC (Nicalon) fiber preforms consisting of through-stitched two-dimensional fabrics are infiltrated. The preform thickness is more than 4 mm, and a 3 μm TiC/TiN layer is subsequently deposited on all the fibers, even in the center of the preform after less than 8 h. The purpose of the CVI layer is not only to bind the fibers together but also to protect the fiber/matrix interfacial carbon film from reaction with the subsequently infiltrated matrix. The remaining porosity of the preform is filled with a Si/Si₃N₄ powder slurry, which is nitrified to form a reaction bonded Si₃N₄ (RBSN) matrix. The advantage of this combined CVI/RBSN route is a substantial cut in processing time compared to a process where most of the porosity is filled using CVI.
- The Fabrication of Metal Matrix Composites by a Pressureless Infiltration Technique, M.K. Aghajanian, M.A. Rocazella, J.T. Burke, and S.D. Keck, *J. Mater. Sci.*, Vol 26 (No. 2), 1991, p 447-454. A novel technique for fabricating metal matrix composites by the spontaneous (pressureless) infiltration of filter preforms with molten aluminum alloys is described. Numerous reinforcing materials, including Al₂O₃ and SiC of various configurations, such as particles, agglomerates, and fibers, have been incorporated as fillers. The effects of processing variables, such as alloy chemistry, process temperature, and filler material, on the infiltration kinetics and resultant microstructures are discussed. Comparisons with existing infiltration technology and preliminary composite properties are presented.
- High Pressure Infiltration Casting: Manufacturing Net Shape Composites with a Unique Interface, R.B. Bhagat, *Mater. Sci. Eng. A*, Vol 144, 1991, p 243-251. An overview of the major casting-based manufacturing techniques of metal matrix composites is presented (compocasting or rheocasting, squeeze casting, infiltration, investment casting, and pressure casting or squeeze infiltration casting). Attention is focused on high pressure infiltration casting, which uses a rapid application of a relatively high pressure to force-infiltrate molten metal into fiber preforms. Reaction between fiber and matrix metal is negligible, and the cast composites are free from voids, gas porosity, and shrinkage cavities.
- Pressure Infiltration Casting of Metal Matrix Composites, A.J. Cook and P.S. Werner, *Mater. Sci. Eng. A*, Vol 144, 1991, p 189-206. In pressure infiltration casting, a pressurized inert gas forces the liquid metal into a preform of reinforcement material. The method utilizes an enclosed die chamber with controlled pressurization that makes possible the use of low-strength molds with high infiltration pressures. This is an inexpensive method to produce composite materials, prototypes, and near-net shapes. The parts can be infiltrated and directionally solidified.
- Combustion Synthesis of Ceramic-Metal Composite Materials: the TiC-Al₂O₃-Al System, H.J. Feng, J.J. Moore, and D.G. Wirth, *Metall. Trans. A*, Vol 23 (No. 9), 1992, p 2373-2379. One of the main disadvantages of combustion synthesis of ceramic and composite materials is the relatively high levels of porosity (≥50%) present in the product. The article discusses a novel application of combustion synthesis for producing ceramic-metal composites with reduced levels of porosity by allowing an excess amount of liquid metal, generated by the exothermic reaction, to infiltrate the pores. This application of combustion synthesis of ceramic-metal composite materials is discussed with respect to a model reaction system that utilizes an inexpensive oxide, i.e., TiO₂, reacted with carbon and an excess stoichiometric amount of aluminum. The aluminum is in the liquid state at the ignition temperature and is intentionally allowed to infiltrate the porous ceramic matrix (i.e., TiC-Al₂O₃) produced from the combustion synthesis reaction. This in situ process for producing ceramic-metal composites by the simultaneous liquid-metal infiltration of the pores in a ceramic matrix using the combustion synthesis approach provides considerable advantages over a conventional process.
- Observations on Infiltration of Silicon Carbide Compacts with an Aluminum Alloy, R. Asthana and P.K. Rohatgi, *J. Mater. Sci. Lett.*, 1 Oct 1992, Vol 11 (No. 19), 1992, p 1278-1281. The infiltration process consists of countergravity infiltration of suitably tamped and preheated compacts of SiC platelets under an external pressure in a special pressure chamber for a set period, followed by solidification of the infiltrant metal in the interstices of the bed at atmospheric pressure. Some experimental observations are presented on the infiltration behavior and matrix microstructures that form when porous compacts of platelet-shaped single crystals of α-SiC (hexagonal) are infiltrated under gas pressure with a liquid 2014 aluminum alloy

(nominal composition Al-4.5Cu-0.8Si-0.8Mn-0.5Mg).

- Consolidation of Continuous Fiber Intermetallic-Matrix Composites, S.L. Semiatin, R.L. Goetz, and W.R. Kerr, *Intermetallic-Matrix Composites II Symp.*, 27-30 April 1992 (San Francisco, CA), D.B. Miracle, D.L. Anton, and J.A. Graves, Ed., Materials Research Society, 1992, p 351-364. Processing routes for fabrication of continuous fiber, intermetallic-matrix composites, including conventional and hot isostatic pressing of layups of matrix material (e.g., foil or powder cloth) and fiber mats, consolidation of monotapes made by techniques such as arc, plasma, vapor, or electron beam deposition or tape casting, and liquid-metal infiltration-base methods are reviewed. The advantages and disadvantages of the various methods are discussed.
- Preparation and Properties of Reinforced Mg-Li Superlight Alloys by High Pressure Infiltration in an Autoclave, A. Schweighofer, E. Hornbogen, S. Kudela, and K. Schemme, *Magnesium Alloys and Their Applications*, 8-10 April 1992 (Garmisch Partenkirchen, Germany), B.L. Mordike and F. Hehmann, Ed., DGM, 1992, p 423-430. A high pressure infiltration method is used for the production of Mg-Li matrix composites. Most favorable materials are magnesium-lithium alloys with up to 8 wt% Li combined with coated carbon fibers. Other ceramic fibers such as SiC and Al₂O₃ are also suitable but raise the bulk density much more than carbon fibers.
- Near-Net Shape Long Fiber-Reinforced Intermetallic-Matrix Composites Produced by Reactive Infiltration Process, H. Chen, M. Kaya, and R.W. Smith, Ed., *Mater. Lett.*, Vol 13 (No. 4-5), 1992, p 180-183. A reactive melt infiltration technique is utilized for the processing of intermetallic (NiAl and Ni₃Al) matrix composites. The intermetallic compound matrix can be formed by in situ reaction during the flow of molten metal or alloy into a nickel-powder preform containing reinforcements. With this method, the macrosegregation of nickel can be controlled to produce materials with varying microstructural zones, which can enhance high-temperature mechanical properties.
- Discussion of a Liquid-Metal Pressure Infiltration Process to Produce Metal Matrix Composites (MMCs), J.T. Blucher, *J. Mater. Process. Technol.*, Vol 30 (No. 3), 1992, p 3821-3900. The two major processing techniques to manufacture MMCs are solid state diffusion bonding and squeeze casting. The former has size limitations; it is suitable for flat sheets or plates, and the manufacturing rate is low and expensive. The latter, although suitable for large production of complex shapes, requires heavy and expensive tooling. The described pressure infiltration process was developed at the Massachusetts Institute of Technology. In this process, fiber, whisker, or particulate preforms are placed in inexpensive disposable containers, into which gas pressure forces the molten matrix material. The gas pressure quasi-isostatic, thus reducing the strength requirements for containers and making the process inexpensive. As the processing parameters, such as preform and melt temperatures, infiltration pressure, and cooling rate, can be accurately controlled, the process is particularly suitable for research and limited production.
- An Advanced Melt Infiltration Process for Net Shape Production of Metal Matrix Composites, O. Ottinger and R.F. Singer, *Z. Metallkd.*, Vol 84 (No. 12), 1993, p 827-831. An alternate process to squeeze casting to produce fiber-reinforced light metals for the automotive industry is proposed. This new process is expected to have advantages in certain cases, such as low volume production, intricate shapes, and low heat capacity metals. First results for the magnesium alloy MSR reinforced with 20 vol% Saffil short fiber are presented, indicating that mechanical properties are equivalent to composites obtained by squeeze casting.
- Graded Compositions and Microstructures by Infiltration Processing, B.R. Marple and D.J. Green, *J. Mater. Sci.*, Vol 28, 1993, p 4637-4643. Mullite/alumina particulate composites are fabricated by infiltrating porous alumina preforms with an SiO₂-containing sol, followed by a heating step for mullite formation and densification. Electron microprobe analysis is performed to obtain concentration profiles across sections of the sintered composites. These profiles indicate concentration gradients with mullite content decreasing with increasing distance from the surface of the bodies. An increase of the alumina grain size is also noticed in the same direction. These two effects (microstructural and compositional) have been related, and it has been concluded that while the mullite presence limits grain growth in alumina, the mullite content has to be at least ~5 wt% in order for grain growth to occur in a controlled fashion.
- Processing of Molybdenum Disilicide Using a New Reactive Vapor Infiltration Technique, N. Patibandla and W.B. Hillig, *J. Am. Ceram. Soc.*, Vol 76, 1993, p 1630-1634. In this new process, a loosely compacted molybdenum powder is exposed to a gaseous silicon precursor. Initially, a surface MoSi₂ layer forms that

subsequently progresses inward. At 1200 °C, the silicide layer grows at a rate of about 20 μm/h. No excess silicon or molybdenum is present, unlike in chemically vapor deposited MoSi₂. Irrespective of the volumetric increases involved in siliciding molybdenum to MoSi₂, none of the samples silicided between 1100 and 1300 °C showed swelling or surface cracks.

- Reactive Melt Infiltration of Silicon-Niobium Alloys in Microporous Carbon, M. Singh and D.R. Behrendt, *J. Mater. Sci.*, Vol 9 (No. 7), 1994, p 1701-1708. Reactive melt infiltration of silicon-niobium alloys in microporous carbon preforms prepared by the pyrolysis of a polymer precursor is studied by modeling, differential thermal analysis (DTA), and melt infiltration experiments. Mercury porosimetry results indicate a very narrow pore size distribution with all open pores. The morphology of the residual phases (NbSi₂ and Si) in the infiltrated material can be tailored by the control of pore size and distribution of the carbon preform and alloy composition. The average room temperature four-point flexural strength of a reaction formed SiC (made by infiltration of medium pore size preforms with Si-5at%Nb) is 290 ± 40 MPa (42 ± 6 ksi), and the fracture toughness is 3.7 ± 0.3 MPa√m. The flexural strength decreases at high temperature due to relaxation of the residual thermal stresses and the presence of free silicon in the material.
- Silicon-Aluminum Network Composites Fabricated by Liquid Metal Infiltration, Y.Y. Chen and D.D.L. Chung, *J. Mater. Sci.*, Vol 29 (No. 23), 1994, p 6069-6075. A new method for fabricating interpenetrating silicon-aluminum network metal matrix composites is presented. The method involves infiltration of an aluminum-silicon alloy (Al-12Si-1Mg or Al-30Si-1Mg) liquid into a SiC (50 vol%) preform. The silicon particles are partially dissolved by the liquid alloy and contribute to the formation of a silicon network after solidification. The composites are metallurgically sound with no porosity. The thermal expansion coefficient is low (7.7×10^{-6} at 50-100 °C) with compressive strength up to 580 MPa, tensile strength up to 160 MPa, and Vickers hardness up to 390.
- Application of Ultrasonic Vibration to Molten Aluminum Infiltration, Y. Tsunekawa, H. Nakanishi, M. Okumiya, and N. Mohri, *Key Eng. Mater.*, Vol 104-107, 1995, p 215-224. A new method of infiltration at a very low applied pressure has been developed. Ultrasonic vibration has been applied to improve the wettability of Al₂O₃ particle or fibers by molten aluminum. This ultrasonic vibration allows infiltration to take place at a very low pressure. At the same time, noninfiltrated defects are minimized. The method has been successfully applied for the fabrication of in situ metal matrix composites starting with titanium powders and Al₂O₃.
- Development of the Technique of Extrusion Directly Following Infiltration for the Manufacturing of Metal-Matrix Composites, L.X. Hu, S.J. Luo, W.C. Huo, and Z.R. Wang, *J. Mater. Process. Technol.*, Vol 49, 1995, p 287-294. A new technique that involves extrusion directly after infiltration is aimed at providing a good bond between the matrix and the reinforcement and eliminating the voids. The new method combines melt infiltration, squeeze casting, and semi-solid extrusion and is particularly suitable for the manufacturing of bars, pipes, plates of fiber, or particulate MMCs.
- Reactive Melt Infiltration of Silicon-Molybdenum Alloys into Microporous Carbon Preforms, M. Singh and D.R. Behrendt, *Mater. Sci. Eng. A*, Vol 194 (No. 2), 1995, p 193-200. Reactive melt infiltration of Si-1.7at%Mo and Si-3.2at%Mo alloys into microporous carbon preform is studied by modeling, differential thermal analysis (DTA), and melt infiltration experiments. These results indicate that pore volume fraction of the carbon preform is an important parameter for the final composition of the reaction formed SiC and secondary phases. The liquid silicon-carbon reaction exotherm temperatures are influenced by pore and carbon particle size and the compositions of infiltrants. Room temperature flexural strength and fracture toughness of Si-3.2at%Mo alloy infiltrated into medium ore size preforms are presented. Various undesirable results (e.g., choking-off, specimen cracking, silicon veins, and lake formation) are presented in relationship to inadequate preform properties.
- Fabrication of Intermetallic Compound Matrix Composite by Spontaneous Infiltration and Subsequent In Situ Reaction Process, T. Choh, T. Mohri, and M. Kobashi, *J. Mater. Process. Technol.*, Vol 63 (No. 1-3), 1997, p 379-383. Titanium aluminides intermetallic compound matrix composites were in situ synthesized by spontaneous infiltration of liquid aluminum into a powder mixture of titanium and Al₂O₃.
- Fabrication of Al₂O₃ Composites by Reactive Melt Infiltration, W.P. Tai, *Am. Ceram. Soc.*, Vol 76 (No. 4), April 1997, p 86-89. Near-net shape Al₂O₃ composites containing a small amount of silicon metal are fabricated by infiltrating aluminum into Al₂O₃ particle preforms with the aid of borosilicate glass. The

process is conducted under oxygen atmosphere at ambient pressure (1 atm) using a conventional furnace. The growth rate and mechanical properties of the composites are investigated by changing the processing factors.

Infiltration Systems

- Wetting and Infiltration of Porous Tungsten and Molybdenum by Liquid Gallium, A.V. Ivanov, T.S. Ivanova, L.I. Kostenetskaya, Y.I. Smirnov, and M.M. Churakov, *Sov. Powder Metall. Met. Ceram.*, Vol 23 (No. 56-58), 1984. Electrical contacts with a solid skeleton of tungsten or molybdenum have been produced by liquid gallium infiltration. Specimens are compacted under a pressure of 390 MPa and sintered for 2 h in hydrogen at 1400 and 1200 °C, respectively, with resulting porosities of 38 and 44%. Wetting experiments are carried out in helium, hydrogen, or vacuum. An intermetallic compound and sintered molybdenum layers that formed at 600 °C prevented gallium infiltration.
- Kinetic Laws for Infiltration of Porous Titanium by Lead and Indium Melts, A.A. Kurilko, G.A. Kurshev, V.A. Rudyuk, and Y.V. Naidich, *Sov. Powder Metall. Met. Ceram.*, Vol 23, 1984, p 686-689. This process is similar to active soldering of nonmetallic oxide materials. A molten solder (e.g., tin, lead, or indium) infiltrates and spreads over its surface. The work is aimed at studying the kinetics of infiltration of titanium powders by two metallic melts: indium and lead.

Metal Matrix Composites (MMC)

- Casting Particulate and Fibrous Metal Matrix Composites by Vacuum Infiltration of a Liquid Metal Under an Inert Gas Pressure, J. Yang and D.D.L. Chung, *J. Mater. Sci.*, Vol 24 (No. 10), 1989, p 3605-3612. MMCs are fabricated by a combination of three techniques: vacuum infiltration, infiltration under an inert gas pressure, and squeeze casting. The particulate or fiber preform is placed in a mold with the matrix alloy above the preform. A gas under pressure (7 to 17.3 MPa or 1000 to 2500 psi) forces the melt to infiltrate the preform. The temperature and pressure are below those used in squeeze casting, thus minimizing the interfacial reactions. The method has been used to fabricate aluminum-matrix composites with short ceramic or continuous ceramic fibers (e.g., SiC whiskers) and particle reinforcements (e.g., SiC, Al₂O₃, graphite flakes).
- Infiltration of Aluminum into Silicon Carbide Compacts, P.B. Maxwell, G.P. Martins, D.L. Olson, and G.R. Edwards, *Metall. Trans. B*, Vol 21, 1990, p 475-485. Although liquid-metal processing of MMCs offers economic advantages, problems related to the nonwetting nature of the ceramic discontinuous reinforcement create obstacles to its ready implementation. Infiltration can occur only if a threshold pressure is applied to overcome the unfavorable interfacial forces in the system. Experiments were carried out to infiltrate SiC compacts with pure aluminum, Al-1wt%Mg and Al-1wt%Si. An incubation time was found to be necessary before infiltration can proceed, even though the threshold pressure is exceeded. It is suggested that the mechanism responsible for the incubation phenomenon might be related to a surface modification produced by either reaction of liquid aluminum with an oxide film on the surface of the particles or coverage of the surface by a capillarity-induced aluminum condensate.
- Ceramic Metal Composite Produced by Melt Infiltration, C. Toy and W.D. Scott, *J. Am. Ceram. Soc.*, Vol 73 (No. 1), 1990, p 97-101. A new ceramic-metal composite with continuous interconnected phases is fabricated from sintered AlN infiltrated with aluminum metal. A dense, lightweight, hard material with high strength is obtained. Advance of the infiltration front is linear with time. The activation energy for the process is high (330 kJ/mol) suggesting a chemical reaction rather than viscous flow as the rate controlling mechanism. The infiltration rate is inversely proportional to the pore size. The thermal and mechanical properties of the composite are promising.
- Interface Studies in Cast Fiber-Reinforced Metals, V.D. Scott and Y. Ming, *Advanced Structural Inorganic Composites, Proc. of the Satellite Symp. 2 on Advanced Structural Inorganic Composites of the 7th Int. Meeting on Modern Ceramics Technologies, 27-30 June 1990 (Montecatini Terme, Italy)*, P. Vincenzini, Ed., Elsevier, 1991, p 95-108. The microstructures of a number of composite materials manufactured by liquid-metal infiltration of a fiber preform are described, with particular reference to the fiber/matrix interface. Examples are given whereby the interface is related to the type of bond developed (i.e., physical or chemical). The complexities introduced by the presence of matrix second phases, including impurities, are mentioned. The results, as well as demonstrating the importance of carrying out full and detailed

microstructural studies of the fiber/matrix interface, emphasize the need to explore and to assess every aspect of composite structure.

- Directed Metal Oxidation and Pressureless Metal Infiltration: New Technologies for the Fabrication of Reinforced Ceramics and Metals, C.R. Kennedy, *Advanced Structural Inorganic Composites, Proc. of the Satellite Symp. 2 on Advanced Structural Inorganic Composites of the 7th Int. Meeting on Modern Ceramics Technologies*, 27-30 June 1990 (Montecatini Terme, Italy), P. Vincenzini, Ed., Elsevier, 1991, p 691-700. Key features and advantages of new technologies for fabricating reinforced ceramics and metals are reviewed. Microstructures and properties of composites tailored for a variety of applications are presented.
- Magnesium-Base Hybrid Composites Prepared by Liquid Infiltration, J. Schroeder and K.J. Kainer, *Mater. Sci. Eng. A*, Vol 135 (No. 1-2), 1991, p 33-36. Liquid infiltration of ceramic fiber preforms is an economical alternative to produce magnesium matrix composites with discontinuous fibers. The high cost stems from the preform and reinforcements (short fibers or whiskers).
- Two-Dimensional SiC/SiC Composites Processed According to the Isobaric-Isothermal Chemical Vapor Infiltration Gas Phase Route, R. Naslain, *J. Alloy. Compd.*, Vol 188, 1992, p 42-48. Chemical vapor infiltration (CVI) is a process according to which a ceramic material is deposited from a gaseous precursor in the open pores of a heated substrate. It has been used to elaborate ceramic matrix composites, starting from porous fiber preforms. SiC/SiC composites consist of an SiC CVI-matrix reinforced with Si-C-O expolycarbosilane yarn fibers. These composites exhibit nonbrittle mechanical behavior in tension loading when a thin layer of compliant interphase material (turbostratic pyrocarbon or hexagonal boron nitride) with a low shear failure stress is deposited onto the fibers prior to infiltration of the SiC-matrix. When exposed to oxidizing atmospheres, SiC/C/SiC composites are selfhealing if their carbon-interphase is thin enough and the temperature is high. Their oxidation resistance can be improved by replacing the vulnerable carbon-interphase by a BN-interphase (low temperature exposures) and/ or adding a glass-former coating on the external surface of the composites.
- Effect of Pore Size on the Infiltration Kinetics of Aluminum in Titanium Carbide Preforms, D. Muscat, R.L. Harris, and R.A. Drew, *Acta Metall. Mater.*, Vol 42, 1994, p 4155-4163. Infiltration by capillarity is a simple and attractive way of fabrication metal/ceramic composites. Four different TiC preforms of approximately 58% density with different pore sizes ranging from 1 to 30 μm are produced. They are suspended in a thermogravimetric analyzer (TGA) and infiltrated with molten aluminum under flowing argon. Infiltration profiles are obtained by continuously monitoring the weight change of the preform at temperatures from 860 to 1300 °C. Kinetic analysis of the infiltration profiles yields activation energies ranging from 105 to 450 kJ/mol, depending on pore size. It is suggested that the driving mechanism changes from a diffusion controlled process for smaller pore size to one that is driven by a surface reaction at the interface of larger pores.
- Reactive Infiltration Processing of SiC-Metal and SiC-Intermetallic Composite, L. Hozer and Y.M. Chiang, *J. Mater. Res.*, Vol 11 (No. 9), 1996, p 2346-2357. Reactive infiltration is used to infiltrate carbon with silicon-aluminum and silicon-copper melts to prepare composites consisting of interpenetrating networks of β -SiC and a secondary phase assemblage containing ductile metal (silicon-aluminum) or a metal silicide (silicon-copper). The mechanisms of phase formation are characterized. A rapid initial reaction upon infiltration forms a largely stationary SiC network, within which the secondary phase evolves due to solute rejection and liquid phase diffusion processes. Both homogeneous composites and controlled composition gradients are synthesized.
- Fabrication and Analysis of an In Situ TiB₂Al Composite by Reactive Spontaneous Infiltration, M. Kobashi and T. Choh, *Scr. Mater.*, Vol 34 (No. 8), April 1996, p 1257-1265. An in situ reactive spontaneous infiltration is used to fabricate an Al-MgTiB₂, AlN composite using TiN, TiC_xN_{x-1}, boron powders and aluminum-magnesium ingot as starting materials. An experimental setup is also employed in order to study the infiltration process by using a precision multirecorder, which continuously monitors the temperature change in the powder mixture of TiN or TiC_xN_{x-1} and B as the metal infiltrated.

Particulate MMC

- The Structure and Properties of Infiltrated Titanium Carbide Cemented Carbide, R.F. Mamleev and V.N. Antsiferov, *Sov. Powder Metall. Met. Ceram.*, Vol 29 (No. 2), 1990, p 153-156. The influence of the titanium carbide skeleton porosity and its temperature of infiltration with a multialloyed (9.5% Co, 9.5 Cr,

2.0 Mo, 10.0 W, 2.6 Ti, 5.4 Al, 0.3% Si) nickel alloy (SNS) on the structure and mechanical properties of the composite created at temperatures up to 1150 °C was studied. TiC powder to TU 6-09-492-75 with an average grain size of 3 to 4 μm and individual aggregates up to 20 μm is used to produce the skeletons. The powder is pressed with additions of 5% plasticizer under a pressure of 10 to 400 MPa and sintered in vacuum with a residual pressure of less than 10^{-2} Pa at 1400 to 1800 °C for 0.5 h. The infiltration is done by application of the metal to the skeleton in vacuum at 1450 to 1600 °C for 0.5 h. The yield strength in compression is established and the bend strength is determined by the three-point bend method.

- Pressureless Sintering of SiC-Whisker-Reinforced Al₂O₃ Composites II: Effects of Sintering Additives and Green Body Infiltration, H.-W. Lee and M.D. Sacks, *J. Am. Ceram. Soc.*, Vol 73 (No. 7), 1990, p 1894-1900. Pressureless sintering of SiC-whisker-reinforced Al/Al₂O₃ composites is investigated. The effects of Y₂O₃/MgO sintering additives and green body infiltration on the densification behavior and microstructure development are reported. Both sintering additives and green body infiltration result in enhanced densification. However, the infiltration approach is more effective for samples with high SiC whisker concentrations. Samples with 27 vol% whiskers could be pressureless sintered to approximately 93% relative density and approximately 3% open porosity. Fracture toughness values and microstructural features (e.g., grain size) for the infiltrated samples remained approximately the same as observed in the uninfiltrated samples.
- Squeeze Infiltration--A Potential Process to Develop Aluminum Ceramics Particulate Composites, R.S. Solanki, A.K. Sing, K. Basu, and C.B. Raju, *Advanced Structural Inorganic Composites, Proc. of the Satellite Symp. 2 on Advanced Structural Inorganic Composites of the 7th Int. Meeting on Modern Ceramics Technologies*, 27-30 June 1990 (Montecatini Terme, Italy), P. Vincenzini, Elsevier, 1991, p 747-756. All recent effort on metal matrix composites (MMCs) has considered the light metal, especially aluminum matrix composites (AMCs). The present investigation deals with the development of aluminum ceramic particulate composite using a low cost squeeze infiltration process. The defect-free AMCs were produced by a squeeze infiltration of suitably treated ceramic particulate porous preform by application of pressure up to 150 MPa. These AMCs were characterized by optical and scanning electron microscopes. Improvement in hardness value over AMCs produced by the Vortex method was observed.
- Properties of TaC-Based Metal-Matrix Composites Produced by Melt Infiltration, K. Shanker, L.T. Mavropoulos, R.A.L. Drew, and P.G. Tsantrizos, *Composites*, Vol 23 (No. 1), 1992, p 47-53. TaC/metal-matrix composites were developed for use as electrodes in plasma systems; in addition, they were observed to possess excellent mechanical properties. Composites of TaC/Al, formed by infiltrating TaC preforms with pure aluminum under optimal infiltration conditions of 1500 °C for 0.5 h, had yield strengths of approximately 100 to 125 MPa, ultimate tensile strengths of approximately 440 MPa, and elongations of 7% while containing 48 to 63% TaC. The composite consists of discrete TaC particles in a continuous aluminum matrix. Increasing the metal infiltration temperature results in a rapid decrease in the tensile properties of these composites. Composites of TaC/Cu were not as easy to fabricate as those of TaC/Al. Infiltration without distortion or cracking was feasible over a narrow TaC range (43 to 50%) and required the infiltration to be carried out in vacuum. Under these conditions, the composites had a yield strength of 90 to 135 MPa, ultimate tensile strength of approximately 760 MPa, and elongation of approximately 15.3%. All the composites had excellent machinability and could be machined using conventional methods and equipment.
- Al/TiC Composites Produced by Melt Infiltration, D. Muscat, K. Shanker, and R.A.L. Drew, *Mater. Sci. Technol.*, Vol 8 (No. 11), 1992, p 971-976. An Al/TiC composite has been developed using a melt infiltration technique. Green preforms of TiC were partially sintered to densities ranging from 50 to 85%. They were then infiltrated with molten aluminum in argon at atmospheric pressure at temperatures ranging from 950 to 1350 °C. The variations in mechanical properties of this composite material with ceramic content and fabrication conditions are presented and the resulting microstructures are discussed. The composite exhibited excellent tensile strength values of approximately 475 MN/m² and up to 5% elongation. Fracture behavior mechanisms are also described in relation to the stress-strain curves. High infiltration temperatures were found to be detrimental to the mechanical properties because the TiC particle network, which formed during sintering, was broken down by the metallic phase.
- Melt Infiltration of Silicon Carbide Compacts, R. Asthana and P.K. Rohatgi, *Z. Metallkd.*, Vol 83 (No. 12), 1992, p 887-892. Countergravity, pressure-assisted infiltration with a 2014 aluminum alloy of suitably tamped porous compacts of platelet-shaped single crystals of α (hexagonal) SiC was used to measure

particulate wettability and infiltration kinetics under dynamic conditions relevant to pressure casting of composites. A threshold pressure (p_{th}) for ingress of the infiltrant was identified based on the experimental penetration length versus pressure profiles for a range of experimental variables that include infiltration pressure, infiltration time, SiC size, and SiC surface chemistry (plain, copper coated, and nickel coated). The results showed that p_{th} decreased whereas the penetration length increased with increasing SiC size and infiltration time. Copper coated SiC led to lower p_{th} (and lower estimated wetting angles) and larger (60 to 80%) penetration lengths compared to uncoated SiC under identical conditions. These observations have been discussed in the light of theoretical models of infiltration and the kinetics of wetting.

- Infiltration Processing of Metal-Matrix Composites: A Review, R. Asthana, P.K. Rohatgi, and S.N. Tewari, *Process. Adv. Mater.*, Vol 2 (No. 1), 1992, p 1-17. An overview of the current understanding of some fundamental materials phenomena relevant to infiltration processing of metal-matrix composites (MMCs) is presented. The fundamental aspects of wettability, chemical reaction-induced interfacial phenomena, capillarity, infiltration kinetics and fluid flow, and structure evolution in infiltrated MMCs are discussed in light of results of recent experimental and theoretical studies on some commercially important MMCs, such as Al_2O_3 -Al and SiC/Al. The lack of a comprehensive theoretical framework suitable for rationalizing observations on processing and microstructural aspects of infiltrated MMCs is emphasized and potential areas for further research effort have been identified.
- Threshold Pressure for Infiltration in Mica-Ceramic Particle/Aluminum Composite, H. Nakanishi, Y. Tsunekawa, M. Okumiya, M. Higashi, and M. Kanatani, *J. Jpn. Inst. Light Met.*, Vol 42 (No. 2), 1992, p 92-97. Threshold pressure method was used to evaluate wettability of mica-ceramic particles by molten aluminum. Three ceramic particle sizes were used (L, M, S). Pressure infiltration of the particle preforms were performed at 998 K in vacuum and air. The threshold pressures were found to be 80.9 (L), 77.8 (M), and 159 (S) in vacuum and 96.9 (L), 96.1, (M) and 162 (S) kPa in air. The lower threshold pressure in vacuum is attributed to the better wettability. Noninfiltrated defects with a meniscus configuration were observed in the vicinity of two-particle contact. Flat defects were noticed in L preforms and aggregate defects in S preforms. Modeling of defects with meniscus configuration has been performed, and a contact angle between mica-ceramic and molten aluminum of 2.39 rad was calculated. The relationship between the threshold pressure and contact angle is dependent on defect configuration.
- Diamond/Aluminum Metal Matrix Composites Formed by Pressureless Metal Infiltration Process, W.B. Johnson and B. Sonuparlak, *J. Mater. Res.*, Vol 8 (No. 5), 1993, p 1169-1173. The diamond particles were coated with SiC prior to pressureless infiltration to prevent the formation of Al_4C_3 compound. The measured thermal conductivity of the initial diamond-aluminum composite is as high as 259 W/m · K. The effects of coating thickness on the physical properties of the composite, including Young's modulus, 4-point bend strength, coefficient of thermal expansion, and thermal conductivity, are presented.
- Sintering by Infiltration of Loose Mixtures of Powders: a Method for Metal Matrix Composite Elaboration, V. Constantinescu, R. Orban, and H. Colan, *J. Phys.*, Vol 3 (No.7), 1993, p 1781-1786. A comparison between infiltration of loose powder mixtures and the classical melt infiltration is carried out. Factors that prevent excessive hydrostatic flow of the melt and, consequently, dispersion of the reinforcing particles and that promote wettability in both infiltration and liquid phase sintering were identified. Results for fusion tungsten carbide and diamond reinforced metal matrix composite are presented.
- Effect of Ceramic Particle Size, Melt Superheat, Impurities, and Alloy Conditions on Threshold Pressure for Infiltration of SiC Powder Compacts by Aluminum-Based Melts, S.Y. Chong, H.V. Atkinson, and H. Jones, *Mater. Sci. Eng. A*, Vol 173 (No. 1-2), 1993, p 233-237. An instrument heated pressure vessel was used to determine the effect of some experimental variables on the pressurized infiltration of SiC powder preforms by a series of aluminum-base melts. Threshold pressure for infiltration of 2014 aluminum alloy decreased with increasing SiC particle size and increasing melt superheating. Impurities in pure aluminum and copper addition (4.2 wt%) to 99.999% pure aluminum increased the threshold pressure, while the addition of an extra 1.0 wt% Mg to 2014 alloy lowered it. Superheating the melt reduced the incidence of entrapped porosity in compacts that have a tendency to increase in the infiltration direction. Partial SiC dissolution was noted during infiltration.
- Zirconia-Alumina Particulate Composites by Infiltration Processing, S. Riou, F. Queyroux, and P. Boch, *Ceram. Int.*, Vol 21 (No. 5), 1995, p 339-343. ZrO_2/Al_2O_3 particulate composites were prepared by infiltration of presintered alumina skeletons with a precursor of zirconia and subsequent sintering at 1600

°C. The composite specimens exhibit a gradient in composition; the zirconia content being higher in the superficial zones than in the core. The influence of the ZrO₂ content on the volume fraction of *t*-ZrO₂, the *t* to *m* transformation temperature, and the microstructural development were studied.

- Particulate Composites in the Al₂O₃-SiO₂-TiO₂ System by Infiltration Processing, S.J. Li, F. Queyroux, and P. Boch, *J. Eur. Ceram. Soc.*, Vol 13 (No. 1), 1994, p 3-9. Particulate composites in the Al₂O₃-SiO₂-TiO₂ system were prepared by infiltration of presintered alumina skeletons with precursors of silica and titania and subsequent reaction sintering at temperatures ≤ 1600 °C. The microstructure of composites is finer than that of the corresponding "pure" alumina. It is constituted of alumina grains surrounded by a mullitic, continuous phase.
- Fabrication of Particulate Aluminum-Matrix Composites by Liquid Metal Infiltration, S.W. Lai and D.D.L. Chung, *J. Mater. Sci*, Vol 29 (No. 12), 1994, p 3128-3150. The technology was developed to infiltrate high volume fraction (up to 75%) particulate preforms (AlN, SiC, Al₂O₃) with molten aluminum. A 0.1 wt% acid phosphate binder (with P/Al molar ratio of 23) was used for the preform, in contrast to higher binder amounts necessary for a whisker composite. After infiltration by a slurry that consists of the reinforcing particles, binder, and carrier (preferably acetone), a baking at 200 °C was applied for drying. Baking in air at 500 °C instead of 200 °C caused oxidation of AlN and subsequent decrease of composite thermal conductivity. The binder reinforcement reactivity was larger for AlN than SiC, but it did not affect overall composite properties due to the small amount of binder used. The best thermal conductivity and ductility were obtained in Al/AlN, and the poorest were obtained in Al/Al₂O₃ (due to Al₂O₃ particle clustering).
- Pressureless Infiltration of Aluminum Metal Matrix Composites, Y. Kajikawa, T. Nukami, and M.C. Flemings, *Met. Mater. Trans.*, Vol 26 (No. 8), 1995, p 2155-2159. The ceramic preforms are SiC with varying amounts of particulate aluminum, titanium, and nickel. The infiltrants used are aluminum and Al-12.5%Si. It is shown that a pressure differential within the preform is required for infiltration; measurements are made of pressure changes in the preform during infiltration. Results indicate that atmospheric pressure is essential for infiltration, but that capillarity can play a role as well.
- Synthesis of Composite Materials by Infiltration of IVa, Va Metals and BN Powder Mixtures with Molten Aluminum, M. Kobashi, N. Tonokura, and T. Choh, *J. Jpn. Inst. Light Metals*, Vol 46 (No. 12), 1996, p 638-643. Ceramic phases were in situ synthesized by the reaction: $2Al + 2BN + Me = MeB_2 + 2AlN$, where *Me* is a metal (Ta, Nb, Zr, or Hf). Each of these metals was mixed with BN powder. The spontaneous infiltration occurred with a 3600 s hold at 1473 K. Neither pores nor cavities were observed. TaB₂ and NbB₂ were completely formed together with AlN after holding for 3600 s in systems with tantalum and niobium. The in situ formed particles were uniformly distributed in the aluminum matrix. In systems with zirconium and hafnium, ZrB₂ and HfB₂, along with BN, were found. Differential thermal analysis indicated that the heat of Al-Ta and Al-Nb reactions can ignite a reaction involving BN. However, the Al-Zr and Al-Hf reactions that occur at 1000 K do not ignite a reaction with BN. Therefore, the processing time was longer for zirconium and hafnium systems. The Ta-BN powder mixture was infiltrated with molten aluminum at temperature above 1173 K, and both TaB₂ and AlN were found as a result of the in situ reaction.
- Fabrication of Metal Matrix Composites (MMCs) by Spontaneous Infiltration and Subsequent In Situ Reaction Processes, T. Choh, M. Kobashi, M. Nakata, and H. Kaneda, *Mater. Sci. Forum*, Vol 217-222, 1996, p 353-358. Fabrication of MMCs was developed by applying the in situ reaction followed by spontaneous infiltration of liquid aluminum into a mixture of ceramic and metal powders. Next, the spontaneous infiltration of liquid magnesium into SiC powder phase was completed using SiO₂ as an infiltration agent in the SiC powder phase.
- Precipitation during Infiltration of A201 Aluminum Alloy into Al-Fe-V-Si Preform, C.-C. Yang, Y.-C. Chen, and E. Chang, *Scr. Mater.*, Vol 34 (No. 7), 1996, p 1059-1065. A new near-net casting process is proposed in which liquid aluminum is infiltrated around the Al-Fe-V-Si particles to form a composite material. A preliminary study of the Al-Fe-V-Si particle reinforced A201 aluminum alloy demonstrates that the compression strength at 300 °C can be twice as high as A201 aluminum alloy.
- Metal Matrix Composites Fabricated by Pressure Assisted Infiltration of Loose Ceramic Powder, M.A. Taha and N.A. El-Mahallawy, *J. Mater. Process. Technol.*, Vol 73 (No. 1-3), 1998, p 139-146. Pressure was applied by two methods: centrifugal and squeeze casting. The structural features of the composite, including particle distribution, metal/ceramic interface, and part soundness, are shown. A comparison of the two

techniques using a high volume fraction of Al_2O_3 (50-65%) is made.

Metal Matrix Composites (MMC) (Fiber)

- Characterization of Ceramic Matrix Composites Fabricated by Chemical Vapor Infiltration, D.P. Stinton, D.M. Hembree, Jr., K.L. More, and B.W. Sheldon, *Chemical Vapor Deposition on Refractory Metals and Ceramics Symp.*, 29 Nov-1 Dec 1989 (Boston, MA), T.M. Besmann and B.M. Gallois, Ed., Materials Research Society, 1990, p 273-280. A process for the preparation of fiber-reinforced SiC composites by chemical vapor deposition has been developed at Oak Ridge National Laboratory. Composites are prepared by infiltrating fibrous preforms with reactant gases that decompose at elevated temperatures to deposit silicon carbide between and around the fibers. Because the infiltration process utilizes both temperature and pressure gradients, SiC is deposited under conditions that vary considerably from the hot face to the cool face of the composite. Matrix characterization of composite samples by transmission electron microscopy and Raman spectroscopy is described.
- Carbon Coated Alumina Fiber/Glass Matrix Composites, R.L. Lehman and C.A. Doughan, *Compos. Sci. Technol.*, Vol 37 (No. 1-3), 1990, p 149-164. Carbon coated alumina fiber-reinforced borosilicate glass composites were fabricated by slurry infiltration and hot pressing. For fiber contents of 20 vol%, composite strengths of 118 and 263 MPa were observed for uncoated and carbon coated composites, respectively. Fiber pull-out was observed in fracture surfaces only for carbon coated composites, and pull-out lengths were approximately 30-60 μm . The fiber/matrix interface was studied to characterize the interfacial frictional stress. Direct measurements by indentation were compared with calculated values based on pull-out lengths and fiber strengths. Direct indentation measurements gave interfacial frictional stress values of 100 MPa, which were reduced by as much as 40% after a correction for Poisson's ratio effects. Values calculated from pull-out lengths suggested a value of 63-84 MPa, in good agreement with direct measurements. Elastic modulus and thermal expansion measurements confirmed the debonded character of the carbon coated fiber/matrix interface.
- Fiber-Reinforced Silicon Nitride Composites, R. Lundberg, R. Pompe, R. Carlsson, and P. Goursat, *Compos. Sci. Technol.*, Vol 37 (No. 1-3), 1990, p 165-176. Three possible processing routes to obtain silicon nitride reinforced with continuous fibers are identified and demonstrated. Slip-infiltrated, HIPed carbon fiber-reinforced material, slip-infiltrated, SiC fiber-reinforced nitrided Si_3N_4 , and polysilazane solution infiltrated pyrolysed composites with SiC fibers have been successfully fabricated. Possible fiber/matrix reactions are discussed on the basis of scanning electron microscopy observations and the bend fracture behavior of the composites. All materials exhibited nonbrittle fracture and are thus potentially interesting composites for further development.
- Temperature and Concentration Dependence of SiC Deposition on Nicalon Fibers, T.M. Besmann, B.W. Sheldon, and M.D. Kaston, *Surf. Coat. Technol.*, Vol 3-4 (No. 1-3), 1990, p 167-175. Chemical vapor infiltration of Nicalon fiber bundles (approximately 500 filaments) was studied using methyltrichlorosilane to form the SiC matrix. The operating conditions were chosen to simulate those used in composite fabrication. It was determined that the deposition reaction has an activation energy of 66 ± 20 kJ/mol and is first order with respect to reactant concentration.
- Development of Advanced SiC/Al Composite Material, Manufacturing of Preform Wires by Liquid Metal Infiltration, Y. Imai, Y. Tanaka, H. Ichikawa, and T. Ishikawa, *J. Iron Steel Inst. Jpn.*, Vol 75 (No. 9), 1989, p 1555-1562. The continuous SiC fiber produced by polycarbosilane has outstanding properties as MMC reinforcement. SiC/Al (A1050) preform wires were continuously produced by the liquid infiltration method. After heating the SiC fiber yarn at 1373 K for desizing, it was dipped into molten aluminum at 953 K and then passed through a ceramic nozzle hole 0.25 mm in diameter. The tensile strength of the preform wire is 1560 MPa.
- Silicon Carbide/Silicon and Silicon Carbide/Silicon Carbide Composites Produced by Chemical Vapor Infiltration, M. Kmetz and S. Suib, *J. Am. Ceram. Soc.*, Vol 73 (No. 10), 1990, p 3091-3903. Composites of SiC/Si and SiC/SiC were prepared from single yarns of SiC. The use of carbon coatings on SiC yarn prevented the degradation normally observed when chemically vapor deposited silicon is applied to SiC yarn. The strength, however, was not retained when the composite was heated at elevated temperatures in air. In contrast, the strength of a SiC/C/SiC composite was not reduced after being heated at elevated temperatures, even when the fiber ends were exposed.

- Influence of Aluminum Alloy Matrices on the Strength of SiC_pC_s Fiber-Reinforced Preform Wires by Liquid Metal Infiltration, Y. Imai, Y. Tanaka, H. Ichikawa, and T. Ishikawa, *J. Iron Steel Inst. Jpn.*, Vol 76 (No. 1), 1990, p 65-72. The matrices used were aluminum-base binary alloys with 5wt% Si, Cu, and Mg, and commercial A2024, A5052, A6061, and A7075 alloys. No wire with high strength was obtained in any matrix. Silicon precipitated on the surface of SiC fiber in Al-5Si. CuAl₂ was observed in Al-CuAl₂ eutectic and magnesium-diffused into the fiber in Al-5Mg. Similar compounds were found when using industrial alloys. An Al-3Cu-2Ni alloy was designed and the fiber-melt contact was shortened. The tensile strength of the wire obtained was 1 GPa.
- Melt Infiltration and Reaction at the Fiber/Matrix Interface during the Brazing of a Fiber-Reinforced Ceramic to Metal, S. Karunanithy, *J. Am. Ceram. Soc.*, Vol 73 (No. 1), 1990, p 178-181. The presence of silica in the fiber/matrix interface of SiC fiber-reinforced alumina facilitates the brazing of these composites with metals. In addition, molten braze infiltrates the interfacial pores to form reaction layers with the matrix and the fiber. The chemical compatibility, wetting, and thermodynamics of the titanium-base braze leads to a potentially useful method of joining a fiber-reinforced ceramic to metal.
- Chemical Stability of Zirconia-Stabilized Alumina Fibers during Pressure Infiltration by Aluminum, J.A. Isaacs, F. Taricco, V.J. Michaud, and A. Mortensen, *Metall. Trans. A*, Vol 22 (No. 12), 1991, p 2855-2862. MMCs composed of high purity aluminum and continuous zirconia-stabilized polycrystalline Al₂O₃ fibers are fabricated by liquid metal infiltration using three different casting procedures. The microstructure of the composites showed discrete faceted ZrAl₃ particles at the interface that grow into the matrix in samples processed above matrix melting point for more than 13 minutes. This compound formation is in agreement with the thermodynamic stability calculations. There is also a reaction between solid aluminum and the fibers at 913 K, yielding a reaction product of the same morphology as with molten aluminum. When infiltration occurs in a preform heated below the metal melting point and solidification time is less than 1 min, no reaction products are seen in SEM. This leads to the conclusion that aluminum MMC can be cast with no apparent interfacial reaction product using these fibers provided that adequate processing parameters are chosen.
- Influence of Fiber Array on the Threshold Pressure on Infiltration in Alumina Fiber/Aluminum Composite, H. Nakanishi, Y. Tsunekawa, M. Okumiya, M. Higashi, and I. Niimi, *J. Jpn. Inst. Light Met.*, Vol 41 (No. 5), 1991, p 325-330. It was shown experimentally that the fiber arrangement greatly influences the threshold pressure of infiltration in the alumina fiber/molten aluminum system. The threshold pressure for the unidirectionally fiber array is 425 kPa, a value less than theoretical because of the slight disarray in the fiber alignment. By contrast, the experimental value for quasi-planar random array is 245 kPa. The relation between the threshold pressure and wettability is derived for infiltration with noninfiltrated defects at the contact of nonwetted two fibers. The threshold pressure of alumina fiber/molten aluminum system with defects is less than that without defects, and it decreases with decrease in contact angle of two fibers because of increasing defects.
- Influence of Processing Parameters on the Threshold Pressure of Infiltration in Alumina Fiber/Aluminum Composite System, H. Nakanishi, Y. Tsunekawa, M. Okumiya, and I. Niimi, *J. Jpn. Inst. Light Met.*, Vol 41 (No. 9), 1991, p 576-581. Although fiber arrangement in the preform does not affect the interfacial energies or contact angles, it affects the processing parameters like pressurizing rate, pressure holding at the maximum pressure applied, wettability, and therefore, threshold pressure. In this study, a δ -Al₂O₃/molten aluminum composite was selected to investigate such dependence. Pressurizing rate was changed from 0.20 to 16 kPa/s and pressure holding at maximum pressure was 300 s. No effect of these parameters on the threshold pressure was observed in Al₂O₃ preforms with quasi-planar random arrangement. Experimentally, it was shown that the threshold pressure obtained by extrapolation of infiltration distance and applied pressure agrees with that obtained from the Blake-Kozeny equation. The influence of molten aluminum temperature on the threshold pressure that was obtained by the pressure drop was studied at the pressurizing rate of 2.4 kPa/s. The threshold pressure decreases from 259 to 162 kPa when molten aluminum temperature increased from 943 to 1163 K.
- Characterization of Metal-Matrix Composites Fabricated by Vacuum Infiltration of a Liquid Metal under an Inert Gas Pressure, J.-M. Chiou and D.D.L. Chung, *J. Mater. Sci.*, Vol 26 (No. 10), 1991, p 2583-2589. Silicon carbide whisker-reinforced aluminium was fabricated by vacuum infiltration of liquid aluminum into a porous whisker preform under an argon gas pressure, using an infiltration temperature of 665 °C. The

volume fraction of whiskers ranged from 11 to 37%. No whisker pull-out was observed on the fracture surface for an infiltration temperature of 665 °C, but some whisker pull-out was observed for an infiltration temperature of 720 °C. Both the tensile strength and ductility decreased with increasing infiltration temperature above 665 °C. Tensile test results from room temperature to 300 °C are reported. They showed that the quality of these composites was comparable to that of composites made by powder metallurgy or squeeze casting. The coefficient of thermal expansion at 100 to 150 °C was decreased by 45% by the addition of 37 vol% whiskers.

- Synthesis of SiC Platelet Reinforced 2014 Al Alloys by a Pressure Infiltration Technique, R. Asthana and P.K. Rohatgi, *J. Mater. Sci. Lett.*, Vol 10 (No. 4), 1991, p 230-234. A countergravity pressure assisted liquid metal infiltration technique was used to infiltrate prepacked columns of SiC platelets by aluminum. The aluminum alloy composites contain relatively high (50% or more) volume fractions of SiC reinforcement.
- Aluminum-Matrix Silicon Carbide Whisker Composites Fabricated by Pressureless Infiltration, Y. Chen and D.D.L. Chung, *J. Mater. Sci.*, Vol 31 (No. 2), 1991, p 407-412. SiC whisker-reinforced aluminum composites were fabricated by pressureless infiltration of liquid Al-Mg or Al-Si-Mg alloy at 830 to 950 °C into a preform of nickel coated SiC fibers in nitrogen. Nickel coating was obtained by electroless plating. The composite exhibits a slightly lower tensile strength and modulus and slightly higher coefficient of thermal expansion than the same composite fabricated by pressure infiltration. The hardness decreased with increasing distance from the preform-melt interface much more significantly in pressureless composites as compared to pressure infiltrated counterparts. This hardness decrease, which was attributed to porosity increase, was larger in pressureless composites without prior evacuation than in those made by prior evacuation. The Al-SiC reactivity was larger in pressureless composites as compared to those made with pressure application because of a longer infiltration time.
- Effect of Fiber Distribution on Infiltration Processing and Fracture Behavior of Carbon Fiber-Reinforced Aluminum Composites, Z. Xia, Z. Mao, and Y. Zhou, *Z. Metallkd.*, Vol 82 (No. 10), 1991, p 766-768. Composites with bundles of carbon fibers were fabricated by a pressure-regulating infiltration technique. The molten metal infiltrates the preform in finger-like mode, which can make infiltration possible at a low pressure of 0.7 MPa in spite of poor wettability of fibers by the molten metal. The fiber arrangement in bundle resulted in high tensile strength and an increase in fracture energy of the composite.
- Infiltration of Fiber Preforms by an Alloy, Part III: Die Casting Experiments, P. Jarry, V.J. Michaud, A. Mortensen, A. Dubus, and R. Tirard-Collet, *Metall. Trans. A*, Vol 23 (No. 8), 1992, p 2281-2289. Preforms of 20 vol% Saffil alumina fibers are infiltrated with Al-4.4wt%Cu-0.3wt%Mg using a horizontal die casting machine. Fiber preform temperature is varied from 973 to 673 K. Increases in fiber volume fraction are observed in composites downstream of the infiltration path. It is proposed that these result from locking of the compressed fibers by solid metal present during infiltration. With this assumption, a good agreement was found between theory on solute concentration, fiber volume fraction distribution, matrix microstructure, and experiments. For preform temperature of 673 K, freckles, which are interpreted to result from the combined effects of pressure and significant enrichment in solute at the infiltration front, were found in the composite.
- Age-Hardening Behavior of 6061 Aluminum Alloy Reinforced with SiC Whiskers, H. Toda, T. Kobayashi, and M. Niinomi, *J. Jpn. Inst. Met.*, Vol 56 (No. 11), 1992, p 1303-1311. Cast reinforced composites containing 22% volume fraction of SiC whisker were fabricated by a high pressure infiltration technique. The age-hardening behavior of the 6061 aluminum alloy with and without SiC whisker was studied using hardness measurement, calorimetric technique, and transmission electron microscopy. The overall age-hardening sequence is not altered by the addition of SiC whisker. Moreover, the maximum hardness of 6061 with and without SiC whisker is associated with the same transition stage from the GP (II) zone to the intermediate β' phase. However, precipitation kinetics of the matrix alloy is affected by presence of the reinforcement. Times to achieve the peak hardness are shortened in the composites over the whole temperature ranges investigated. However, this tendency becomes marked with low aging temperature, suggesting the contribution from high diffusivity paths, such as dislocations and reinforcement-matrix interfaces. This acceleration is attributed to the drastic decrease of the activation energy required for the formation of the GP (II) zone and intermediate β' phase.

- High-Temperature Mechanical and Material Design for SiC Composites, Part A, N.M. Ghoniem, *J. Nucl. Mater.*, Vol 191-194, 1992, p 515-519. SiC fiber-reinforced composites (FRCs) are strong potential candidate structural and high heat flux materials for fusion reactors. A concise discussion of the main material and design issues related to the use of SiC FRCs as structural materials in future fusion systems is given in this paper. The status of material processing of SiC/SiC composites is first reviewed. The advantages and shortcomings of the leading processing technology, known as chemical vapor infiltration, are particularly highlighted. A brief outline of the design-relevant physical, mechanical, and radiation data base is then presented. SiC/SiC FRCs possess the advantage of increased apparent toughness under mechanical loading conditions. This increased toughness, however, is associated with the nucleation and propagation of small crack patterns in the structure. Design approaches and failure criteria under these conditions are discussed.
- Effect of Reinforcement Architecture on Mechanical Properties of a Short Fiber/Magnesium RZ5 MMC Manufactured by Preform Infiltration, D.J. Towle and C.M. Friend, *Mater. Sci. Eng. A*, Vol 188 (No. 1-2), 1994, p 153-158. Short fiber-reinforced metal-matrix composites (MMCs) produced by the liquid metal preform infiltration route exhibit a planar (two-dimensional) random fiber architecture. The mechanical properties measured in tension and compression of a Saffil fiber-reinforced RZ5 (ZE41) magnesium alloy, both parallel (P) and normal (N) to the fiber arrays, are presented. Generally, the mechanical properties are enhanced in the P orientation compared to the N orientation, and the properties in the N orientation are still better than those of unreinforced alloy. There is a significant effect of deformation mode on the mechanical properties both on the magnitude of the anisotropic effects and on the absolute strengths in tension and compression.
- Pressurized Infiltration of Aluminum Melt into Aluminum Borate Whisker Preform, T. Yamauchi and Y. Nishida, *J. Jpn. Inst. Met.*, Vol 59 (No. 5), 1995, p 564-570. The aluminum borate whiskers and alumina short fibers were used as reinforcements for fiber aluminum composites made by squeeze casting. The pressure was mechanically applied by a punch, and the pressure and punch speed were measured during the infiltration of molten aluminum. Hardness was measured along the infiltration direction. Based on these measurements, the distribution of volume fraction was calculated. The experimental results agree with theoretical analysis using D'Arcy's law. Deformation of fibrous preforms occurred due to compressive stress during infiltration with molten aluminum.
- Infiltration of Al₂O₃ Short Fiber Preforms during Squeeze Casting of A357 Al Alloys, H.-G. Kang, P.R.G. Anderson, and B. Cantor, *Proc. of the 1995 124th Annual Symp. Synthesis/Processing of Lightweight Metallic Materials* (Las Vegas, NV), TME annual meeting, TMS, 1995, p 153-174. Alloy A357 Al-7wt%Si-0.6wt%Mn was infiltrated into 20 vol% Saffil preforms with discontinuous fibers with a diameter of 3 to 3.5 μm and 500 μm long by squeeze casting at 0 to 100 MPa pressure, melt temperatures of 700 to 900 °C, and die and preform temperature of 300 °C. It was found that presolidification of the molten alloy occurs during the time delay between die filling and pressurization. This way, a shell of coarse columnar grains of α -aluminum dendrites forms. The enriched remaining solute that infiltrates the preform produced a macrosegregation within the composite. Needle-like primary FeSiAl₅ and blocky (Fe,Mn)₃Si₃Al_{1/5} intermetallics form due to solute enrichment at the composite/monolithic interface. Stresses build up within the preform leading to cracks and fragmentation. Shrinkage pores, cracks, and uninfiltated regions are all force fed with eutectic liquid as the pressure increases at the end of the ram travel. High applied pressure leads to a fine grained structure.
- Microstructure and Properties of Al₂O₃/Al-1.5Mg Composite Manufactured by Extrusion Directly Following Liquid Infiltration, L. Hu, S. Luo, W. Huo, and Z. Wang, *Trans. Nonferrous Met. Soc. China*, Vol 5 (No. 4), 1995, p 146-150. The microstructure of the extruded composite after infiltration indicated a high density matrix with fine recrystallized grains without defects. The fibers are uniformly and quasi unidirectionally distributed. Mechanical properties (Young modulus, tensile and yield strength) and the thermal expansion resistance of the composite increase with fiber volume fraction, while ductility is still maintained at a high level. The corrosion resistance of Al₂O₃/Al-1.5Mg composite is similar to that of the Al-1.5%Mg alloy.
- Pressure Infiltration of Molten Aluminum Preform of Granulated Whisker, T. Yamauchi, Y. Nishida, and H. Nakae, *J. Jpn. Inst. Met.*, Vol 61 (No. 2), 1997, p 158-165. A granulated aluminum borate whisker preform was prepared to enhance permeability in squeeze casting. The permeability of granulated whisker

was six times larger than that of uniform preforms with randomly distributed whiskers. When the pressure is applied, the molten metal first flows between the whisker granules to the bottom of the preform and then infiltrates into the granules of whiskers as the pressure increases. This way, the preform deformation was suppressed.

- Properties of Continuous Fiber-Reinforced Al- and Mg-Matrix Composites Produced by Gas Pressure Infiltration, H.P. Degisher, P. Schulz, and W. Lacom, *Key Eng. Mater.*, Vol 127-131, 1997, p 99-110. General steps in the production of continuous fiber-reinforced aluminum or magnesium or their alloys are described: preform manufacturing, liquid metal infiltration by gas pressure, solidification, and finishing. Elastic properties and tensile strengths of different fiber (carbon or ceramic multifilament tows)-light metal matrix systems are compared in longitudinal, and if available, transverse directions.

Other Infiltration Products

- Influence of Liquid Metal Infiltration on the Superconducting Characteristics of Niobium Nitride, L.T. Summers, J.R. Miller, M.J. Strum, R.J. Weimer, and D.E. Kizer, *Advances in Cryogenic Engineering*, Plenum Press, Vol 34, 1988, p 835-842. A fully stabilized multifilamentary BN superconductor was prepared using a combination of physical vapor deposition of NbN on graphite followed by liquid metal infiltration using copper or aluminum. The resulting conductor assumed a finely divided multifilamentary form embedded in a matrix of conducting copper or aluminum. The geometry provides high stability to flux jumps and high quench protection. The effects of liquid metal infiltration and process variables on the electrical properties were determined. Critical current dependence on field strength and stabilizer residual resistivity ratio are discussed.
- Anomalous Growth of the Complex Carbide Phase in Carbon-Deficient WC-Co Hard Metal during Infiltration of Eutectic Liquid, J.K. Park, K.Y. Eun, and D.N. Yoon, *Mater. Sci. Eng. A*, Vol 105-106, 1988, p 233-236. Large angular grains of η phase ($\text{Co}_3\text{W}_3\text{C}$) around WC grains formed during infiltration of the carbon-deficient 97WC-3Co with 25WC-75Co infiltrants. In contrast, in the uninfiltrated region, the fine η and CoW_3C phases were uniformly distributed. Some elongated η grains grew at the infiltration boundary. The anomalous growth of η phase is attributed to the composition change in the specimen from WC to η to potassium region to the WC-K liquid region during infiltration.
- Correlation Among Process Routes, Microstructures, and Properties of Chemically Vapor Deposited Silicon Carbide, R.F. Davis, *Chemical Vapor Deposition on Refractory Metals and Ceramics Symp.*, 29 Nov-1 Dec 1989 (Boston, MA), T.M. Besmann and B.M. Gallois, Materials Research Society, 1990, p 145-158. *Silicon carbide* is a generic term for a host of different materials produced by several process routes that yield a variety of microstructures and associated property characteristics. The route of chemical vapor deposition (CVD) is used primarily to deposit SiC for wear- and corrosion-resistant coatings and for diffusion barriers to and from the underlying substrate. Presently this technique is also being used to deposit monocrystalline semiconductor thin films of SiC and to infiltrate various high temperature woven fabrics. The paper describes the results of thermodynamic calculations to define SiC CVD diagrams using various precursor gas mixtures, discuss various CVD techniques, and detail the results of deformation, infiltration, and thin film deposition studies that have been recently conducted on vapor deposited SiC.
- Fabrication Aspects of Glass Matrix Composites for Gas Turbine Applications, D.A. Clarke, *New Materials and Their Applications 1990*, Proc. of the 2nd Int. Symp., 10-12 April 1990 (Warwick, U.K.), D. Holland, Ed., IOP Publishing, Bristol, U.K., 1990, p 173-183. A brief background to the development of glass matrix composites (GMCs) including the basic fabrication methods is presented. Some of the key problems involved in manufacturing production quantities of GMC gas turbine components are described and the need for highly repeatable, and hence largely automated, processing methods are highlighted.
- Processing and Properties of Silicon Carbide-Reinforced Aluminum Metal Matrix Composites for Electronic Applications, K.K. Aghajanian, *Proc. 1991 Int. Symp. Microelectronics*, International Society of Hybrid Microelectronics, Reston, VA, 1991, p 368-372. Alternative packaging materials with high thermal conductivity, high specific strength and stiffness, and low density are in demand for the microelectronic industry. SiC particulate reinforced aluminum MMCs satisfy these requirements. Using the Primex pressureless metal infiltration process, SiC loadings can be varied over a wide range, thus providing a family of composites with tailorable properties. The processing and properties, as well as the electronic applications of silicon carbide reinforced aluminum composites, are discussed.

- Microstructure and Properties of Metal Infiltrated Reaction-Bonded Silicon Nitride (RBSN) Composites, N.A. Travitzky and N. Claussen, *J. Eur. Ceram. Soc.*, Vol 9 (No. 1), 1992, p 61-65. RBSN-metal composites were fabricated using gas-pressure infiltration. Various RBSN types have been infiltrated with molten aluminum, an Al-Si-Mg alloy, a Ti-Al intermetallic, and silicon, resulting in considerable increase in mechanical properties when compared to uninfiltrated RBSN. For example, strength was raised to 510 from 227 MPa when infiltrated with a Ti-39wt%Al alloy and the toughness to >5 from $2.7 \text{ MPa}\sqrt{\text{m}}$ when pure aluminum was infiltrated. Silicon infiltration proved to be most effective in enhancing the wear resistance.
- Low Shrinkage Refractories by an Infiltration Technique, N. Lequeux, P. Larose, P. Boch, and N. Burkarth, *J. Eur. Ceram. Soc.*, Vol 14 (No. 1), 1994, p 23-27. Infiltration of presintered silica-zircon preforms with silica of alumina precursors and subsequent heating lead to the development of crystallized segregation (e.g., silica, alumina, or mullite), which decreases the sintering shrinkage. The decrease in shrinkage is very sensitive to the nature of segregations.
- Mechanical Properties of $\text{Al}_2\text{O}_3/\text{Si}$ Composites Fabricated by Pressureless Infiltration Technique, N.A. Travitzky, E.Y. Gutmanas, and N. Claussen, *Mater. Lett.*, Vol 33 (No. 1-2), 1997, p 47-50. A microstress-induced strengthening concept was applied to $\text{Al}_2\text{O}_3/\text{Si}$ composites fabricated by pressureless infiltration of porous Al_2O_3 preforms with molten silicon. The mechanical properties (strength, hardness, fracture toughness) were superior to a material with the same amount of Al_2O_3 with aluminosilicate phase instead of silicon. For example, at 30% Si, the composite exhibits a bending strength of 320 MPa and K_{Ic} of $4.8 \text{ MPa}\sqrt{\text{m}}$ as compared to 230 MPa and $3.5 \text{ MPa}\sqrt{\text{m}}$, respectively, for a technical alumina AD-85. This strengthening is attributed to the compressive residual microstresses in an inherently weak silicon phase generated as a result of solidification-related expansion of silicon.
- Mullite/SiAlON/Alumina Composites by Infiltration Processing, M.P. Albano and A.N. Scian, *J. Am. Ceram. Soc.*, Vol 80 (No. 1), Jan 1997, p 117-124. The formation of mullite/SiAlON/alumina composites was studied by infiltrating a SiAlON/alumina-base composite with two different solutions, followed by thermal treatment. The base composite was prepared from a mixture of Al_2O_3 grains, fume SiO_2 , and alumina powders. The mixture was pressed into test bars and nitrided in a nitrogen gas (N_2) atmosphere at 1480°C . The infiltrants were prehydrolyzed ethyl polysilicate solution and ethyl polysilicate-aluminum nitrate solution. The composites were infiltrated under vacuum, cured at 100°C , and precalcined in air at 700°C . This infiltration process was repeated several times to produce bars that had been subjected to multiple infiltrations, then the bars were calcined in a N_2 atmosphere at 1480°C to obtain mullite/SiAlON/alumina composites. The infiltration process increased the percentage of nitrogenous crystalline and mullite phases in the matrix; therefore, a decrease of the composite microporosity was observed. The infiltration increased the mechanical strength of the composites. Of the two composites, the one produced using prehydrolyzed ethyl polysilicate as the infiltrant had a higher mechanical strength, before and after being subjected to a severe thermal shock.
- Infiltration of Porous Aluminum Bodies with Solution Precursors, P. Honeyman-Colvin and F. Lange, *Am. Ceram. Soc.*, Vol 79 (No. 7), July 1996, p 1810-1814. Alumina powder compacts, partially densified with a low-temperature heat treatment and then cut into bars, were infiltrated with liquid precursors that decomposed to either mullite (Al_2O_3 , SiO_2), fully stabilized zirconia (cubic $\text{Zr}(\text{8Y})\text{O}_2$), or partially stabilized zirconia (tetragonal $\text{Zr}(\text{4Y})\text{O}_2$). The specimens were repeatedly infiltrated and pyrolyzed to achieve a higher concentration of the precursor near the surface. The infiltrated bodies were then densified at 1500°C for 2 h. Residual stresses developed during cooling from the densification temperature because of the higher concentration of the second phase near the surface and their differential thermal expansion relative to the matrix material. At least ten bars of each two-phase material were fractured in four-point bending to determine the effect of the second phase on strength. The alumina bars without a second phase had a larger grain size ($\cong 7 \mu\text{m}$) and a mean strength of 253 MPa. The intruded phases significantly reduced the Al_2O_3 grain size to $\cong 1 \mu\text{m}$. Despite their higher concentration near the surface and apparent surface tensile stress, both of the $\text{Zr}(\text{Y})\text{O}_2$ phases increased the mean strength to 413 MPa (cubic $\text{Zr}(\text{8Y})\text{O}_2$) and 583 MPa (tetragonal $\text{Zr}(\text{4Y})\text{O}_2$, an apparent toughening agent). The mullite second phase produced a high mean strength of 588 MPa, apparently due to its concentration gradient creating a compressive surface stress.

Liquid-Phase Sintering

Rajiv Tandon, Phillips Powder Metal Molding; John Johnson, Howmet Corporation

Introduction

SINTERING is a process in which particles bond together when heated to a sufficiently high temperature. The driving force is the net reduction in the surface energy. Liquid-phase sintering (LPS) involves the formation of a liquid phase to promote higher densification rates and lower the sintering temperatures. Because of cost and productivity advantages, it is estimated that over 70% of sintering products are processed using liquid-phase sintering. Common systems for liquid-phase sintering include Cu-Co, W-Cu, W-Ni-Fe, W-Ag, Cu-Sn, Fe-Cu, WC-Co, TiC-Ni, and Fe-Cu-P. Key factors in determining whether a liquid phase forms during sintering of a specific material system include surface energies, solubilities, and diffusivities.

There are two main forms of LPS. When a liquid phase is obtained by inducing melting in a mixture of powders and is persistent throughout the high-temperature portion of the sintering cycle, the process is termed as persistent LPS. Classic LPS systems such as W-Ni-Fe and WC-Co are excellent examples of LPS with a persistent liquid. A persistent liquid can also be obtained by partially melting a prealloyed powder above its solidus temperature (termed as supersolidus LPS, or SLPS) and is widely used for processing tool steels, stainless steels, and superalloys. In some systems (for example W-Cu and Mo-Cu) with a low inter-solubility even in the presence of a persistent liquid, an activator can be used to enhance sintering. This is termed as activated liquid-phase sintering (ALPS). Alternatively, transient liquid-phase sintering (TLPS) involves liquid that disappears due to dissolution into the solid or formation of a new phase/compound. Although each material system has its own set of fabrication concerns, many general LPS concepts can be used to guide their processing. The following sections outline these concepts and provide specific examples of how they apply to industrially relevant materials.

Liquid-Phase Sintering

Rajiv Tandon, Phillips Powder Metal Molding; John Johnson, Howmet Corporation

Thermodynamic and Kinetic Factors

Surface Energy. When a liquid forms during sintering, the microstructure consists of solid, liquid, and vapor phases. Successful LPS requires a reduction in surface energy as the liquid spreads across the surface of the solid particles. Thus, the solid-liquid surface energy must be less than the solid-vapor surface energy. In this case, the liquid "wets" the solid and provides a bonding force between the particles to aid densification.

Wetting is aided by solubility of the solid in the liquid, formation of intermediate compounds, and interdiffusion. Interfacial energies can be highly dependent on surface purity, so the wetting behavior can be drastically altered by contaminants or processing steps that clean the powder surface. Clean surfaces are especially important for metal-metal systems. Reactive metals tend to wet oxidized surfaces better than noble metals due to chemical reactions at the interface. Metal powders contain an oxide surface layer, so a reducing atmosphere or high vacuum is generally required to break down these surface oxides to obtain good wetting with less reactive liquid metals. In certain systems, the penetration of the liquid by capillary action is sufficient to mechanically break down oxide layers.

Surface energies also establish important microstructural features such as contiguity (the surface area of solid-solid contacts as a fraction of the total interfacial area), connectivity (the number of observed contacts per grain in a two-dimensional cross section), grain size, and dihedral angle. The dihedral angle characterizes the energy ratio between the grain boundaries and solid-liquid surfaces and is defined in Fig. 1. This ratio changes with sintering time and has a strong influence on microstructural development. Dissolution reactions during liquid formation decrease the solid-liquid interfacial energy below its equilibrium value, promoting particle rearrangement. With further sintering time, the interfacial energy increases back to its equilibrium value. The contiguity also increases with time as neck growth proceeds

until an equilibrium neck size is reached. The contiguity is uniquely related to the solid volume fraction, dihedral angle, and grain size ratio (Ref 1). Connectivity is also strongly related to contiguity. A large dihedral angle gives a larger connectivity and contiguity for the same solid volume fraction. These microstructural parameters influence the electrical conductivity, strength, ductility, elastic behavior, dimensional stability, and thermal characteristics of LPS materials.

Fig. 1 The dihedral angle and surface energy equilibrium between two intersecting grains with a partially penetrating liquid phase

Solubility of the solid in the liquid is generally required for successful liquid-phase sintering, especially for systems with more than 65 vol% solid (Ref 2). This solubility permits solution reprecipitation and enables a more efficient packing of the grains, leading to higher sintered densities. On the other hand, solubility of the liquid in the solid is generally undesirable, because it can result in swelling as the liquid diffuses into the solid grains (leaving behind large pores that are typically difficult to eliminate during subsequent sintering). However, in certain systems, such as Cu-Sn and Cu-Zn, transient liquid phase can be controlled to yield unique properties. These two cases are schematically shown in Fig. 2.

Fig. 2 A schematic diagram contrasting the effects of solubility on densification or swelling during liquid-phase sintering

The solubility parameter, which is defined as the ratio of the solid solubility in the liquid to the liquid solubility in the solid, provides a reasonable estimate of whether swelling or shrinkage occurs during liquid-phase sintering. Several examples are given in Table 1, which shows a potential for shrinkage at higher ratio values. The actual amount of dimensional change depends on processing conditions.

Table 1 Solubility effects on densification in liquid-phase sintering

Base	Additive	Solubility ratio, at. %	Behavior
Al	Zn	0.004	Swell
Cu	Al	0.1	Swell
Cu	Sn	0.001	Swell
Cu	Ti	4	Shrink
Fe	Al	0.02	Swell
Fe	B	7	Shrink
Fe	Cu	0.07	Swell
Fe	Sn	0.01	Swell
Fe	Ti	3	Shrink
Mo	Ni	20	Shrink
Ti	Al	0.0003	Swell
W	Fe	5	Shrink

Phase diagrams are useful in identifying solubility parameters and other characteristics conducive to LPS (Ref 3, 4, 5). An ideal phase diagram for LPS is shown in Fig. 3. A deep eutectic is favorable due to the large reduction in sintering temperature with the formation of the liquid phase. The formation of intermediate compounds is generally unfavorable.

High-temperature phases can lower diffusion rates, while brittle intermetallic phases that form during cooling can degrade mechanical properties. Phase diagrams also indicate the tendency of alloying elements and impurities to segregate to grain boundaries. The greater the separation of the solidus and the liquidus, the greater the solute segregation to interfaces. A downward sloping liquidus and solidus also indicate a tendency for solute segregation and lower surface energies (Ref 6).

A sintering temperature just above the eutectic temperature is optimal for a composition in the $L + \beta$ region. A classical LPS microstructure for such a case, as shown in Fig. 4, consists of relatively large, rounded grains suspended in a liquid matrix, with the degree of grain contact governed by the dihedral angle.

Fig. 3 Phase diagram of an ideal system for liquid-phase sintering

Fig. 4 Typical microstructure of a liquid-phase sintering system with the phase diagram characteristics shown in Fig. 3

For systems that lack solubility of the solid in the liquid phase, a rigid skeletal structure is expected with densification governed by solid-state diffusion. High sintered densities are possible with the use of extremely fine starting powders or by using segregating activators that enhance solid-state sintering in the presence of the liquid phase. These techniques are covered in more detail in the section "Activated Liquid-Phase Sintering" in this article.

Diffusivity. One of the benefits of LPS is the rapid densification and homogenization that occurs due to the high diffusion rates of base metal atoms in a liquid. Additives that have low melting temperatures are preferred due to their low activation energies and high diffusivities at lower temperatures. For certain systems, during heating, significant densification can occur due to enhanced solid-state sintering through the additive phase. In such cases, the diffusivity increases exponentially with temperature until the additive melts. Once the liquid phase forms, there is a rapid jump in both the solubility and diffusivity, due to the much weaker bonding associated with a liquid phase. An exponential

increase in diffusivity accompanies further increases in temperature. Thus, higher temperatures are favorable for densification, but they also increase the vapor pressure of the liquid. Preferential evaporation of the liquid can change the overall composition of the sintered component. In addition, redeposition of vapors on furnace walls can result in damage to furnaces. Problems with preferential evaporation can be assessed through relative vapor pressures. A vapor pressure of 10^{-3} Pa provides a practical limit for vacuum sintering, while a vapor pressure of 1 Pa can lead to a measurable weight loss during sintering at atmospheric pressure.

In general, melting temperatures are good indicators of diffusion rates. Materials with lower melting temperatures have weaker atomic bonding and higher molar volumes, which allow faster diffusion at a given temperature. Liquid-phase sintering materials often involve mixed powders that have significantly different melting temperatures and thus unequal diffusivities. Unequal diffusion rates between the base alloy and the additive result in the Kirkendall porosity. For sufficient sintering times, the material will homogenize, and equilibrium factors, such as solubility, will dominate. Thus, unbalanced diffusivity ratios contribute to initial pore formation, but sustained shrinkage or swelling depends on the solubility ratio. Homogenization occurs more rapidly for small particles with a high initial homogeneity. Higher sintering temperatures and longer sintering times also aid microstructural uniformity of the sintered component.

Liquid-Phase Sintering

Rajiv Tandon, Phillips Powder Metal Molding; John Johnson, Howmet Corporation

Sequence of Stages

Densification during liquid-phase sintering commonly occurs in three stages after the liquid forms: rearrangement, solution-precipitation, and final-stage sintering. However, in many systems there is a strong solid-state diffusion contribution to the overall densification. A brief description of these stages follows.

Solid-State Sintering Prior to Liquid Formation. The same solubility, segregation, and diffusivity criteria that are favorable for LPS can lead to enhanced solid-state sintering prior to liquid formation. Powders prepared for LPS generally consist of admixed powders designed to lower the activation energy for diffusion, so solid-state sintering during heating can be greatly enhanced. This can result in significant densification prior to liquid formation. In fact, for systems such as the W-Ni-Fe heavy alloys, more than 95% of the total densification occurs prior to liquid formation (Ref 7). Thus, solid-state sintering is an important part of the overall LPS process. The relative contribution of solid-state sintering to total densification increases with increasing solubility of the base in the additive, increasing homogeneity of the additive compound, decreasing heating rates, and decreasing particle size. For the liquid to further assist densification, it must dissolve any solid-state sinter bonds that form during heating, and thus the solid must be soluble in the liquid. Indeed,

even with the achievement of near-theoretical densities in the solid state, complete dissolution of solid-state sinter bonds has been demonstrated for the W-5Ni system (Ref 8).

Rearrangement. Once the liquid phase forms, typically the first step during classical LPS is rearrangement. At the onset of liquid formation, capillary forces pull the wetting liquid into particle necks and pores. These capillary forces also exert an attractive bonding force on the particles, resulting in rapid shrinkage. This is termed as primary arrangement. The liquid further enhances the packing by attacking and disintegrating clusters of particles by a process known as secondary rearrangement. Repacking and further densification occur by redistribution of the small particles between the large particles. Pore elimination occurs by viscous flow during this stage.

The dimensional behavior immediately after liquid formation is affected by both the processing conditions and material characteristics. The material and process variables that influence shrinkage and swelling are summarized in Table 2. A smaller base particle size is beneficial to rearrangement due to an increase in capillary forces (Ref 9). For systems with a small solubility ratio between the base alloy and additive, the amount of swelling can be reduced by the use of a smaller additive particle or by increasing additive homogeneity (Ref 10, 11). Particle shape is also important. Smooth, round particles tend to pack more homogeneously and are more easily rearranged, resulting in greater densification (Ref 12). Solubility also has a smoothing effect on the particle surfaces, decreasing interparticle friction and improving packing. High green densities and slow heating rates can restrict rearrangement due to a greater degree of bonding between the solid particles. A low contact angle and high liquid-vapor surface energy increase the capillary forces between the particles (Ref 13).

Table 2 Characteristics affecting initial-stage behavior in liquid-phase sintering

Factor	Swelling	Shrinkage
Solid solubility in liquid	Low	High
Liquid solubility in solid	High	Low
Diffusivities	Unequal	Equal
Additive particle size	Large	Small
Base particle size	Large	Small
Green density	High	Low
Contact angle	High	Low
Dihedral angle	High	Low
Temperature	Low	High
Time	Short	Long

Solution-Reprecipitation and Grain Shape Accommodation. In most LPS systems, insufficient liquid is present to fill all the pores following rearrangement. Additional densification is accomplished by mass transport or solution reprecipitation in which the grains change shape and size distribution, resulting in a higher packing density. In this case atoms at point contacts between solid particles and at other convex surfaces have higher solubility in the liquid than atoms at concave surfaces. The atoms on the convex surfaces dissolve and diffuse through the liquid to neighboring concave surfaces where they reprecipitate. As the grains change shape, they are able to pack better and release liquid to fill any remaining pores (Ref 14, 15). Densification occurs as the centers of the grains grow closer to each other. The reduction in energy associated with the elimination of pores offsets the increase in the solid-liquid surface area. Equilibrium grain shapes are determined by the packing characteristics, surface energies, and liquid volume fraction (Ref 16).

Compared to the rearrangement stage, the shrinkage rate during the solution-reprecipitation stage is lower. However, for systems with only small amounts of liquid phase, solution reprecipitation can be the most significant densification mechanism. The kinetics of solution reprecipitation may be governed by interfacial dissolution or reprecipitation (reaction controlled) or by the rate of mass transfer through the liquid (diffusion controlled). In cases where the base material is a chemical compound, such as tungsten carbide, the kinetics are generally reaction controlled, while alloys are generally diffusion controlled. For diffusion-controlled cases, the densification rate is enhanced by a smaller particle size, higher solubility of the base in the liquid, and higher diffusivity of the base in the liquid. Concurrent with densification, there can be a significant degree of microstructural coarsening by the same diffusional processes.

Grain growth occurs concurrently with shape accommodation as small grains dissolve and reprecipitate on larger grains through Ostwald ripening or grain coalescence, or even solid-state grain growth of skeleton. The driving force is a decrease in interfacial energy through a reduction in both the amount and curvature of the solid-liquid interface. The rate of coarsening is generally described by:

$$G^n - G_0^n = K(\phi, T)(t - t_0) \quad (\text{Eq 1})$$

where G_0 is the initial grain size, G is the average grain size after time t , $K(\phi, T)$ is the growth rate constant that is dependent on the solid volume fraction (ϕ) and temperature T , and n is the growth exponent (the value of n varies between 2 and 5, depending on what mechanisms dominate mass transport). A cubic relationship is often observed in systems with rounded grains, such as the heavy alloys. In the case of reaction control, the exponent n is 2 and growth occurs at preferred crystal orientations, leading to a prismatic shape as in the cemented carbides. For a constant liquid volume fraction, an increase in temperature increases the value of K (Ref 17). In addition, the grain growth rate constant K increases with increasing solid fraction ϕ at a given temperature.

Generally it is desirable to avoid the microstructural coarsening stage of LPS, because it can degrade the mechanical properties. Pore coarsening is also a concern, especially if the sintering atmosphere or decomposition products become entrapped in closed pores (Ref 18).

Final Stage Sintering. The final stage of LPS is controlled by the slow densification of the solid skeleton structure. As noted, microstructural coarsening continues, and the residual pores enlarge if they contain trapped gas (Ref 18). If the entrapped gas is insoluble in the material, the gas pressure inside the pores restricts densification. If the entrapped gas has slight solubility in the matrix, large pores grow at the expense of smaller pores via an Ostwald ripening mechanism. This leads to compact swelling, which becomes more pronounced with large volume fractions of liquid. Pore coarsening due to gas entrapment is greatly reduced if the gas is highly soluble in the material; pore coarsening can be avoided with vacuum sintering.

Fabrication Concerns

Liquid-phase sintering is primarily limited to compositions with high solid volume fractions due to the poor dimensional stability associated with excess liquid. Although high liquid contents aid densification, they give distortion due to a lack of contact between the solid particles. However, the solid/liquid ratio needed to avoid distortion depends on the alloy system. Classic LPS systems, such as W-Ni-Fe, exhibit solubility of the solid in the liquid phase and generally display distortion at solid volume fractions of about 0.75 to 0.80 (Ref 19, 20). However, combinations of metals with little chemical similarities, such as tungsten and copper or molybdenum and copper, resist distortion for solid volume fractions as low as 0.2 (Ref 21). These systems generally have a much smaller grain size and are characterized by a high solid-liquid dihedral angle. An estimate of the critical solid volume fraction for structural rigidity as a function of the dihedral angle is plotted in Fig. 5.

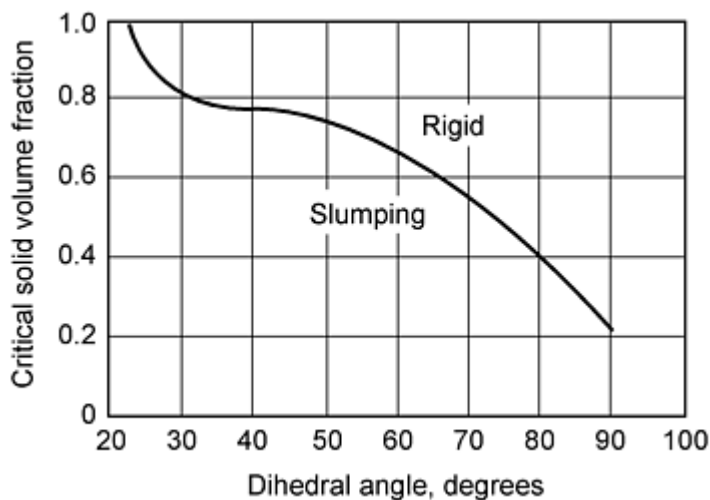

Fig. 5 Effect of the dihedral angle on the critical solid volume fraction for freestanding structural rigidity

The microstructure of LPS materials is also affected by gravity. For systems with density differences between the solid and liquid phases, gravity may cause solid-liquid segregation leading to compositional, microstructural, and property gradients. For example, the high-density tungsten grains in W-Ni-Fe alloys tend to settle to the bottom of the sample resulting in localized higher density (Ref 19, 20, 22, 23, 24, 25, and 26). Increases in grain size, contiguity, and connectivity are associated with the higher solid volume fraction in the settled region. X-ray diffraction on this region indicates that there is no preferred orientation. However, a preferred orientation arises at the top of the sintered compact, indicating that grain rotation to a low-energy configuration occurs in this region (Ref 19).

Applications

Iron-Copper Alloys. Liquid-phase sintering is extensively used for Fe-Cu alloys in structural components for automobiles, household appliances, farming equipment, office machines, and electrical motors. An especially large market is for drivetrain components for the automotive industry. These parts require the high production rates, excellent mechanical properties, and dimensional control to within ± 0.025 mm available through uniaxial die compaction and LPS (Ref 27). The Fe-Cu system is characterized by a high solubility of copper in iron and a low solubility of iron in copper. These characteristics result in swelling with the initial copper melt formation, as shown in Fig. 6. Swelling occurs due to the penetration of copper into the iron grain boundaries. Pores form at the prior-copper particle sites. The amount of swelling is dependent on the green density, amount of copper addition, particle sizes, internal powder porosity, copper distribution, amount of carbon, and atmosphere. Normally, swelling would be undesirable, but under controlled conditions, it enables the sintered dimensions to match the die dimensions to greatly simplify tooling design and achieve better dimensional tolerances. Zero dimensional change is accomplished by using the swelling to offset the die-to-green shrinkage and any other shrinkage that may occur during heating. Carbon and atmosphere control are critical because of their role on the surface energies and consequently the degree of penetration of the bonds between the iron particles. The solid solution-strengthening of copper in iron provides adequate mechanical properties, even with the presence of 10 to 15% porosity. Properties improve with increasing density or by heat treating, as shown in Table 3. Further increases in strength and ductility are possible by infiltrating the remaining pore space with copper.

Table 3 Typical properties of an Fe-10Cu-0.3C alloy after liquid-phase sintering

Property	6.4 g/cm ³ , sintered	6.4 g/cm ³ , heat treated	7.1 g/cm ³ , sintered	7.1 g/cm ³ , heat treated

Fig. 6 Swelling in the Fe-Cu system associated with liquid copper penetration of the iron grain-boundaries, leading to a separation of the solid grains and formation of a pore at the prior copper site

Cemented Carbides. Another large commercial application of LPS is in the fabrication of cemented carbides for machining inserts, punches, dies, cutting tools, milling inserts, and saw blades. They are also used in rock drilling equipment, electrical contacts, armor-piercing projectiles, and in applications that require resistance to wear, erosion, cavitation, abrasion, and/or penetration. Cemented carbides consist of transition metal compounds of carbon in matrix phases, which are typically composed of cobalt, iron, or nickel alloys. Typical properties of industrial cemented carbides are given in Table 4.

Table 4 Typical properties of industrial cemented carbides after liquid-phase sintering

Type	Binder, wt%	Density, g/cm ³	Elastic modulus, GPa	Transverse strength, GPa	Hardness, HRA
TiC-Fe	55	6.6	300	1.9	87
WC-Co	14	14.1	520	2.8	87
WC-Co	11	14.4	550	2.7	90
WC-Co	6	15.0	630	1.9	91
WC-Co	3	15.2	680	1.5	93
WC-TaC-TiC-Co	5	12.0	500	1.5	92

Source: Ref 12

Practically all commercial cemented carbides, including the carbides of titanium, tantalum, vanadium, and niobium, are liquid phase sintered. WC-Co is a classic example. Densification occurs during heating prior to liquid formation, due to a high stored strain energy and defect structure introduced by milling applied to the fabrication of these powders.

The anisotropic surface energy of the hexagonal close-packed tungsten carbide results in grain polygonization on heating. Additions of TiC or TaC are effective in controlling the grain shape and size during sintering. The peak sintering temperature is about 1400 °C under a vacuum of approximately 100 Pa. Carbon control is key in attaining the desired attributes, including hardness, strength, wear resistance, and fracture strength.

Liquid-Phase Sintering

Rajiv Tandon, Phillips Powder Metal Molding; John Johnson, Howmet Corporation

Supersolidus Liquid-Phase Sintering

Supersolidus LPS involves heating a prealloyed powder between the solidus and liquidus temperatures to form a liquid phase (Ref 28, 29). The fundamental difference between classic LPS and SLPS lies in the sequence of events leading to densification. A schematic of the stages in SLPS is shown in Fig. 7. In the first stage, liquid forms as a prealloyed powder is heated above the solidus temperature. The commonly observed liquid formation sites are the grain boundaries within a particle, the interparticle neck region, and the grain interior. These sites depend on several factors, such as powder microstructure, alloy chemistry, particle size, and the heating rate. As the liquid volume increases, at a critical temperature above the solidus a threshold amount of liquid exists along the grain boundaries (Ref 28, 29, 30, and 31). Above this threshold, the grains possess enough mobility to rearrange, leading to particle fragmentation and capillary-induced rearrangement. Thus, densification during SLPS is analogous to viscous flow sintering, because the semi-solid particles turn mushy and flow once the liquid spreads along the grain boundaries. Subsequently, continued densification occurs by solution reprecipitation, grain shape accommodation, and pore removal, as in classic LPS.

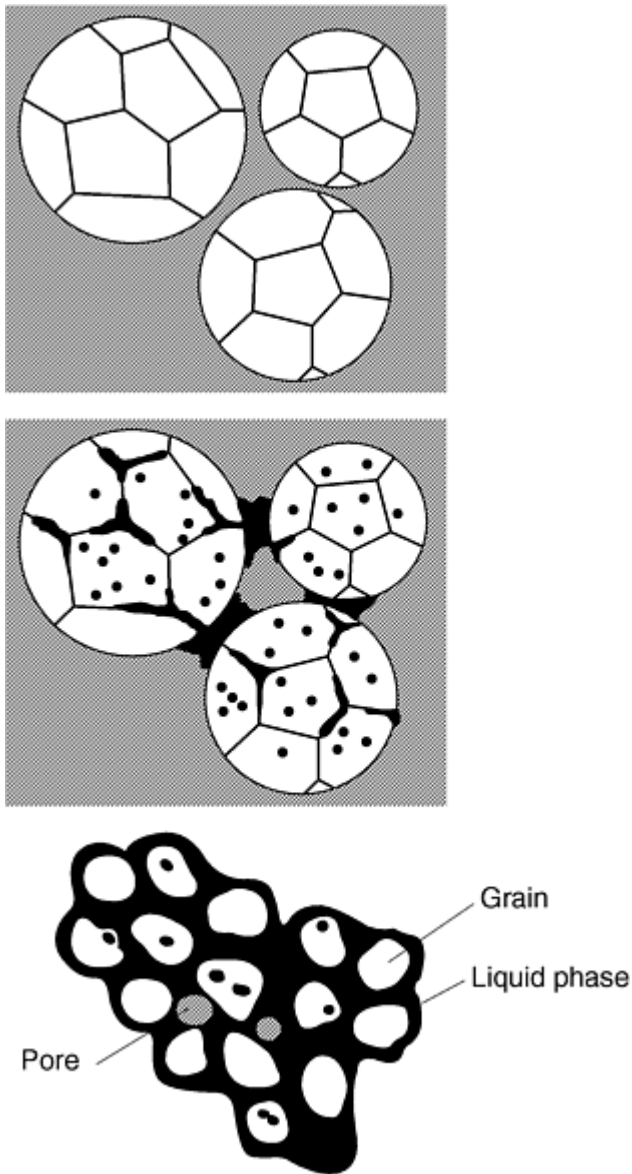

Fig. 7 Sequence of stages leading to densification via supersolidus sintering

Processing Variables. Both material and processing parameters affect SLPS. The former include the phase diagram characteristics and the chemical constituents of the alloy, especially with respect to the presence of additives or impurities. The latter include powder size, heating rate, sintering temperature, sintering time, and sintering atmosphere.

A phase diagram is an important tool for predicting the sensitivity of the liquid volume variation with respect to the sintering temperature. Figure 8 shows a section of a schematic binary phase diagram where T_s and T_l are the solidus and liquidus temperatures, respectively. A greater separation between the solidus and liquidus (i.e., $T_l - T_s$) is desirable, because the liquid volume fraction dependence on temperature is proportionate to the inverse of this separation. Similarly, a steep solidus and liquidus slope implies less sensitivity in the liquid volume with respect to an increase in temperature, thus simplifying the process control. In reality, atomized powders experience non-equilibrium solidification. Therefore, an equilibrium phase diagram can only be used as a qualitative predictor of sintering behavior.

Fig. 8 Section of a hypothetical binary phase diagram showing the characteristics of a two-phase (solid + liquid) region that can influence supersolidus sintering. T , sintering temperature; T_s , solidus temperature; T_l , liquidus temperature; X_s , composition of solid phase; X_l , composition of liquid phase; X_A , alloy composition

During SLPS, the commonly observed sites for liquid melting are the neck region between particles, the grain boundaries within a polycrystalline particle, and intragranular isolated pools, as shown in Fig. 9. Each of these liquids contributes to densification in a unique way, depending on the region where it is present. For example, the liquid at the neck region provides the capillary force for rearrangement, as in classic LPS. The grain boundary liquid is responsible for particle fragmentation. However, the liquid in intragranular pools is essentially trapped and hence does not contribute directly to densification (Ref 32, 33). The optimal quantity of liquid for densification varies from 5 to 30%, depending on the system and sintering conditions. The liquid volume fraction is also dependent on the powder microstructure, heating rate, and powder chemistry. For example, large particles experience a slow cooling rate, resulting in greater segregation of the constituents, especially if the partition coefficient is small with respect to the base alloy. Therefore, the solidus temperature of large particles is expected to be slightly lower than that of fine particles. In reality, the difference depends on both the extent of segregation and the nature of additives in the large and small powders. Heating rate is also a factor, because a slow heating rate allows for homogenization of the segregated species, thus raising the solidus. Conversely, a rapid heating rate can lead to incipient liquid formation at a lower temperature, due to localized melting of the segregated additives.

The identification of sintering temperature for a given alloy composition is of fundamental concern in SLPS. Rapid densification occurs above a critical temperature due to viscous flow of the solid grains in a liquid matrix (Ref 28, 34, 35). The viscous flow is facilitated by the lowering of solid-liquid viscosity with an increase in temperature. Too high a sintering temperature results in degraded mechanical properties due to excessive grain coarsening (Ref 36, 37, 38), besides leading to compact slumping. Typically, the transition from an undersintered state to a fully sintered state occurs over a narrow temperature interval. In many cases, the sintering window is narrow (10 to 20 °C in the vicinity of the solidus temperature). Thus, for any alloy system the sintering temperature has to be optimized for a given starting particle size and heating rate. This is shown in Fig. 10, which is the plot of density versus normalized temperature for several different systems sintered via SLPS (Ref 29, 39, 40). The temperature is represented using a parameter ϕ , defined as:

$$\phi = \frac{T - T_s}{T_1 - T_s} \quad (\text{Eq 2})$$

where T is the sintering temperature.

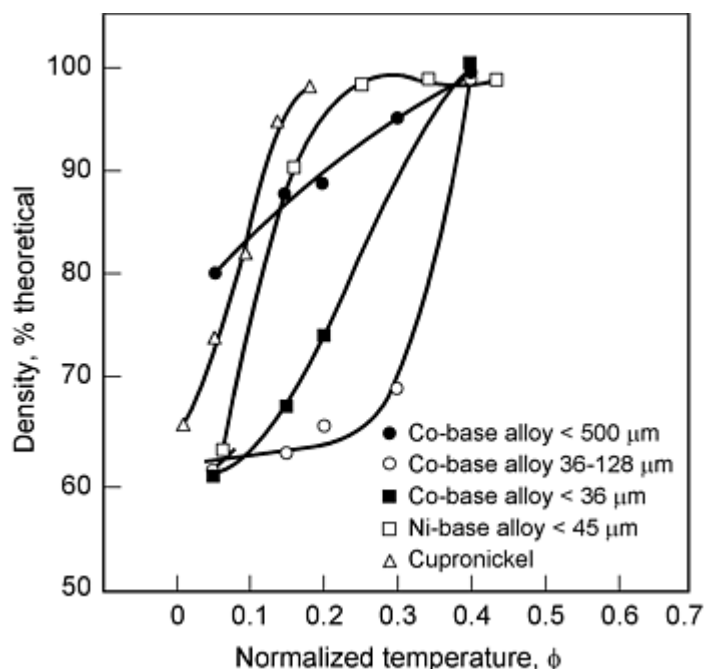

Fig. 10 Sintered density vs. normalized temperature for selected prealloyed powders, showing the dependence of particle size and alloy composition on the sintering behavior. Source: Ref 29, 39, 40

A slow heating rate can induce significant densification by solid-state sintering prior to the formation of liquid phase. This implies that the liquid has to penetrate the solid-solid bonds to cause rearrangement, thus leading to restrained densification kinetics via particle rearrangement (Ref 41). A slow heating rate allows time for segregated species to homogenize. However, in most alloys that rely on the presence of trace amounts of segregated species (e.g., boron, phosphorous, sulfur, or carbon) to induce grain-boundary melting for enhanced densification, chemical homogenization can reduce liquid formation, thus restraining shrinkage.

The optimum sintering time is determined by the sintering temperature. For example, if sufficient liquid exists, complete densification can be achieved by rearrangement processes alone. In this case, the sintering time can be as low as 10 to 15 min, as shown in Fig. 11 (Ref 42). Alternatively, a lower sintering temperature implies less liquid; hence, time-dependent mechanisms such as solution reprecipitation, grain shape accommodation, and pore removal are required to attain full density. These mechanisms are concomitant with grain coarsening.

Fig. 11 Sintered porosity for a tool steel powder processed by supersolidus liquid-phase sintering for two hold times at the indicated sintering temperatures. Source: Ref 42

The choice of sintering atmosphere does not affect the sintering mechanism. However, the degree of densification and the resulting mechanical properties can be significantly affected by the sintering atmosphere (Ref 36, 37). Vacuum sintering is widely employed for high-performance tool steels and nickel- and cobalt-base superalloys (Ref 40, 43, 44, 45, and 46). This is because vacuum avoids trapping gas in the pores at the final stage of densification, giving higher density and hardness. However, studies on T15 tool steel (Ref 36) have shown that sintering in a gas atmosphere of N_2 , H_2 , and CH_4 reduces the optimal sintering temperature and decreases the grain size as compared to vacuum. This is due to the tendency of nitrogen to substitute for carbon in vanadium nitride, which releases carbon into the matrix and lowers the solidus temperature. The vanadium carbonitride pins the grain boundaries and retards grain growth. Opposite results have been obtained for M2 (Ref 36), where the nitrogen dissolution in the matrix increases the solidus temperature. Thus the choice of sintering atmosphere depends mainly on the alloy system, in addition to economic considerations.

Grain coarsening during SLPS is analogous to that in classic LPS. However, in SLPS, the effects of temperature and liquid volume fraction are not separable, because the two are directly related. Simultaneously, the solubility of the solid and liquid continuously changes with temperature. Qualitative studies on T15 and M2 (Ref 36), BT42, and T42 (Ref 47) have shown that grain coarsening is rapid above the solidus temperature and is dependent on the sintering atmosphere, as shown in Fig. 12 and 13. Some alloys, such as boron-doped austenitic steels, exhibit a 20-fold increase in the grain growth rate constant between the subsolidus and supersolidus (Ref 48), as shown in Fig. 14. Therefore, factors such as sintering atmosphere, temperature, and time are important variables in SLPS processing.

Applications and Fabrication Concerns. Over the past 30 years, SLPS has been widely used for sintering both ferrous and nonferrous alloys. The former include stainless steels (including the 300 and 400 series), tool steels (e.g., T1, T2, T6, T15, T42, M2, M42), and precipitation-hardened steels such as 17-4 PH. The latter ranges from simple systems such as monels, brasses, and bronzes to complex nickel- and cobalt-base superalloys. Several existing applications based on SLPS include superalloy jet engine defect repair, self-lubricating bearings, corrosion-resistant components from stainless steels, high-conductivity solder pastes, wear surfaces from cobalt-chromium alloys, diamond bonds from molybdenum or cobalt alloys, gas turbine blades from martensitic stainless steels, and cutting tools from high-speed steels. Of these listed applications, the processing of tool steels and stainless steels are most important.

Current commercial full-density sintering of tool steel involves consolidation of water-atomized powders using either uniaxial die pressing or cold isostatic pressing to about 70 to 85% of theoretical density. Sintering is commonly performed in a vacuum furnace in the vicinity of the solidus temperature with tight temperature control. Typical sintering temperatures for tool steel powders such as M2, M3, M4, M35, M42, and T15 range from 1220 to 1260 °C with a recommended temperature uniformity of ± 8 °C.

High-density processing of stainless steels such as 304, 316L, and 17-4PH to densities greater than 96% of theoretical is performed in a vacuum, batch-atmosphere, or continuous furnace at temperatures ranging from 1300 to 1350 °C. The use of a reducing atmosphere such as hydrogen, low dewpoint (less than -40 °C), and fast cooling rate are some of the parameters that dictate the final properties.

From a practical consideration, temperature control plays the most important role during SLPS. Sintering below a threshold temperature results in incomplete densification due to insufficient liquid. The upper critical temperature is dictated by the shape distortion that results from the presence of excess liquid. Simultaneously, the temperature deviations that can be tolerated during the sintering cycle are alloy specific. In most commercial alloys, the sintering temperature has to be controlled to within ± 5 °C. Some examples of commercial sintering cycles are listed in Table 5. In addition, the interactions between process parameters, such as the interaction between heating rate and sintering time, and the material parameters, such as powder chemistry, particle size, and grain size, are complex and are just beginning to be fully understood (Ref 49, 50, 51).

Table 5 Examples of supersolidus liquid-phase sintering cycles

Material	Powder size, μm	Sintering temperature, $^{\circ}\text{C}$	Time, h	Atmosphere	Density, % theoretical
316L	<20	1300 to 1350	1 to 2	Vacuum or hydrogen	96 to 99
316L + boron	<20	1230 to 1245	0.5 to 1	Hydrogen	98 to 100
17-4PH	<20	1300 to 1325	1 to 2	Vacuum or hydrogen	97 to 99
Bronze	100 to 200	850 to 880	0.5 to 1	Hydrogen	92 to 96
Ni superalloy	50 to 250	1250 to 1375	0.5 to 2	Vacuum	96 to 100
M2	<100	1265 to 1280	1 to 2	Vacuum or $\text{N}_2\text{-H}_2\text{-CH}_4$	99 to 100
T15	<100	1225 to 1270	1 to 2	Vacuum or $\text{N}_2\text{-H}_2\text{-CH}_4$	99 to 100
T42 modified	...	1150	1	$\text{N}_2\text{-H}_2\text{-CH}_4$	99 to 100
Tool steels + Cu_3P	<45	1160	0.5 to 1	Vacuum	99 to 100

Transient Liquid-Phase Sintering

Transient LPS is observed in mixed powder systems where the liquid phase has a high solubility in the base material. Some examples of transient LPS include the Cu-Sn, Cu-Al, Ni-Cu, Fe-Mo-C, Fe-P, and Fe-Ti alloys. Figure 15 gives two sample phase diagrams of systems that could be processed using a transient liquid from mixed A and B powders. When a liquid forms, it initially results in melt penetration and shrinkage due to rearrangement. Unlike classic LPS, which involves the presence of a persistent liquid, the liquid in TLPS has a high solubility in the solid. As a consequence, the low-melting additive is replaced by a pore after liquid homogenization occurs. The advantage of a transient liquid is that the short liquid duration eliminates coarsening and results in uniform dimensional change. However, because the liquid content depends on several processing parameters, TLPS is highly sensitive to processing conditions such as the particle size, amount of additive, heating rate, and maximum temperature. Additionally, the solubility ratio necessary for the liquid to be transient can induce swelling during heating to the sintering temperature for certain systems. For applications such as porous bronze bearings this is beneficial, while for structural materials the porosity and swelling are detrimental. Some commercial applications for TLPS include dental amalgam based on silver and mercury, self-lubricating porous bronze bearings, and soft magnetic materials, such as Fe-Si and Fe-P.

Fig. 15 Two binary-phase diagrams showing possible conditions where transient liquid-phase sintering occurs. The mixed powders form a temporary liquid, either by melting the low-temperature constituent or by eutectic formation. The final composition is in a single-phase region. T , sintering temperature; T_s , solidus temperature; X_s , composition of solid phase

Transient LPS of Fe-P and Fe-Si Magnetic Alloys. Ferro-phosphorus, Fe_3P , which is used as the source for P in the Fe-P system, exhibits a transient sintering response above its melting temperature near 980°C (1800°F). The Fe-0.45%P is the most common composition in this alloy system. Likewise, the ferrosilicon masteralloys (usually containing 9 or 17 wt% Si) exhibit a transient liquid phase above 1200°C (2200°F). A common alloy composition, Fe-3%Si, is used in applications involving high resistivity and low core loss, such as in relays and printer actuator mechanisms. Both the Fe-P and Fe-Si systems benefit from using high sintering temperatures that result in enhanced densities due to transient liquid phase sintering and a corresponding increase in the magnetic properties.

Liquid-Phase Sintering

Activated Liquid-Phase Sintering

Activated LPS can be used to improve the sintering behavior of systems with little or no solubility of the solid in the liquid. Densification is enhanced by the addition of elements that segregate to grain boundaries and lower the activation energy for solid-state diffusion. Such elements can be identified by phase diagram characteristics. Limited additive solubility in the liquid helps to ensure segregation to grain boundaries, while the formation of low-melting temperature intermetallic phases with the base metal provides the high-diffusivity phase needed for enhanced solid-state sintering in the presence of the liquid. For liquid volume fractions of 35 vol% or more, high sintered densities can be achieved in systems that lack mutual solubility, because grain shape accommodation is not required. Thus, activators are only needed for compositions with low volume fractions of liquid. In this case, volume diffusion through a high-diffusivity interboundary phase provides the grain shape accommodation necessary to achieve high sintered densities.

Systems in which ALPS is particularly applicable are those in which high electrical or thermal conductivity is desired, such as W-Cu, Mo-Cu, and WC-Cu (Ref 52, 53). In the case of W-Cu, the base metal is practically insoluble in the liquid, but other transition elements, such as cobalt, iron, nickel, and palladium have substantial solubility for tungsten. Traditionally nickel, which has complete solubility with copper, is added to W-Cu to increase densification by solution reprecipitation through the Cu-Ni liquid phase, but the alloying of copper and nickel degrades the electrical and thermal conductivity. High conductivities can be maintained if the amount of activator (i.e., nickel) is small; however, this results in only a small increase in solubility in the liquid phase, which is not highly beneficial to improved density. On the other

hand, cobalt and iron also have substantial solubility for tungsten but have only limited solubility in copper. As shown in Fig. 16, they are much more effective activators of W-Cu, Mo-Cu, and WC-Cu, which all have similar phase relationships with these four activators.

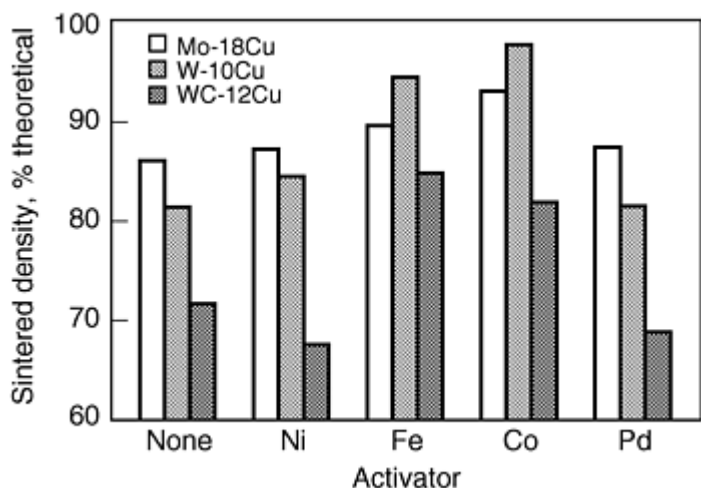

Fig. 16 Effects of transition elements on the sintered densities of W-Cu, Mo-Cu, and WC-Cu

Increasing the amount of additive in a system that densifies by ALPS above a certain amount hinders densification and lowers properties, as shown in Fig. 17. The optimal amount of additive for ALPS corresponds closely with the amount of activator needed to coat the particle surfaces plus the amount of activator that remains in solution in the liquid phase. For systems that densify via solution reprecipitation, such as W-Cu-Ni, increasing the solubility of the liquid phase by increasing the nickel concentration improves the densification behavior.

Fig. 17 Effects of activator concentration on W-10Cu for samples sintered at 1300 °C for 1 h in H₂

Densification in an ALPS system is further improved by a high initial homogeneity and a fine particle size. In fact, with particle sizes below 1 μm , solid-state diffusion in the presence of the liquid phase can provide near-theoretical densities without the need for an activator (Ref 54). Low compaction pressures are beneficial because much of the densification occurs via rearrangement. When there are low volume fractions of liquid a greater portion of densification occurs through the surface layer, due to more contacts, and thus, there is more opportunity for solid-state sintering. Slow heating rates are detrimental to the densification behavior due to the formation of solid-state sinter bonds, which must be dissolved prior to rearrangement. Sintering temperatures and times can be optimized according to the desired properties and specific powder characteristics.

Cold Sintering--High Pressure Consolidation

Elazar Y. Gutmanas, Technion-Israel Institute of Technology, Haifa, Israel

Introduction

COLD SINTERING or high pressure consolidation at ambient temperature, or at temperatures not exceeding 450 °C, of rapidly solidified and mechanically alloyed powders, as well as of very fine elemental powder blends, is an alternative method to achieve full density without compromising very fine and/or metastable microstructures (Ref 1, 2, 3, 4).

Development of fine microstructures is a primary goal in the design of high performance materials (Ref 5, 6). Mechanical properties of materials with complex microstructures are controlled by the superposition of several strengthening mechanisms. Refinement of grain size, second phase precipitates or dispersoids, and the development of a homogeneous microstructure result in a combination of high strength and ductility.

Fine-scale microstructures can be obtained using advanced powder metallurgy processing techniques. Rapid solidification of powders yields supersaturated solid solutions, fine-scale precipitates, fine grain sizes, and homogeneity of composition and microstructure, as well as results in the retention of metastable phases including amorphous metal glasses (Ref 6, 7, 8, 9). Alternatively, mechanical alloying of metal powders and ceramic particles results in extremely fine microstructures with a uniform distribution of dispersoids in the metal matrix (Ref 10, 11, 12, 13). Similar features are observed in metal-oxide composite powders obtained by chemical methods (Ref 14, 15, 16) or by blending very fine micron/submicron elemental metal and ceramic powders (Ref 17, 18).

To produce high performance materials from rapidly solidified or other fine-scale powders, consolidation to full density is mandatory. Hot processing methods, such as extrusion, hot isostatic pressing (HIP), or powder forging, are normally employed for the consolidation of rapidly solidified or mechanically alloyed powders (Ref 7, 13, 16). The temperatures of hot processing are often higher than the subsequent service temperature. Thus, the refined microstructures obtained by rapid solidification or by mechanical alloying can coarsen, and the metastable constituents can dissolve in the matrix during hot consolidation. In the blends of very fine elemental powders, grain growth can take place.

Cold Sintering--High Pressure Consolidation

Elazar Y. Gutmanas, Technion-Israel Institute of Technology, Haifa, Israel

Experimental Techniques of Cold Sintering

Most elemental powders and rapidly solidified alloys can be consolidated at ambient temperature to densities close to the theoretical (>95% TD) at the pressure of 3 GPa. With careful design, tool steel dies and punches can be used at this pressure for hundreds of cycles. Dies and punches made from CPM T15 high-speed steel have been used by the authors of the present article over the last 10 years. The T15 high-speed steel (12W-5V-5Cr-5Co-1.6C (wt%)), fabricated from the inert-gas-atomized powder by HIP, has a fine homogeneous structure and, as a result, a considerably higher strength than that of the ingot tool steel of the same composition (Ref 19). The high concentration of fine homogeneously dispersed carbides in the steel results in very good wear resistance. Some of the punches used for high pressure consolidation were prepared from the water-atomized T15 powder by cold sintering. Schematic of a pressure cell for cold sintering with punches, die walls, and punch supports made from high-speed tool steel is shown in Fig. 1. The inner and outer supporting rings are made of the high strength 4340 steel. Provided the alignment of the tooling is maintained, it is possible to use dies and punches made from CPM T15 steel up to ~ 3.5 GPa. The outer diameter of the die is usually only three times larger than the diameter of the part being consolidated (die opening). Typically, the compact is loaded to 2 GPa in a few seconds, further loading proceeding more slowly over the 10 to 15 s interval to achieve the pressure of 3 GPa. Pressures as high as 4.5 GPa are possible utilizing cemented carbide dies. These dies are more brittle, and high pressure consolidation of composite materials containing hard or super-hard particles often results in a failure of a cemented carbide die after several cycles.

Fig. 1 Schematic of a pressure die for cold sintering

Cylindrical dies with diameters ranging from 3 to 50 mm and rectangular dies with cross sections ranging from 2 by 18 to 40 by 42 mm have been used, the maximum size being limited mainly by the press capacity (Ref 3). Examples of dies and punches are shown in Fig. 2. A laboratory press with 5 MN capacity provides applied pressure (P) equal to 2.5 to 3 GPa for the largest dies. A large number of smaller size samples can be produced by placing each of them in a separate rigid cell (see Fig. 2b). Upscaling of the pressure die to an 88 by 88 mm opening has been done, and densities close to the theoretical have been obtained for aluminum, iron, and T15 high-speed steel employing a press with >25 MN capacity (Ref 4).

Fig. 2 Examples of dies and punches for cold sintering

For some prealloyed, rapidly solidified, or mechanically alloyed powders, consolidation at ambient temperature and at $P = 3$ GPa results in densities 96 to 97% TD. Even lower densities have been obtained for some amorphous and microcrystalline rapidly solidified powders. For such powders, densities close to the theoretical can only be obtained by high pressure consolidation at temperatures above the ambient (warm consolidation). Thus, densities >99% TD were achieved at $T = 450$ °C and $P = 3$ GPa for amorphous powders (Allied Signal) and microcrystalline powders (Marco) with compositions corresponding to iron- and nickel-base wear-resistant alloys and high-speed steels (Ref 3). For some highly alloyed, rapidly solidified alloys, such as high-speed steels, stainless steels, and superalloys, consolidation at $T = 400$ °C and $P = 3$ GPa resulted in densities close to the theoretical and good bonding integrity of the powder particles. In many cases, annealing followed by repressing at $P = 3$ GPa provides consolidation to full density. At the pressure of 3 GPa, high-speed T15 steel pressure dies can be used at temperatures ≤ 450 to 500 °C.

Densities >96% TD were obtained by warm consolidation of amorphous ribbons of Fe-B-Si and Fe-B-Si-C alloys at 0.78 GPa and 2 GPa, respectively, at a temperature of 350 to 380 °C, which is below the glass transition temperature (Ref 20).

Cold Sintering--High Pressure Consolidation

Elazar Y. Gutmanas, Technion-Israel Institute of Technology, Haifa, Israel

Densification of Powders under Pressure

Densification of powders under pressure was treated in the past by a number of authors as related to the compaction process, which is an important step in conventional powder metallurgy. Expressions used to describe density-pressure relationship were empirical in nature. For example, Heckel (Ref 21) used the following expression for compaction of powders in a rigid die:

$$\ln[1/(1 - \rho)] = kP + A$$

where ρ is relative density, P is applied pressure, and k and A are constants. The expression is in good agreement with the experimental results obtained for a number of powders at conventional pressures (<0.9 GPa) (Ref 6), as well as for the consolidation of powders under high pressures (Ref 22). The deviations from straight lines observed in $\ln[1/(1 - \rho)]$ versus P plots for stainless steel powders (see Fig. 3) were attributed to a martensite transformation at higher pressures. The empirical relationship developed by Balshin (Ref 23):

$$\ln P = K_1 \rho + B$$

where K_1 and B are constants, is also in good agreement with experimental results. Figure 4 shows the experimental results of Fig. 3 in terms of Balshin's expression.

Fig. 3 Compaction curves ($\rho = f(P)$) of a stainless steel powder: $\ln[1/(1 - \rho)]$ versus P

Fig. 4 Experimental data of Fig. 3 as ρ versus $\ln P$

In the frames of the theory of plasticity, Torre (Ref 24) obtained an expression for the final density ρ_f as a function of the applied external pressure, P , and the yield stress of the material, σ_y , for spherical particles with spherical voids:

$$\rho_f = 1 - \exp\left(\frac{3}{2}P/\sigma_y\right)$$

According to this expression, $\rho_f = 87.7\%$ at $P = \sigma_y$, $\rho_f = 95.3\%$ at $P = 2\sigma_y$, $\rho_f = 98.9\%$ at $P = 3\sigma_y$, and $\rho_f = 99.75\%$ at $P = 4\sigma_y$. Experimental results obtained during high pressure consolidation of powders are in good agreement with this expression. For example, the data for pure iron and pure nickel powders in Fig. 5 fit the expression, if for iron $\sigma_y = 0.55$ and 0.7 GPa for iron and nickel, respectively. Experimental values for yield stress in compression of samples prepared from these powders at $P = 2$ GPa are $\sigma_y = 0.45$ and 0.5 GPa for iron and nickel, respectively.

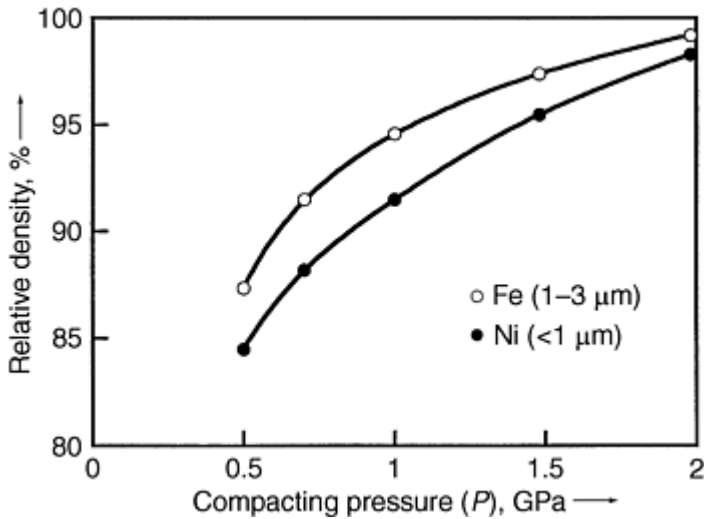

Fig. 5 Compaction curves for fine iron and nickel powders

Attempts were made to introduce yield stress and strain hardening of the material as densification parameters of powders (Ref 21). Such an approach usually fails because during powder densification, and especially at its final stage, the flow stress and strain hardening in the region of still open pores can be quite high and not typical for plastic deformation of a bulk sample in compression.

The final stage of densification of powders under pressure is worth additional discussion and requires a critical analysis of up-to-date results. In a number of materials densified by plastic flow, cusp-shaped pores $<0.1 \mu\text{m}$ in size have been observed. The radius of material on the pore surface is much smaller than the particle radius. The material surrounding the pore has a hemispherical shape resembling the edge of a wire produced by extrusion or deep drawing (see Fig. 6). The pore radius decreases with deformation. Such cusp-shaped pores are less stable under applied pressure than the spherical pores considered by Torre (Ref 24) formed by diffusional flow. What in principle opposes the closure of cusp-shaped pores is the increasing surface tension force on the concave surfaces, resulting in LaPlace compressive stresses on these surfaces, $\sigma = \gamma_s/r_{\text{curv}}$ (γ_s is surface energy and r_{curv} is the radius of curvature). These stresses oppose tensile stresses caused by stress/pressure gradient. Enhanced surface diffusion from the concave surfaces to the convex parts of the cusp-shaped pores can be important for the final stage of densification even at a relatively low temperature.

Fig. 6 Schematic of a cusp-shaped pore (triple point) in compacted spherical powders; r_1 is the radius of curvature of the pore after densification by plastic deformation.

What can be a more important problem for the final stage of densification by plastic flow is that generation of mobile dislocations is required in order to provide necessary plastic strain. Indeed, if we consider a powder particle under external pressure during the final stage of densification, the gradient of stress/pressure will result in shear stresses only in the regions adjacent to the surface of the pore. The inner part of the particle is under hydrostatic pressure. Regions adjacent to the pore become very small as the pore becomes smaller. For a pore $\sim 0.1 \mu\text{m}$ in size, the particle region that can supply dislocations for plastic flow should be about the same size ($\sim 0.1 \mu\text{m}$). Even for a microcrystalline material, this will most probably be a single grain. Most fine micron/submicron size metal particles are single crystals. For nanoscale particles $< 0.1 \mu\text{m}$ in size, the pore size will be $< 0.01 \mu\text{m}$. The probability of the presence of an operative dislocation source in such a small region is very low. Thus, for the pore closure by plastic flow at the final stage of densification, shear stresses exceeding the theoretical shear strength are required that are able to nucleate dislocations in a perfect lattice. This requirement can indicate a real change of the densification mechanism at the final stage.

Stresses necessary for dislocation nucleation in a perfect lattice are usually estimated to be in the range of $G/10$ to $G/30$, where G is shear modulus. If the shear stresses, σ_{sh} , acting on the material adjacent to the pore surface are assumed equal to the applied external pressure, the pressure $P = 3 \text{ GPa}$ yields $\sigma_{\text{sh}} = G/10$ for aluminum ($G = 28.6 \text{ GPa}$) and $\sigma_{\text{sh}} = G/30$ for iron ($G = 86.9 \text{ GPa}$). Higher shear stresses are expected around cusp-shaped pores. In the solution of the Hertzian problem for two spherical bodies of equal radius in contact under pressure (Ref 25), the maximum pressure is given by:

$$P_{\text{max}} = 0.388 \cdot 3\sqrt{2E^2P}$$

and the maximum shear stress for $\nu = 0.3$ is:

$$\sigma_{\text{sh}}^{\text{max}} = 0.31 P_{\text{max}}$$

where P is applied pressure, E is Young's modulus, and ν is Poisson's ratio.

Maximum shear stresses for a number of metals calculated using a simplified approach that is based on the solution of the Hertzian problem and considers regions adjacent to pores as spheres being in contact under pressure are summarized in Table 1. The results indicate that increasing shear stress can result in nucleation of dislocations even in materials with high shear modulus, e.g. tungsten.

Table 1 Calculated shear stresses σ_{sh}^{max} in regions adjacent to a cusp-shaped pore

Material	Young's modulus (E), GPa	Shear modulus (G), GPa	σ_{sh}^{max} , GPa, at applied P , GPa			σ_{sh}^{max} , in G , at applied P , GPa		
			1	2	3	1	2	3
Aluminum	77.4	28.6	2.7	3.4	4.0	$G/11$	$G/8$	$G/7$
Iron	223	87	5.6	7.0	8.0	$G/15$	$G/12$	$G/11$
Copper	127	47	3.8	4.8	5.5	$G/12$	$G/10$	$G/8$

It should be noted that stresses required to move dislocations in high performance materials with high concentrations of very fine precipitates or in supersaturated solid solutions can exceed the stresses needed for dislocation nucleation in a perfect lattice of the pure metal, especially if superposition of different strengthening mechanisms takes place. According to the estimations made for iron, nickel, and cobalt base alloys (Ref 14), grain boundary strengthening for a nanocrystalline material with ~ 10 nm grain size is ~ 3 GPa, whereas dispersion strengthening due to the presence of fine particles with ~ 10 nm interparticle spacing is ~ 5 GPa. Because the high stresses required for the consolidation of prealloyed powders with very fine microstructures are rarely attainable in practice, another approach has been suggested, namely consolidation of very fine elemental powder blends. The flow stress of such blends will be affected by strain hardening only and will be controlled, at the final stage of consolidation, by stresses required to nucleate dislocation in a perfect lattice.

Cold Sintering--High Pressure Consolidation

Elazar Y. Gutmanas, Technion-Israel Institute of Technology, Haifa, Israel

The Mechanism of Cold Sintering

Plastic deformation of powder particles leading to intimate contact between oxide- and contamination-free surfaces results in the formation of chemical bonds and adhesion. This has been proved by transmission electron microscopy for pure aluminum powder (Ref 26). Broken oxide layers exist as islands at powder particle interfaces. Similar observations were made for cold sintered copper, nickel, iron, and stainless steel powders. In a consolidated material, the interface between powder particles is transformed into a grain boundary. New grain boundaries formed at the former powder

particle interfaces are unusual and worth special attention. Surfaces that are brought together by plastic deformation during high pressure consolidation have random orientation. Thus, the formed grain boundaries are mostly noncoherent. Usually, plastic deformation of polycrystals introduces defects in the lattice and thereby results in an increasing degree of disorder, becoming a driving force for recrystallization. In the case of consolidation of powders under high pressure and relatively low temperature, plastic deformation and surface diffusion at the interfaces can result in the partial ordering of the structure. Enhanced diffusion should also take place along interfaces in cold sintered samples. Such diffusion promotes adhesion and bonding integrity of consolidated powder particles.

Cold Sintering--High Pressure Consolidation

Elazar Y. Gutmanas, Technion-Israel Institute of Technology, Haifa, Israel

Processing by Cold Sintering

Reduction of Surface Oxides

Consolidation to full density requires densification with the formation of strong adhesive bonds between the particles. When oxide- and contamination-free surfaces are brought into intimate contact, strong chemical bonds arise resulting in good integrity among the powder particles. Plastic deformation, through the breaking of oxide layers, can result in an intimate contact between the freshly formed surfaces. At higher temperatures, diffusional flow can result in dissolution or spheroidization of oxide layers on metal particle surfaces. Processing routes involving a pronounced shear deformation provide better conditions for breaking of surface oxide.

For a number of pure metals and alloys, oxide layers can be removed by heat treatment in hydrogen or in vacuum at relatively low temperatures, which guarantees the retention of the fine microstructure. Adhesion is considerably improved after such treatment. This has been demonstrated by the high bending strength ($\sigma_{TRS} > 600$ MPa) and high ductility (>20%) of cold sintered iron, nickel, and copper powders treated in hydrogen prior to consolidation (Ref 13). The formation of bonded chains of very fine oxide-free particles produced by vapor condensation was observed for Fe, Co, Ni, Ag, Cu, Mg, Zn, and Al by Tholen (Ref 27). For a number of alloys (e.g. aluminum and magnesium alloys), oxide layers cannot be removed by heat treatment. For stainless steels, chromium-containing high-strength or high-speed steels, superalloys and titanium alloys, reduction of surface oxides can require unduly high processing temperatures (Ref 28, 29, 30).

Good adhesion is also important to prevent partial fracture of adhesive bonds as a result of the elastic springback of consolidated powder particles. Elastic springback can be responsible for the lower effective density of consolidated powders after unloading, as compared to the density measured under load. A higher density was obtained in copper and nickel powders high pressure consolidated at 2 GPa, when the powders were treated in hydrogen at $T = 200$ °C and kept in vacuum prior to consolidation, as compared to the powders left in open air for ~ 1 h after the H_2 treatment (~ 99.5 versus $\sim 98.5\%$). The effect of springback is even more pronounced when consolidation of nanoscale metal powders is considered.

Reduction diagrams can be used to establish temperature limits within which surface oxides on metal, carbide, or nitride powders are reducible (Ref 30, 31). An apparatus used for experimental determination of such diagrams is shown schematically in Fig. 7. A sample (a loose powder or a compact with an interconnected system of pores) is placed into a quartz reactor in a stream of hydrogen. The temperature of the furnace can be increased at a constant rate, so that the reduction behavior can be studied with a steady increase of temperature. In the hydrogen atmosphere, reduction of oxides, sulfides, carbides, etc. can take place, as well as reaction of hydrogen with dissolved carbon, nitrogen, or other elements with the formation of water vapor, hydrogen sulfide, methane, and other gases. The amount of the gaseous reaction product is proportional to the amount of the compound reacted with hydrogen. For example, the amount of water vapor is

proportional to the amount of oxides reduced. Reaction kinetics can be studied by measuring the amount of gas released as function of time at a constant temperature. This is done by connecting the reactor to a thermal conductivity (TC) detector; the TC signal being proportional to the amount of evolved gases. The starting temperature for a reaction depends on thermodynamic parameters of the reagents and products. Thus, for each reaction, a peak of the TC signal versus temperature can be found within a specific range. Peaks corresponding to different reactions can be separated by using a number of cold traps at different temperatures. For example, if a dry ice cold trap is placed between the reactor and the TC detector, water vapor is removed and the peak corresponding to oxide reduction does not appear in the diagram. At the same time, peaks corresponding to reactions of hydrogen with carbon (CH_4), nitrogen (NH_3), etc. will remain. Examples of reduction diagrams for high-speed T15 steel and 410L stainless steel (12 wt% Cr) are shown in Fig. 8. In both cases, the first peak corresponds to the removal of iron oxide and the second to the reduction of mixed oxides (e.g. iron-chromium spinel, FeCr_2O_4). Figure 9 shows the room temperature transverse rupture strength, σ_{TRS} , of cold sintered T15 and 410L steel samples as a function of the preconsolidation reduction treatment temperature (80% dense compacts in hydrogen flow, 1 h). In both cases, an increase of σ_{TRS} was observed in agreement with the reduction peaks in Fig. 8. T15 samples cold sintered after reduction treatment at $T > 1000$ °C measured $\sigma_{\text{TRS}} > 600$ MPa, and a very high value of $\sigma_{\text{TRS}} > 1500$ MPa was obtained for 410 steel cold sintered after reduction treatment at $T > 1100$ °C. The high strength of these cold sintered steels is the result of good adhesion between the surface of oxide-free alloy particles.

The apparatus for reduction studies shown in Fig. 7 was also used for the investigation of decomposition of hydrates in aluminum alloys (Ref 4). Removal of hydrates formed on the surface of aluminum alloy powders in the process of atomization is important for improving the bonding integrity of consolidated materials (Ref 32, 33). Degassing leading to dehydration of atomized aluminum alloys is usually done at temperatures >400 °C, which is higher than the planned service temperature. At such temperatures the coarsening of fine metastable microstructures can take place (Ref 4). Decomposition diagrams of $Al(OH)_3$ and of hydrates obtained employing the apparatus with the TC detector for a number of aluminum alloy powders are shown in Fig. 10. It can be seen that, for a number of the aluminum alloys, degassing can be performed at <300 °C.

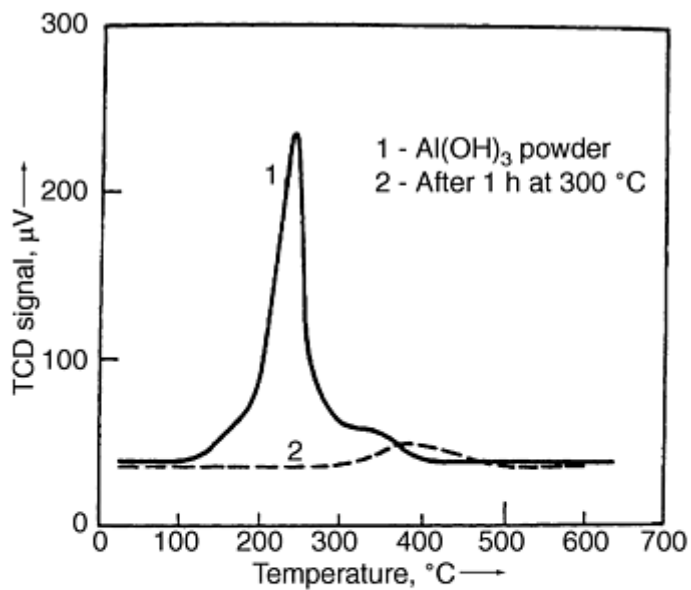

Fig. 10 Decomposition diagram for aluminum hydrates obtained by employing the apparatus shown in Fig. 7

Determination of a temperature range necessary for the reduction of surface oxides is important for retention of fine microstructures of rapidly solidified/mechanically alloyed or of blends of very fine powders.

Processing of Aluminum Alloys for Elevated Temperatures

The main goal of the development of aluminum alloys for temperatures $>200\text{ }^{\circ}\text{C}$ was to replace high-strength aerospace materials for elevated temperatures based on iron or titanium. The disadvantages of the latter include a relatively high specific weight and high cost. A wide variety of alloy systems employing rapid solidification, mechanical alloying, or a combination of both techniques, followed by hot consolidation, were investigated. Alloying elements with low solubility and low diffusion rates in aluminum, such as Ni, Fe, Co, V, Mo, W, Ti, Zr, and Ce, were used in the development of alloys for elevated temperatures.

Normally, the processing temperatures for aluminum alloys are $>400\text{ }^{\circ}\text{C}$, which is higher than planned service temperatures. Processing includes the removal of hydrates from the surface of rapidly solidified powders, hot forging, and hot extrusion. In many alloys, the partial coarsening of microstructure takes place during hot processing, resulting in deterioration of mechanical properties. As it has already been mentioned, for a number of aluminum alloys, especially those which do not contain magnesium, hydrates can be removed at $T < 300\text{ }^{\circ}\text{C}$ (Ref 31). Because cold sintering guarantees the retention of metastable microstructures of rapidly solidified powders of aluminum alloys (Ref 26, 34, 35, 36), the method can be used for investigating the relationship between microstructure and properties, starting from the microstructure of an as-atomized powder.

The thermal stability of cold sintered samples can be monitored indirectly by measuring the room temperature yield stress, σ_y , after annealing at various temperatures. The dependence of σ_y on annealing temperature (1 h anneal) for the cold sintered (curve 1) and hot extruded at $371\text{ }^{\circ}\text{C}$ (curve 2) Al-6.2Ni-5.9Fe (wt%) alloy is shown in Fig. 11. It can be seen that up to $\sim 300\text{ }^{\circ}\text{C}$, there is no significant decrease in σ_y of the cold sintered samples, and that σ_y of the cold sintered samples is $\sim 30\%$ higher than that of the hot extruded samples. Pronounced coarsening of intermetallic precipitates is observed at temperatures $>350\text{ }^{\circ}\text{C}$. The effect of annealing time at $300\text{ }^{\circ}\text{C}$ on the room temperature yield stress, σ_y , of the cold sintered Al-6.2Ni-5.9Fe alloy is shown in Fig. 12. There is almost no drop in σ_y after long (up to 300 h) exposures, which is consistent with the thermally stable microstructure observed in TEM (Ref 18). Other rapidly solidified aluminum alloy powders for elevated temperatures (Al-Ni-Co, Al-Fe-Ce), as well as mechanically alloyed rapidly solidified Al-Fe-Ce alloys, were successfully consolidated to full density employing cold sintering.

Cold Sintering of Rapidly Solidified Iron- and Nickel-Base Alloys

Rapidly solidified high-speed steel powders (T15, M2, M35) were successfully consolidated to full density via cold sintering with retention of very fine microstructure (Ref 4, 30, 37, 38). Two processing routes can be used for full density consolidation of high speed steels: (a) high pressure consolidation at $P = 3$ GPa and temperature from 300 to 350 °C; and (b) cold sintering at ambient temperature at $P = 3$ GPa, followed by annealing at 900 to 1000 °C and repressing/cold sintering at room temperature. Both routes result in finer carbide dispersions compared to similar high speed steels prepared by HIP (Ref 4).

Rapidly solidified high-speed tool steel powders are characterized by a fine cellular structure of carbides (Ref 4), as shown in Fig. 13. Such structure of carbides results in high microhardness and should result in a high elastic modulus, which can be advantageous for some applications. However, exposure to the high processing temperatures (>1200 °C) during consolidation or/and austenizing treatment results in the breaking up of the cell structure and in the partial coarsening of carbides. High pressure consolidation at 400 °C provides full density without destruction of the fine cellular structure. Rapidly solidified nickel-base superalloys can be successfully consolidated to full density using the same cold sintering routes (Ref 4, 29).

Fig. 13 A representative cell structure of carbides in a water-atomized high-speed steel powder cold sintered at 400 °C (SEM)

Processing of High Performance Materials by Cold Sintering of Fine Elemental Powder Blends

Materials with fine microstructure can be produced by cold sintering of very fine elemental powders, followed by a homogenization treatment. The main advantage of this approach, compared to consolidation of prealloyed (rapidly solidified or mechanically alloyed) powders, is the higher compressibility of elemental powders. To utilize high

compressibility, all the preconsolidation heat treatments (removal of surface oxides, annealing, etc.) should be performed at relatively low temperatures in order to prevent interparticle diffusion which occurs in alloying and strengthening. Compaction curves of a prealloyed water-atomized high-speed T15 steel powder and of the fine elemental powder blend of the same overall composition are shown in Fig. 14. Significantly higher densities are achieved at the same pressure for the blended powders. The same applies to 410 stainless steel, nickel- and cobalt-base superalloys, nickel, cobalt, and titanium aluminides, and nickel, cobalt, and iron titanides (Ref 39, 40, 41, 42). When a blend of two or more metal powders is consolidated, a metal with a lower flow stress and higher ductility flows around the harder particles, the shape of the latter remaining practically unchanged (Ref 4, 43).

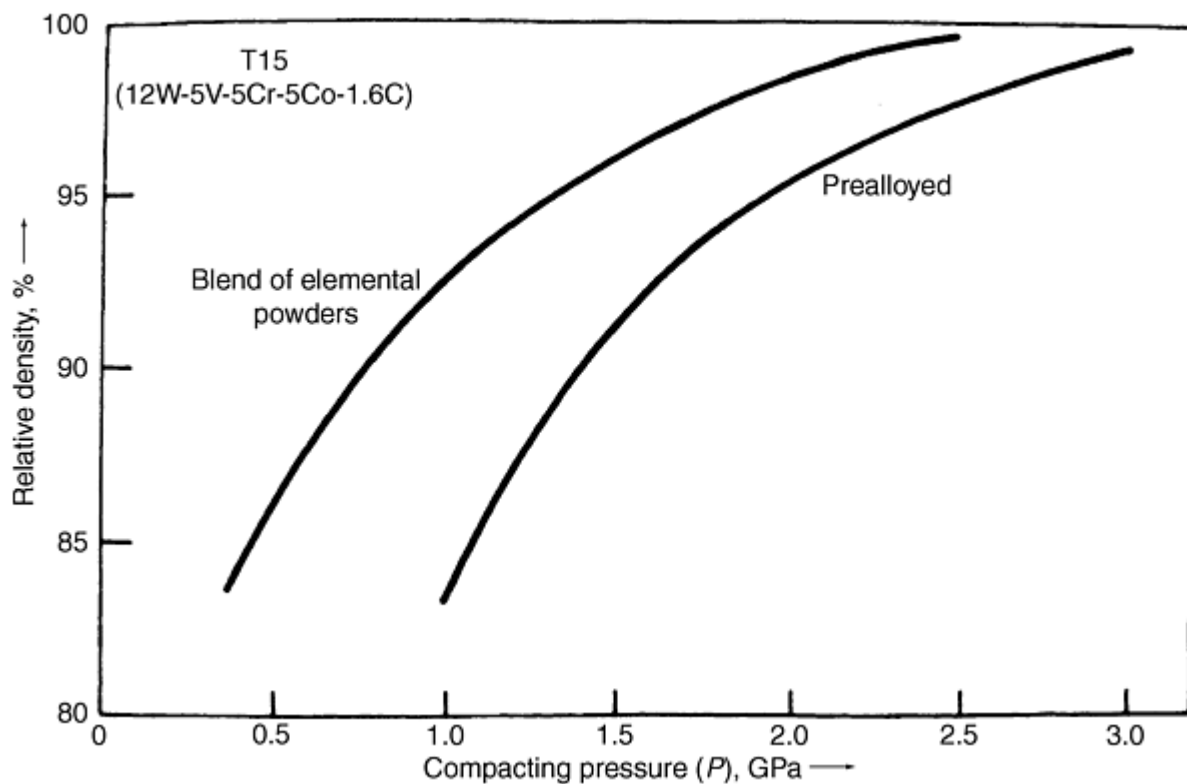

Fig. 14 Compaction curves for high-speed T15 steel

Prior to cold sintering, ~80% dense compacts with an interconnected system of pores are prepared and annealed in a reducing atmosphere (H_2) at temperatures $T < 400$ °C, which is high enough for the removal of surface oxides from elemental nickel, cobalt, iron, and copper powders. Titanium may be added as very fine TiH_2 , which decomposes in vacuum at temperatures >400 °C. In this case, reduction treatment can be replaced by vacuum degassing where hydrogen evolved during the decomposition of TiH_2 will promote the reduction of metal oxides. After cold sintering, the dense samples are annealed to homogenize the material by diffusion. This can be followed by heat treatment to optimize mechanical properties (aging, quenching, tempering, etc.). Homogenization can lead to diffusion alloying, precipitation hardening, and solid state reactions, resulting in the synthesis of intermetallics or amorphization. In some cases, the reactions of new phase (intermetallic) formation are accompanied by a substantial volume decrease leading to the so-called intrinsic porosity of the final product. In such cases, external pressure should be applied during postconsolidation heat treatment in order to obtain a fully dense product.

Fine elemental metal powders are often agglomerated. To obtain homogeneous distribution of different metal powders and ceramic particles in the blend, high energy attrition milling has been used for the blending of powders (Ref 3, 44, 45). By choosing a low grinding media (steel balls) to powder ratio (1:1 to 2:1), and by adding neutral organic liquid, welding and mechanical alloying (by diffusion) during milling can be avoided. The much higher 5:1 to 10:1 media-to-powder ratios are typically used for mechanical alloying. Homogeneous distribution of powder particles on a microscopic scale (areas <10 by $10 \mu m$) is normally achieved after 1 to 2 h blending.

Processing of Composites by Blending of Very Fine Powders

Preparation of iron-base materials by blending of elemental powders offers wide possibilities in the design of thermally stable microstructures by adding carbides or nitrides that are resistant to coarsening. This applies to the carbides and nitrides of elements which have high affinity for carbon and nitrogen and are strong formers and stabilizers of carbides and nitrides (e.g., V, Nb, and Ta). This approach has been utilized for the design of wear-resistant iron-base materials containing unusually large volume fractions of thermally stable carbides, nitrides, and carbonitrides (Ref 3, 38). For example, the abrasive wear resistance of cold sintered Fe-25VC-5Cr₃C₂ and Fe-50VC compositions containing large volume fractions of a hard VC carbide is two times higher than that of the wear-resistant T15 high-speed tool steel. Representative microstructures of the cold sintered and heat treated Fe-25VC-5Cr₃C₂ material with the homogeneous distribution of carbides are shown in Fig. 15. The initial chromium carbide, Cr₃C₂, has been dissolved at a relatively high austenizing temperature (1200 °C) and has reprecipitated in the form of fine mixed carbides. Vanadium carbide particles ~1 μm size have been partially dissolved, but they are stable to coarsening at austenizing temperatures <1300 °C. For Fe-50VC, carbides form a skeleton after austenizing treatment at $T > 1200$ °C. Still finer microstructures can be obtained if finer starting powders of elemental iron and milled carbides, nitrides, etc. are used. It should be mentioned that compositions containing higher volume fractions (up to 80 vol%) of micron-size carbides in micron-size iron- and nickel-base matrices have been successfully consolidated to full density employing cold sintering.

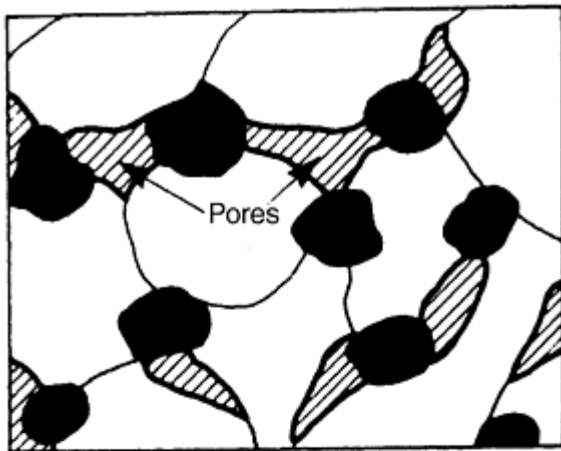

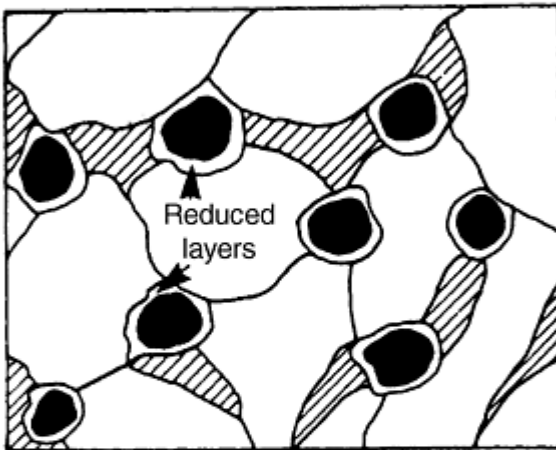

Fig. 15 A representative microstructure (SEM) of cold sintered and heat treated Fe-25VC-5Cr₃C₂ alloy prepared from the fine elemental powder blend

Cold Sintering of Metal Matrix Composites with Partial (Surface) Reduction of Ceramic Particles

Bonding integrity between a metal matrix and ceramic particles can be improved by partial (surface) reduction or metallization of the ceramic particles prior to consolidation of the composite to full density. Such an approach has been applied to the processing of iron-base matrix composites (cermets) reinforced with Cr₂O₃ and VC particles (Ref 31, 46). A schematic of the process is shown in Fig. 16. Metallization of ceramic particle surfaces result in an increased composite strength. The fracture path moved from the particle-matrix interface (in the untreated cermet) to the metal matrix. Some of the coarser ceramic particles were cleaved, which indicates a very good adhesion to the metal matrix (see Fig. 17). An improvement in strength was also obtained for Co-WC composites prepared according to the scheme in Fig. 16. Surface metallization of ceramic particles by such a reduction treatment can only be utilized for oxides, carbides, nitrides, etc., that are reducible at relatively low temperatures when no coarsening of the matrix microstructure takes place. In principle, ceramic particles (or fibers) can be metallized by reduction treatment before being added to the metal matrix. In this case, higher reduction temperatures can be employed and matrices with metastable structures can be used; these useful structures will not be destroyed during cold sintering.

For oxides or other ceramics that are impossible or difficult to reduce, coating by a reducible layer can be used as an intermediate step. Such coatings are produced by annealing an Al_2O_3 plate placed in contact with a nickel, cobalt, or chromium powder in an oxidizing atmosphere followed by partial reduction/metallization of the formed surface layer (NiAl_2O_4 , CoAl_2O_4 , and $(\text{AlCr})_2\text{O}_3$ for nickel, cobalt, and chromium, respectively) (Ref 47).

Coating of non-oxide ceramic particles and fibers employing Powder Immersion Reaction Assisted Coating (PIRAC) (Ref 48, 49, 50) results in the formation of conducting metal-covalent carbide, nitride, etc. surface layers that can lead to a better chemical bonding between ceramic reinforcements and a metal matrix in cold sintered products. Ceramic particles or fibers with conductive PIRAC surface layers can further be coated by electrodeposition before introducing them into a metal matrix. This approach has been successfully used for the fabrication of metal bonded diamond composites for stone cutting (Ref 51).

Cold Sintering of Nanocrystalline Powders and Nanocomposites

Dense nanocrystalline materials can be synthesized by assembling atom clusters that are obtained by physical or chemical methods or by mechanical attrition. Because it is difficult to produce bulk materials by physical or chemical vapor deposition or by electrochemical deposition methods, consolidation of nanosize powders is the only practical way to fabricate bulk nanocrystalline materials (Ref 52, 53, 54). Until recently consolidation of nanoscale powders has resulted in densities $\sim 85\%$ TD and not $>95\%$ TD. Porous nanocrystalline materials find a variety of useful applications as catalysts or extra fine molecular filters/sieves. However, the potential of nanoscale materials in the field of high performance structural and functional applications, as well as the properties of dense nanoscale materials, remain practically unexplored due to inability to achieve full density.

Cold sintering performed immediately after reduction treatment has been successfully used for consolidation of nanocrystalline aluminum, nickel, and iron powders as well as Ni-TiC nanocomposites, and densities $>99\%$ have been obtained (Ref 55). It should be emphasized that the effect of surface oxides is especially pronounced for nanoscale powders characterized by an unusually high grain boundary density. These films are formed during the manufacturing of powders, because contamination of nanosize particles cannot be completely prevented at this stage. It is believed that the relatively low densities reported in most publications dealing with consolidation of nanocrystalline metal powders (e.g., 95% TD for untreated nickel powder consolidated at 5 GPa and 900 °C (Ref 55) compared to $>99\%$ TD obtained by cold sintering in vacuum (10^{-3} Torr) at 3 GPa and 300 °C of a similar powder heat treated in a hydrogen flow) are the result of poor adhesion caused by the presence of surface oxides.

High strength and microhardness values were obtained in cold sintered nanocrystalline materials (Ref 55). Thus, $\sigma_y = 600$ and 1100 MPa were obtained for pure nanocrystalline nickel (65 nm) and iron (30 nm), respectively. This is considerably higher than the strength of these metals cold sintered from 1 μm size powders: $\sigma_y = 200$ and 300 MPa for nickel and iron, respectively.

Cold Sintering--High Pressure Consolidation

Elazar Y. Gutmanas, Technion-Israel Institute of Technology, Haifa, Israel

Fabrication of Net Shape Parts

Because cold sintering uses rigid dies and achieves full density, parts with very close tolerances can be produced: <0.01 mm for a 10 mm opening (Ref 18). Thus the method can be used for the fabrication of parts with final shape and dimensions that do not need any additional machining. Elastic expansion after unloading (pressure release) should be taken into account. Wear resistant parts, tools, parts made of difficult to machine superalloys, stainless steels and titanium alloy, as well as parts made of metal glasses are of primary consideration. Examples of parts produced by cold sintering are shown in Fig. 18. Rectangular (3.2 by 10 by 40 mm) segments for stone-cutting tools were fabricated from metal-bonded (cobalt alloy or tool steel) diamond composites employing cold sintering followed by heat treatment at temperatures lower than the typical hot processing temperatures. Up to 28 segments could be produced in one pressure die, the processing cycle duration being 3 to 4 min. The performance of the cold sintered segments in field tests was better than that of similar segments manufactured by hot processing.

Field-Activated Sintering

Joanna R. Groza, University of California

Introduction

IN POWDER CONSOLIDATION, the imposition of an electric current is known to enhance sintering kinetics and therefore high densities are achieved at lower temperatures or in shorter times as compared to conventional sintering methods. This way, full or near-full densification may be realized with minimal undesirable microstructural changes. A shorter processing time usually results in productivity gains. In addition, there is less sensitivity to initial powder preparation, such as no need for sintering aids and subsequent debinding steps. Most of the time, air sintering is appropriate; that is the need for controlled environment is eliminated. Finally, interparticle bonding is improved. As a consequence, sintered parts of higher quality may be expected.

Numerous processes have been developed that apply an external current to assist powder consolidation. The initial idea to use resistance sintering of metal powders started with Taylor in 1933 in hot pressing of cemented carbides (Ref 1). Cremer patented a field-assisted sintering method in 1944 (Ref 2). He used a 60 Hz current for 1 to 2 cycles at a current density of 62 kA/cm² under 70 to 140 MPa pressure to sinter copper, brass, bronze, and aluminum. In late 1950s, resistance sintering under pressure was applied to metal powders by Lenel using equipment similar to spot welding machines (Ref 3). Presently, resistive hot pressing is commonly used and consists of a low-voltage (5 to 40 V), high-amperage (up to 25 kA) current passing through the powders with a simultaneous pressure application. The electrically conductive powders are contained in an internally insulated die. The passage of the electric current provides the resistive heating of the powders by Joule effect; that is, the electric power is used as the heating source for the consolidating compact. Therefore, the processing times are extremely short, on the order of seconds. Pressure levels are low to moderate (15 to 340 MPa).

In another case of field-assisted sintering, large electric currents induce magnetic forces that contribute to powder compaction due to a pinch effect. By concentrating the pulse in the compaction zone, the magnetic field forces may reach high values, up to an equivalent to 5 GPa pressure (Ref 4). Examples of such consolidation methods are dynamic magnetic compaction (DMC) (Ref 5) and indirect high-energy, high-rate processing (HEHR) (Ref 6, 7).

In *field-activated sintering*, an initial activation of powder particles is achieved by the application of electrical discharges on either conductive or nonconductive materials. (It is also sometimes called electroconductive sintering for conductive

materials.) These discharges are produced by pulsed electric power. The electrical discharge per se does not densify powders and, therefore, additional energy is required to increase the final density. This extra energy may be mechanical, as an applied pressure, and/or thermal energy. The electrical discharge only activates the sintering mechanism (i.e., neck formation) for densification by these other means.

In one of these methods, known as electrical discharge compaction (EDC), the electrical energy is suddenly released by discharging a capacitor bank through the powder preform contained in an insulating container (Ref 8, 9, 10, 11, 12, and 13). Usually, there is only one discharge. Repeating up to three discharges increases activation and thus contributes to final density. No further density improvement is observed beyond 4 to 5 discharges. The discharge period is on the order of hundreds of μ s at a high voltage (up to 30 kV) and current density (~ 10 kA/cm²). After discharge, a high amperage current is passed through the metal powder column for Joule heating. In this stage, an external pressure may also be applied.

Neck formation between powder particles takes place in the discharge stage. The experimental measurement of the powder column electrical resistance has shown an initial rapid drop in the discharge step. The reduction of initial high resistivity of powder column was first attributed to the neck formation between metal powder particles (Ref 8, 11). Later, Okazaki and coworkers demonstrated that the resistance drop is caused by oxide removal rather than only neck buildup. To verify this, they documented oxide film disruption on nickel powders by electron microscopy studies (Ref 8, 10). Some quantitative oxygen measurements in initially heavily oxidized powder and final EDC consolidated part indicated that most of the nickel oxide was dissociated by the sudden heat generated by discharge. This explosive disruption of surface oxides on metal powders due to electric discharge contributes to neck formation. The actual pore elimination and powder consolidation to high densities is achieved by Joule heating and pressure application in the second stage of the process. The method has been applied to compact a variety of metal powders in England (Ref 11, 12, 13), Japan (Ref 14), and the United States (Ref 8, 9, 10). In many cases, electrical discharge compaction was not the final fabrication step. It was aimed to produce at a high-density compact capable of withstanding subsequent processing such as forging or rotary swaging (Ref 8, 11, 12). The initial EDC compacts may be obtained as bars with the same or stepped various cross sections, L-shaped, or hexagonal (Ref 12). More details about EDC may be found in Ref 8.

A sustained activation of the powder particle surface may be achieved by the application of multiple power pulses that produce repeated electrical discharges. This activated consolidation has been pioneered in the spark-sintering technique, which was developed in the 1960s (Ref 15, 16, 17). This technique comprises two steps. The first step consists of the application of an alternating current of 500 to 1000 Hz frequency at a low pressure for 15 to 30 s. The spark discharges generated in this step activate powder particle surfaces. The next stage proceeds with resistance heating of the powders under the same or increased pressure. An increase of pressure in the second step provides the best results. All tools--die and plungers--are made of high-density graphite. Extensive experimental spark-sintering work was performed on various materials such as aluminum, beryllium, copper, nickel, iron, titanium, and their alloys; superalloys; refractory metals; carbides; borides; oxides; and beryllides in the late 1960s and early 1970s (Ref 18, 19, 20, and 21). Bars up to 250 mm (~ 10 in.) in diameter and complex near-net-shape parts have been processed. Multilevel components that involve sinter bonding of various parts were also fabricated by spark sintering. In the latter case, the main attraction was the solid metallurgical bonding achieved while minimizing side effects such as grain coarsening or other microstructural alterations involved in joining materials. The process was advanced to an industrial scale using a semiautomatic system in the commercial production of beryllium and titanium parts (Ref 18, 19). Mechanical properties were comparable to those of wrought metals, particularly when postconsolidation forging was applied. The main difficulty reported was the temperature measurement and control. Other problems were related to the mechanical strength of the graphite die, powder reaction with graphite, tooling cost for complex parts, and in some cases, low productivity. Frustration due to the lack of understanding of the physics of electrical activation often surfaced.

A similar method termed impulse resistance sintering was used in the mid 1970s (Ref 22). The main efforts were directed toward achieving balanced heating and densification by the control of heating rate and distribution and of heat losses. A large difference in temperature between the specimen center and the die wall due to the cooling of the edges by the die was documented. In some cases (e.g., for conductive ceramics such as TiB₂), the die temperature was only 50 to 60% of that of the densifying specimen. A mushroom-shaped punch was used to minimize heat losses at the water-cooled contact with the copper electrodes (small cross section) and thus to provide the highest temperatures at the powder-punch interface (large cross section).

In the last decade, the benefits of a pulse discharge have been recognized more widely, and numerous field-activated sintering techniques have been developed. Such techniques are instrumented pulse electrodischarge consolidation, spark/plasma sintering, or plasma-activated sintering developed in Japan (Ref 23, 24, 25, 26, 27, and 28), resistance/spark sintering under pressure in Korea (Ref 29), pulsed electrical discharge with pressure application in Russia (Ref 30, 31),

HEHR processing in the United States (Ref 6, 7) and plasma sintering in Brazil (Ref 32). All these methods are similar concepts to pulse discharge and subsequent resistance sintering. The pulsed electrodischarge stage may be built in as an added option for powder activation in other nonfield sintering techniques such as the piston-cylinder high-pressure method (Ref 33). This article addresses only pulsed-electrical-discharge activated-pressure sintering that is generally called field-activated sintering technique (FAST). Because an in situ plasma generation may be possible among discharged particles, plasma-activated sintering (PAS) is another common name given to such field-activated densification. A distinction has to be made in the latter case to differentiate PAS from plasma sintering techniques where the specimen is "bathed" in an external plasma environment such as in microwave sintering.

Field-Activated Sintering

Joanna R. Groza, University of California

Process Description

All electrical field-activated techniques use pulsed electrical discharge combined with rapid heating and pressure application to achieve fast powder sintering. A schematic of the FAST process is shown in Fig. 1. The equipment consists of a mechanical device capable of uniaxial pressure application and the electrical components to apply the pulsed and steady current. The loose powders are directly loaded into a punch-and-die unit. Graphite die and graphite punches are commonly used. This limits the pressure levels to low values, generally <100 MPa. The graphite confinement provides a reducing component to the sintering environment. Spark discharges may have the ability to clean the powder particle surfaces. For sintering more sensitive powders, the machines are equipped with chambers for vacuum or controlled environment.

Step 1: Pulsed current and pressure application (switch position A)

Step 2: Resistance heating and pressure application (switch position B)

Fig. 1 Fast process

The consolidation process consists of two stages: (1) an initial activation through the application of a pulsed voltage and (2) the subsequent heating and densification using direct current (dc). These stages may be applied sequentially or simultaneously. Throughout the process, a uniaxial pressure is applied. The pressure may be constant or changed in the second stage. Sometimes, the initial pressure level is light (~ 10 to 15 MPa) and then increased during the heating stage.

The FAST processing parameters are shown in Table 1 and Fig. 2. A typical pulse discharge is achieved by the application of a low voltage (~ 30 V) and a 600 to 1000 A current. In PAS machines, an alternating current (ac) rectifier is used to achieve a controlled dc pulsing. The result is a square-wave current with adjustable on and off pulses. The duration of each pulse may be varied between 1 and 300 ms. The total pulsing time is typically 30 s, but may go up to 300 s. In some FAST methods, an ac current is used for powder particle activation stage (Ref 29). In the second stage, when regular sintering takes place, the current is essentially dc at a level that depends on the powder type. The conductive powders are mainly heated due to the Joule effect. For nonconductive powders, heating occurs through heat transfer from the die and plungers. In this case, the die and punches are heated through their own resistance.

Table 1 Typical FAST processing parameters

Parameter	Value
Applied pressure, MPa	10-65
Pulse stage:	
Voltage, V	30
Current, A	750
Pulse on-stage duration, ms	30-80
Pulse off-stage duration, ms	30-80
Total pulsing time, s	30-60
Resistance heating:	
Current, A	1000-4000

Duration (hold time), min	3-5
Atmosphere	Air or controlled
Total time, min	<10

Fig. 2 Processing parameters in FAST sintering

The sintering time is dependent on the type of powder. To determine sintering time, the PAS machines are equipped with a linear gage that monitors the powder shrinkage and shrinkage rate during densification. The shrinkage decreases continuously while the shrinkage rate is at a maximum and then decreases to essentially zero. The densification is considered complete when the shrinkage rate reaches the zero value. When sintering is completed, the temperature is allowed to ramp down and the compact is removed. Stripping the compact out of the punch-and-die unit is easier for a simple configuration such as a circular or square disk. Generally, the part is cooled in the die because ejection of hot compact is difficult. Cooling rates are usually not controlled, although fans can be used or hot specimens can be ejected from the die and quenched afterwards. The entire operation, from the loading of the die to the ejection of the finished part, may be accomplished in less than 10 min.

Temperature measurements are difficult in all field-assisted sintering techniques. The process is fast, and the steady-state conditions are extremely short. These conditions make the use of conventional pyrometers and thermocouples troublesome. Insertion of a thermocouple in the compact is mechanically difficult. A pyrometer sighting of the compact is possible only for transparent dies. Therefore, die rather than part temperature is generally measured using a pyrometer or a thermocouple. The latter is inserted in the die cavity as close to the heating specimen as possible. Large temperature differences between die and compact have been noticed, particularly in the heating stage. For the sintering step, that is, steady heating, these differences have been measured to be 70 to 100 °C for metal powders (Ref 34). Because current passes through the powders, they reach a higher temperature than the external graphite die. For nonconductive powders that are heated from the dies, powders are at a lower temperature than the die.

Process Mechanisms

Because loose powders are directly loaded into the sintering machines, the use of binders to achieve the strength of the green part becomes unnecessary. Consequently, the debinding step commonly used to burn out the volatiles is rendered superfluous. This is not only helpful in eliminating processing steps and increasing productivity, but part purity also may be enhanced.

The accelerated densification by electric field application may be partly explained by the ability to remove the oxides and impurities from the particle surfaces. In general, the remaining oxides on powder particles are known to cause consolidation difficulties and low fracture toughness of the sintered part. If direct boundary contacts between grains can be achieved, this permits full advantage to be taken of the intrinsic strength of the material. Oxide removal may be attributed to phenomena ranging from electric breakdown of the oxide layer to a possible plasma generation among powder particles.

As in any sintering process, field-activated densification starts with a highly porous body in which pores form an interconnected network. The initial pressure application proceeds with neck formation. Because the pressure is at a low level, most of these necks are only interparticle point contacts. At this stage, the pulsed current is applied, and the goal is to achieve a uniform current path rather than local channels that may concentrate all passing current. Usually, the initial 1 to 2 pulse applications ensure a uniform current path, particularly for high resistance powders. Next, the current is forced to choose the path of the least resistance, that is, through the contact points to complete the current path through powders. The powder particles have an inherent oxide layer on their surface. This way, small capacitors are formed across any two particle contact points. Electrical discharges are generated across these capacitor gaps. The interfering surface oxide films are "broken" when a certain voltage level is achieved. This level, or electrical breakdown voltage, is dependent on the dielectric strength of the oxide layer. The mechanisms of electrical failure that take place at the breakdown voltage involve arcing across adjacent points on particles and electrical breakdown of dielectric film on the powder particle surface.

Alternatively, the electrical discharges across the sample may generate a plasma, that is, an ionized gas among powder particles. It appears that plasma generation occurs only in some conditions that are not yet well defined. If plasma is generated, surface oxide removal and elimination of surface adsorbates take place. The resultant "clean" surfaces provide a better intergranular cohesion, thus enhancing the neck formation. Consequently, enhanced sinterability is observed upon further densification. The dc current applied in the second stage actually promotes diffusion bonding of these clean interparticle contacts.

Presently, the type of surface effects caused by electric field activation has not been unambiguously established. However, experimental evidence suggests that particle surfaces are "cleaned," and direct grain-to-grain contact is observed in the field-sintered specimens. For instance, a transmission electron microscopy (TEM) micrograph of aluminum nitride sintered under an electrical field application shows clean grain boundaries with no secondary or amorphous boundary layers (Fig. 3). A high-resolution electron microscopy image of a typical grain boundary in this aluminum nitride confirmed this direct grain-to-grain bonding (Ref 35). Furthermore, measurements of the oxygen content in electron energy loss spectra did not show any oxygen segregation at the grain boundary.

Fig. 3 Transmission electron micrograph of aluminum nitride sintered by PAS. Courtesy of T.A. Guiton, Dow Chemical Company. 69,000 \times

This result is in contrast to the conventional resistance-sintered specimens that do not involve an activation step. In this case, the higher resistance of the surface oxide films gives rise to higher temperatures than in the interior of the particles themselves and therefore causes melting at particle boundaries. This liquid-sintering mechanism explains the higher densities and shorter times for densification. When molten films develop, secondary phases are observed at grain boundaries of the sintered part (Ref 36).

Another indication of some special surface effects have been noticed in PAS densification of superconductors. Resistivity/temperature curves of Y-Ba-Cu-O (YBCO) superconductors consolidated by PAS showed new transition onsets from 240 to 278 K (Ref 37). Such transitions have not been observed in non-PAS consolidated superconductors. They can be explained by new surface phenomena (i.e., surface accumulation of electronic charge) that may be induced by a plasma generation.

After the particles have been connected, the second stage starts when a direct current is applied. Diffusional processes and plastic flow are the main contributors to the densification in this stage. The highest heating occurs at the thin necks formed by discharge. Diffusion is activated by the passage of the current. The highest temperatures achieved in the necks provide the highest diffusion rates and thus enhance matter transport toward the neck area. This is the area in which most of the matter transport is required for sintering. Therefore, field application intensifies the sintering rate. In addition, plastic flow of metal particles is also enhanced by the combination of applied pressure and high temperatures. The plastic flow may occur through the entire particle or, possibly, only localized plastic flow at the necks. In both cases, plastic flow significantly contributes to pore closure and therefore enhances overall densification rate. As a result, high density may be achieved and in shorter times or at lower temperature than in the absence of the applied current. The final result is a dense compact with good intergranular bonding.

Similar to metals, in ceramics electric charge is built up in the individual powders, which can be considered capacitors. A correlation between the dielectric properties of ceramics and the PAS sinterability has been established (Ref 38, 39). Ceramics with high dielectric constant and low dielectric strength sinter well under electrical field. When the dielectric constant of the ceramic powder is high, the powder surface can hold higher electric charges. This is the case for alumina and aluminum nitride. Conversely, no FAST sintering has been possible for low dielectric constant and high dielectric strength ceramics such as boron nitride and silicon nitride unless oxide additives are used. The favorable effect of a high dielectric constant on sinterability may be also noticed in sintering conditions that increase the dielectric strength of the material (Ref 39). For instance, the dielectric constant of alumina increases by heating. When pulses are applied at higher temperatures, alumina sinterability is enhanced. This has been achieved by multiple pulsing of powders (Fig. 4). The dielectric constant increases when alumina is heated up at increasingly higher temperatures before next pulse is applied.

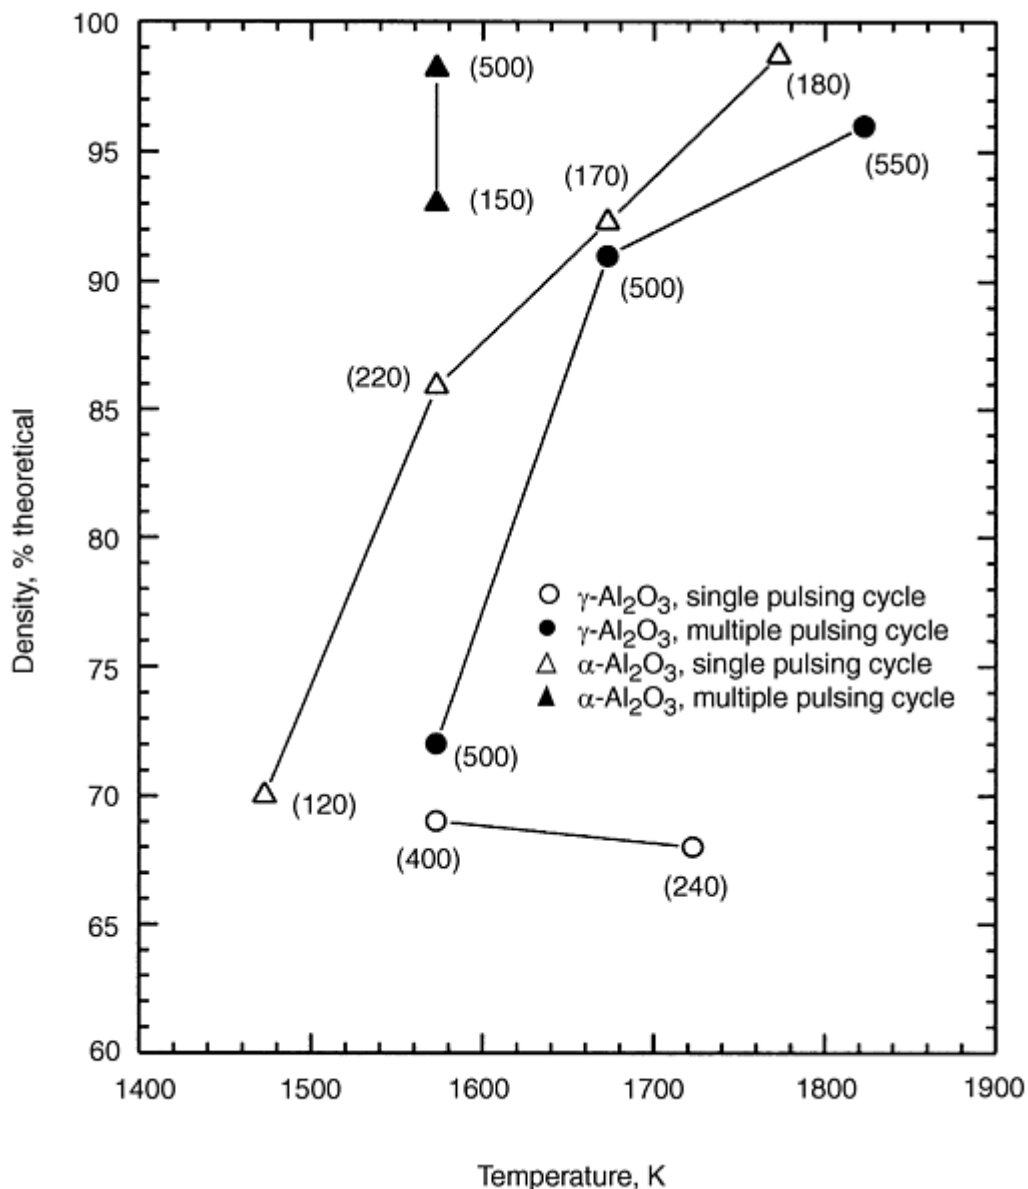

Fig. 4 Effect of multiple pulsing on the densification of α -Al₂O₃ and γ -Al₂O₃ powders. The single pulse cycle was applied at 293 K. The pulse cycle current was 750 A, pulse duration 60 ms for a total of 60 s. The multiple pulse cycle involved 4 cycles, one each at 293, 473, 773, and 1273 K. The pulsing parameters were the same as single pulse cycle and kept constant for all the cycles. The numbers in bracket denote holding time at sintering temperature for each run. The initial pressure was 40 MPa and increased to 66 MPa in the sintering stage. Courtesy of R.S. Misra (U.C. Davis)

Field sintering of alumina indicated a dependence on the pulse duration. Sintering is enhanced when longer pulse duration (30 to 160 ms) is used. The longer discharge times allow the ions in the ceramics more time for polarization and therefore more electric energy to be built up before electrical breakdown.

Field-Activated Sintering

Joanna R. Groza, University of California

Process Fundamentals

The main parameters that control the field-assisted sintering process are pulsing duration and frequency, resistance-sintering current and time, pressure level, and sintering environment.

The effect of electrical discharge on the total sintering time was studied in PAS using pure aluminum powders and is shown in Fig. 5 (Ref 40). The sintering time reported is the duration required to attain final zero-shrinkage rate. The sintering time during resistance heating becomes shorter when a previous pulsed electrical discharge was applied. The effect of electrical discharge application on sintering time is more distinctly observed for currents between 750 and 1200 A. Sintering time is minimum for individual pulse duration of 30 to 80 ms. For pulses longer than 80 ms, sintering time increases, indicating that the efficiency of pulsed current diminished. Similarly, the density increases when alternating current is superimposed on the direct current for sintering in resistance/spark sintering under pressure (Ref 29) (Fig. 6).

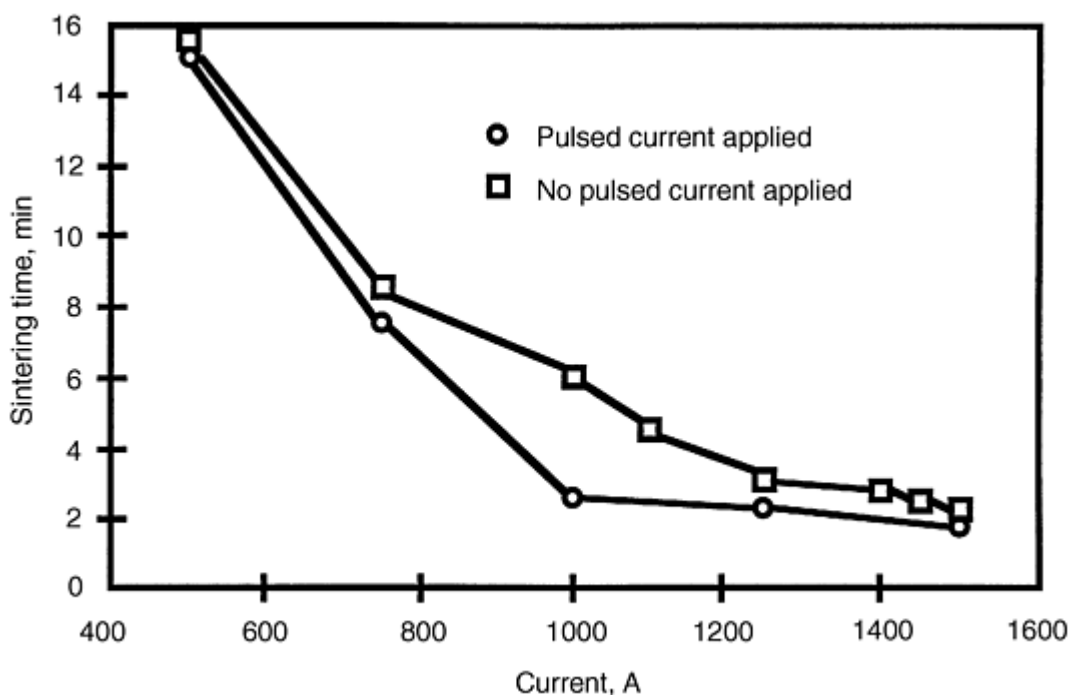

Fig. 5 Effect of pulsed current on the total sintering time for pure aluminum densified by FAST. Source: Ref 40

Fig. 6 Effect of alternating current plus direct current (ac + dc) superimposition on the density variation with current density for TiAl powders. Source: Ref 29

Generally, the field effects in comparison with other sintering techniques are more noticeable when sintering proceeds at lower temperatures. A comparison of conventional hot pressing and PAS sintering of mechanically alloyed Fe-2%C powders is shown in Fig. 7 (Ref 41). The most significant difference in densities is observed at temperatures below 1273 K.

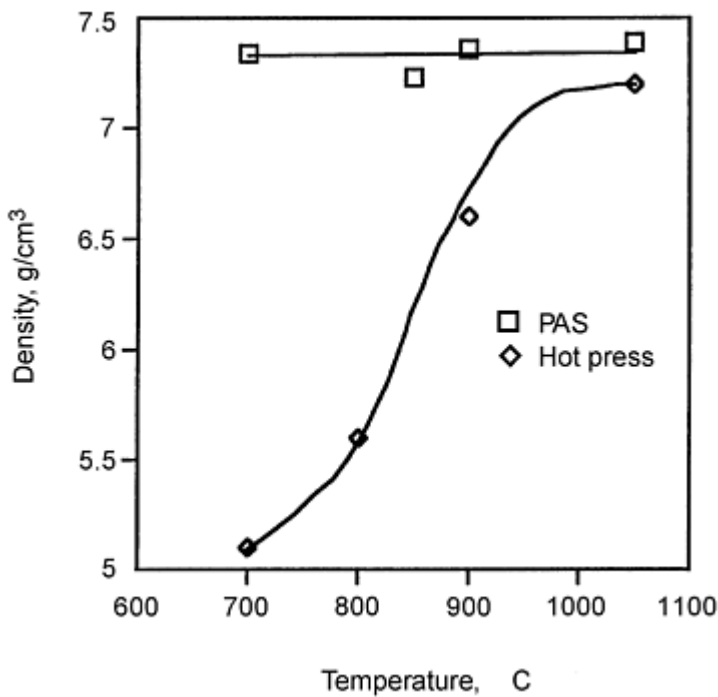

Fig. 7 Comparison of densities of Fe-2%C powders sintered by conventional hot pressing and FAST. Source:

Beyond the electrical discharge stage, the sintering parameters in the resistance heating stage have an effect similar to those in conventional pressure sintering. As an example, the temperature effect is illustrated for the PAS sintering of atomized NiAl powders (Fig. 8) (Ref 42). Overall pressure effects are the same as in conventional hot pressing. The larger the pressure, the higher the density. Studies on PAS sintering of pure nickel powders indicated that the densification rate remains in overall agreement with the pressure-assisted models but becomes faster. A shift in densification behavior has been observed from only power-law creep to grain-boundary contribution to densification. This shift is probably due to field-enhanced diffusivity. Increased densification has been observed when pressure is increased in the resistance-sintering stage (Ref 41).

Fig. 8 (a) Density and (b) hardness variation with sintering temperature during FAST consolidation of atomized NiAl powders. Source: Ref 42

Grain growth during FAST sintering occurs and seems to be governed by temperature level and time at high temperature, similar to conventional sintering. However, the short-time high-temperature exposure characteristic of FAST processes usually minimizes grain growth.

Applications

Presently, industrial application of FAST sintering methods is in the production of both hard and soft magnetic materials and cutting tools in Japan (Ref 43, 44). For instance, manganese-zinc ferrites for high-frequency power supplies are PAS sintered using 60 s pulse current cycle followed by a heating current of 2000 A under 49 MPa pressure (Ref 43). Densities of >99% and grain size of 1 μm are obtained. This fine grain size minimizes the magnetic high-frequency core losses from 1800 kW/m³ for a conventionally sintered 9 μm sample to only 720 kW/m³. Commercial Nd-Fe-Co-B magnets are densified by PAS.

Laboratory-scale experiments have succeeded in field-activation sintering of a large variety of materials from metals to intermetallic compounds to ceramics and composites. Examples of metal powders that have been consolidated include pure metals (nickel, tungsten), intermetallics (TiAl, NiAl, Nb₃Al, FeSi₂), and composites (Ref 23, 27, 28, 41, 42, and 45). The field-sintered ceramics were oxide (Al₂O₃, superconductors) and nonoxide-type (AlN, Si₃N₄) (Ref 25, 37, 38, 39, and 46). The process parameters, density, grain size, and hardness values achieved in PAS-consolidated materials are shown in Tables 2 and 3.

Table 2 Field-activated sintering parameters and properties of metal powders

Material	Temperature, K	Holding time, min	Pressure, MPa	Density, g/cm ³ (%)	Grain size, nm	Hardness
Nickel	1270	2	30	8.57 (96.2)	NA	228 HV
Tungsten	2163	6	61	17.4 (90)	~1500	NA
Fe-2% C ^(a)	973	3	47	7.22	52	41 HRC
Fe-2% Al ^(a)	973	3	47	7.34	38	43 HRC
Nb ₃ Al ^{(a)(b)}	1423	3	30	7.57 (~100)	~200	1073 HV
NiAl	1616	1.5	30	5.88 (99.5)	NA	38 HRC
TiAl ^(c)	1602	<3	39	(100)	>100	NA
Fe-85vol% Fe₃C	723	3	63	(98)	45	1050 HV

YBCO	1173	15	15	100	NA

All specimens were sintered in air.

- (a) Multiple pulsing applied.
- (b) Sintered in a vacuum

To illustrate some advantages of field application, a comparison of conventional and FAST sintering of aluminum nitride powders should be considered. Aluminum nitride was field sintered to near-full density in 5 min at 2000 K without any additives (Ref 46). The resulting densities ranged between 3.18 and 3.24 g/cm³ (97.5 and 99.3%, respectively). For comparison, undoped aluminum nitride can be sintered to 95% at 2200 K for 30 h. When dopants are used, the densities achieved are 97 to 98% by conventional sintering at 2070 to 2220 K for 3 to 4 h.

Simultaneous synthesis and densification of MoSi₂ compound from elemental powders has been achieved by FAST (Ref 47). A density of 99.2% was obtained by using a 30 s pulse cycle at 60 MPa pressure followed by heating to 1700 °C in vacuum. This density is higher than that reported for conventional hot pressing of MoSi₂ powders (95 to 97%). The hardness values of field-densified MoSi₂ compare favorably with conventional specimens (>9.4 GPa).

Functionally graded materials combining refractory ceramics on a metal substrate, such as ZrO₂ on NiCrAlY and TiAl, have been consolidated to high densities using FAST methods (Ref 48, 49). A temperature gradient was achieved by either using punches of different materials (i.e., one graphite and one tungsten) or using a stepped die. The temperature gradient was >100 K in the former case and >700 K for the latter.

Bonding capabilities of FAST process should be similar to those in spark sintering. However, only one attempt was reported on diffusion bonding of cubic boron nitride on metal substrates (Ref 50). The good adhesion obtained suggests that field sintering can be used for ceramic-to-metal joining.

Net-shape parts may be produced by FAST methods. One such example is a diamond-shaped cutting tool insert that was fabricated by PAS using a special punch-and-die set (Ref 51). The diamond-shaped cavity of the mold was formed by divided pieces of graphite to prevent mold destruction during sintering (Fig. 9).

Fig. 9 Die-and-punch configurations for net-shape sintering of cutting tool insert. Courtesy of K. Yamazaki (U.C. Davis)

The rapid rate of densification, no need for preliminary powder preparation steps such as cold compaction, additive use and debinding, and air sintering are some densification characteristics that make the FAST process economically competitive. This is especially true for materials that are difficult to cold press; oxygen-sensitive, metastable materials; or for critical bonding and purity requirements. Final-net-shape and diffusion bonding of different materials with minimal microstructural changes are high-potential capabilities of FAST consolidation that are worth future explorations.

Principles and Process Modeling of Higher-Density Consolidation

W.B. Eisen, Crucible Research; J.C. Hebeisen, Bodycote IMT, Inc.

Introduction

POWDER METAL PARTS are sometimes classified by density, where part production technologies may have low-density and high-density variants. Proponents of a particular technology for "high-density" parts may refer to the technology as a "high-density" or "full-density" process without explicit definition of the term for potential customers or comparison with other processes or materials. For the purposes of this article, "higher-density consolidation" means effectively 100% dense material that will compete with forgings in terms of mechanical properties. The most popular way to achieve 100% density in powder materials is with hot isostatic pressing, although there are a number of pseudoisostatic pressing techniques that can achieve high densities and at times at a cost savings. These are generally not important production processes at this time and are not included in this article.

Hot isostatic pressing (HIP) is a materials processing technique in which high isostatic gas pressure is applied to a powder part or compact at elevated temperatures to produce particle-to-particle bonding. This process usually results in the manufacture of a fully dense body, although partially dense bodies also can be intentionally produced. During processing, the compact is subjected to equal pressure from every side.

Elevated temperature, in reference to HIP of metal powders, ranges from approximately 480 °C (895 °F) for aluminum alloy powder to approximately 1700 °C (3090 °F) for tungsten powder. High-density argon gas is the most common medium used in the process, and pressures range from approximately 20 to 300 MPa (3 to 45 ksi), with 100 MPa (15 ksi) as the most typical pressure.

The HIP process was invented at Battelle Memorial Institute in 1955 by Saller et al. (Ref 1). Early designs utilized the "hot-wall" configuration; the furnace surrounded the pressure vessel. Material limitations precluded scale-up, and the development of a cold-wall vessel design, now used throughout industry, took place.

Hot isostatic pressing was initially used for diffusion bonding of clad nuclear fuel elements. Consolidation of beryllium metal powder "to-shape" was first carried out in 1964. High-volume hot isostatic compaction of high-speed tool steel was achieved in the United States and Sweden by 1972. The U.S. Air Force Materials Laboratories expanded HIP technology to include forging of preforms and near-net shapes of nickel-base superalloy and titanium alloy powders from 1970 to 1980. A comprehensive review of early HIP applications is given in Ref 2. During the 1970s it was also discovered that

HIP could be used to permanently heal internal porosity in complex cast shapes without distortion of major casting features. This has remained a major use for HIP technology but is not discussed here.

Current applications of HIP technology in P/M processing include near-net shapes in steel and stainless steel alloys for power turbine components and for manifolds and valves for oil-field applications; nickel-base superalloys for aircraft engine turbine disks and shafts (such shapes are "squared-off" cross sections suitable for sonic inspection); nickel-base P/M forging and rolling preforms and nickel-base P/M integral pump and turbine impeller wheels; titanium alloy P/M billets, forging preforms, and shapes; tool steel billets (for mill processing), large die blocks, and composite structures; net shapes in P/M beryllium, niobium alloys, and other refractory metals; and dispersion and fiber-strengthened P/M aluminum alloys. Small parts processed by a combination of cold compaction of metal powder, sintering, and HIP include blended elemental titanium-base alloys, tool steel shapes, rare-earth magnets, and tools, dies, rolls, wear parts, and seals manufactured in tungsten carbide/cobalt and other carbide compositions. The iron- and nickel-base parts made for valve and manifold applications represent the leading edge of the technology in terms of size and shape complexity. Nickel-base P/M aircraft engine applications represent the highest technology level of the method in terms of mechanical properties, and tool steels represent the highest production tonnage. Hot isostatic pressing of P/M tungsten carbide/cobalt parts is still employed worldwide; however, most manufacturers have gone to a combined sinter/HIP process to reduce process time and costs.

Principles and Process Modeling of Higher-Density Consolidation

W.B. Eisen, Crucible Research; J.C. Hebeisen, Bodycote IMT, Inc.

Process Equipment

Typical HIP units consist of a pressure vessel, gas storage and handling system, furnace, tooling, power supply, controls, and instrumentation. Figure 1 is a schematic of a complete HIP system. An example of a large-sized HIP unit is shown in Fig. 2.

Fig. 1 Typical schematic of an HIP system

Fig. 2 Large HIP unit. 1.5 m (60 in.) diameter by 3.0 m (120 in.) work zone. Operating pressure: 100 MPa (15 ksi)

Pressure Vessel. Proper design of the pressure vessel is essential. The explosive energy stored inside an operating unit can be equivalent to several hundred pounds of high explosives in destructive capability, depending on unit size. Pressure vessels must be designed to meet appropriate American Society of Mechanical Engineers (ASME) codes and ASTM standards for materials.

Consideration must be given to the maximum allowable stress that the vessel can sustain for a designed service life. Typically, the general primary membrane stress intensity in the vessel wall cannot exceed one-third of the ultimate tensile strength. Due to the cyclic loading of the HIP unit, fatigue life of the vessel is an important design criterion. The

possibility of plastic failure of the vessel caused by the applied test and operating pressures must be considered in the vessel design.

Provisions must be made for suitable ports into the pressure vessel to accommodate instrumentation, electrical power, and pressurization equipment. These penetrations are usually located at the bottom of the vessel in present designs.

The first HIP units were designed with the furnace surrounding the vessel. These hot-wall vessels were constrained to operate within a limited range of pressures and temperatures, up to about 207 MPa (30 ksi) and 790 °C (1460 °F). Currently, all HIP units are cold-wall designs (furnace inside the vessel), with pressure vessel components operating up to about 80 °C (150 °F). A heat shield is placed between the furnace and the vessel to limit heat losses and control vessel body temperature. Additionally, the wall of the pressure vessel is cooled by water or other suitable heat transfer fluids.

The cylindrical portion of the vessel can be cooled using several methods. Cooling fluid can be contained by a jacket and come into direct contact with the vessel wall, plate coils with heat transfer mastic can be clamped around the vessel, or an interior-cooled bore liner can be used. In all cases, careful control of the cooling fluid composition must be maintained to prevent corrosion or fouling of the cooling channels.

Hot isostatic pressing vessels are constructed by several methods: multiwall forged, monolithic forged, wire wound, or multiple ring liner. An example of a monolithic-forged pressure vessel is shown in Fig. 3. Pressure is sealed within the vessel by Bridgman seals, metal-to-metal seals, single or double O-rings, or a combination of these devices.

Fig. 3 Monolithic-forged pressure vessel design. Design conditions: 100 MPa (15 ksi) at 200 °C (400 °F). Material: ASTM A723, grade 3, class 3

Closure of the pressure vessel is accomplished by either a threaded closure, pin closure, or nonthreaded closure supported by a yoke frame. In pressure vessels using threaded or pin-type closures, additional consideration must be given to the end loads carried by the vessel and closures. Threaded closures must be designed carefully to distribute the load evenly over all of the threads so that stress is not concentrated on the first two threads. Use of resilient threads or a specially designed thread form and undercut controls stress concentrations. For rapid opening of the vessel, interrupted threads are available that open the vessel in less than one rotation of the threaded closure.

In pin-type closures, a transverse pin is inserted through the pressure vessel and the end cap to close the vessel. This is accomplished quickly and easily; however, high unit stresses occurring at the pinholes in this type of design limit its application. Designs that reduce stress concentrations by using two pins have been proposed. Currently, this design is used primarily with smaller cold isostatic presses.

As an alternative to threaded-end closures, a yoke frame can be used (Fig. 4) to restrain the end loads. Opening and closing a pressure vessel with a yoke frame requires two actions. First the yoke frame (or the cylindrical body) is moved horizontally; then the end closure is extracted axially and moved to the side to allow access to the vessel. Large production units of both types (threaded closure and yoke frame) are currently in operation. User selection of design (yoke frame or threaded-end closure) depends on such factors as system size, design pressure, system application, space availability, cost, inspectability, and preference.

Fig. 4 Hot isostatic pressing unit with a wire-wound pressure vessel and a yoke frame closure support. Courtesy of ABB-Autoclave Systems

Gas System. The pressure medium used in HIP is gas, usually argon, although nitrogen and other mixtures can be employed. The gas supply system must be able to quickly deliver the gas at the desired high pressure. Additionally, argon must be delivered at a very high purity level to protect the workload and process equipment from detrimental chemical reactions with contaminants. Gas can be delivered from storage tanks and/or a liquid argon storage vessel.

Supplying argon from liquid storage (Fig. 5) ensures that the gas is of very high purity. Argon is delivered from liquid storage to a cryogenic pump by another smaller transfer pump or by gravity. Pressurized liquid argon moves from the cryogenic pump to a vaporizer, which delivers pressurized gas to the vessel.

Fig. 5 Liquid argon storage and tube bank storage for argon gas. Courtesy of Bodycote IMT, Inc.

Argon can be introduced into the system at a high rate. Unfortunately, there is no small-scale economic method of relieving argon and returning it to liquid storage after the HIP cycle. The used and possibly contaminated gas can either be stored in a tube bank (Fig. 5) or vented to the atmosphere. Argon in gas tube banks must be pumped by a compressor for storage. Multiple-stage, oil-lubricated piston pumps have been used for this purpose. The use of multiple stages provides high-pressure gas at a high-volume rate. However, hydrocarbon contamination of the argon is possible with this type of compressor.

Diaphragm compressors are also used in HIP gas systems. They provide a very clean operation. Contamination of the gas can occur only after gross diaphragm failure. The use of multiple diaphragms and failure sensors and routine replacement of the diaphragm prevent this occurrence. Diaphragm compressors have a low volumetric rate capacity and low gain. High inlet pressure maximizes the mass pumping rate and outlet pressure.

Another type of compressor that has been introduced in the HIP industry is of relatively recent design. A double-acting hydraulic cylinder with a dry-lubricated, high-pressure gas cylinder on each end has been used to compress argon to very high pressures (70 to 400 MPa, or 10 to 60 ksi) at a fairly high rate without contamination problems. Figure 6 shows such a typical high-pressure gas compressor.

Fig. 6 High-pressure gas compressor. This compressor is rated for operation at 20 MPa (30 ksi) and is powered by a 20 hp electric motor. Courtesy of Hydro-Pac Inc.

The purity of the gas entering or leaving the HIP unit must be monitored to ensure that the workload and internal process equipment are not contaminated during a cycle. Possible contaminants include nitrogen, oxygen, water vapor, carbon monoxide, carbon dioxide, methane, and hydrocarbons. Analysis for these gases can be performed with an on-line gas chromatograph.

Different HIP applications require gases of varying purity levels. For example, when hot isostatically pressing powder in a can, protection of process equipment is the only factor that must be considered in determining acceptable gas purity.

Furnace. During HIP, a controllable hot-work zone is created and maintained by the furnace. The size of this zone is governed by vessel size and by furnace and insulation system design. Furnaces utilize primarily convection and radiation mechanisms to transfer heat. Convection dominates at lower temperatures, whereas radiation may be the dominant form of heat transfer at elevated temperatures. Presence of high-density gas as a heat transfer medium allows operation at a higher power density than is possible at atmospheric pressure or in a vacuum for comparable furnace elements.

Pressure vessel body temperatures are kept within design conditions by use of a heat shield between the furnace element and the vessel wall. This heat shield must meet several requirements. In addition to minimizing heat transfer to the vessel wall to reduce power consumption, it must shield the vessel wall as well. During cooldown, the shield should allow heat loss to reduce cooldown time. Density gradients in the argon (caused by thermal gradients between the vessel wall, furnace, and workload) can produce convection loops within the unit. These loops must be controlled by the heat shield to maintain uniform operating temperature within the hot zone. The heat shield also must withstand the thermal gradient from the work zone to the vessel wall. These requirements must be satisfied with as little mass as possible to minimize heat-up and cooldown times and with the smallest volume to provide maximum space within the vessel for the workload. Multiple concentric metal shells, some of which are made from molybdenum or molybdenum alloys, are frequently used for the heat-shield elements.

Typically, the furnace consists of resistance heaters arranged in multiple, independently controlled zones below and beside the workload for optimal temperature control. A hot zone operating at 1750 °C (3200 °F) has been achieved with a single-level element beneath the workload. Natural convection in the high-density gas medium within the pressure vessel is the functional heat transfer mechanism in this design. Forced convection within the pressure vessel has been incorporated in this base heater design, producing an increased workload length as well as improved heating and cooling rates. A heat shield, radiation shields, and baffles are also used in this design.

Installation and loading of the furnace, mantle, and workload into the pressure vessel can be accomplished by several methods. The furnace and mantle can have the capability to automatically connect the power supply and load instrumentation within the vessel. The workload can be introduced into the vessel before, after, or along with the furnace. Some HIP units permit loading and unloading of the workload while it is still hot, thus requiring a shorter cycle time.

The type of material used for furnace elements varies, depending on the range of operating temperatures. For applications up to 1230 °C (2250 °F), Kanthal A-1 (Fe-22/23Cr-4.5/5.7-Al-0.5/2.0-Co) (Kanthal Corp., Bethel, CT), or Hoskins 875 (Fe-22.5Cr-5.5Al-0.5Si, Hoskins Manufacturing Co., Detroit, MI) is used. Kanthal can be exposed to air at elevated temperatures; consequently, the workload can be hot loaded into a furnace of this type. However, this material is prone to oxidation and may embrittle. Broken elements can be repaired by conventional welding. Because Kanthal is a relatively poor thermal conductor, low-power densities must be used or overheating can occur, causing sagging and melt out. To compensate for this tendency, Kanthal frequently is manufactured and used in ribbon form.

Molybdenum furnace elements can operate in the temperature range of 500 to 1600 °C (930 to 2900 °F). They cannot be exposed to air at elevated temperatures because rapid oxidation occurs. Molybdenum usually is used as stranded wire or a band. Figure 7 shows the stranded molybdenum heater on a 1.5 m (60 in.) HIP system. During extended use, molybdenum recrystallizes, thus causing an embrittlement condition at ambient temperature. However, stranded molybdenum that becomes damaged can be repaired by lashing, a technique of splicing across the break using molybdenum wire wrapping. In the frequent presence of carbon monoxide in a hot isostatic pressure system, molybdenum case carburizes. The electrical resistivity of the wire becomes greater, increasing the heating capability of the wire.

Graphite is also used as both structural and resistance heating elements for HIP furnaces operating in the range of 400 to 2200 °C (750 to 3990 °F). Graphite is advantageous because of its excellent strength and dimensional stability at very high temperatures, its low cost compared to refractory metals, and its ready availability in various grades and stock sizes. Two forms of graphite are used: bulk and fiber reinforced. Bulk graphite is machined into the required furnace element shapes. Fiber-reinforced graphite is used because it can be fabricated into thinner (and higher electrical resistance) sections while retaining good resistance to mechanical damage and breakage.

The principal shortcoming of graphite furnaces is that the system must be kept dry. This is frequently done by a combination of heating, purging, and/or evacuation. When moisture is present, carbon monoxide can be generated by reaction of water vapor and graphite. Carburization of workload pieces can occur unless proper care is taken in the evacuation cycle. Also, contact between graphite and most metals must be avoided to prevent melting reactions. Currently, graphite furnaces up to 75 cm (30 in.) in diameter are used in routine production at temperatures up to 1750 °C (3180 °F).

Controls and Instrumentation. The control system of the HIP unit must provide for the safe and reliable operation of the entire system, as well as accurate measurement and control of pressure and temperature parameters throughout the

entire processing cycle. Pressure inside the vessel is measured by a Bourdon tube gage or a strain-gage pressure transducer. Temperature is measured with thermocouples that are distributed throughout the hot zone. With a multizoned furnace, each furnace element or zone must be monitored and controlled to adequately control the entire hot zone. Measurements are taken at several points on large workpieces, as well as throughout the working volume, to guarantee that process conditions are met. Permanent pressure and temperature records should be maintained.

The power supply to the furnace is usually a silicon-controlled rectifier system. Phase-angle firing is used to control power input for molybdenum element furnaces. Zone current, zone voltage, and total power are monitored to control furnace performance. Power consumption of a well-designed 25 cm (10 in.) diam HIP unit is about 15 kW; a 38 cm (15 in.) diam unit consumes about 40 kW, and a 102 cm (40 in.) diam unit uses about 200 kW. Ground-fault protection can be provided to prevent extensive furnace damage in the event of electrical insulation failure.

Other system parameters that should be monitored include gas purity, gas pressure, vessel temperatures, and water system conditions. If a system failure is detected, the control system should provide a warning, take corrective action, and/or initiate system shutdown.

Control equipment consists of automatic controllers, analog data presentation devices, and remotely operated valves and switches. Minicomputers are capable of automatically monitoring and controlling all system parameters. Minicomputers also can provide complete and reliable detection of process errors or system malfunction and take corrective action.

Processing Sequence. Figure 8 presents a basic process flowchart for production of various-sized encapsulated and unencapsulated P/M parts. This chart applies to both production and development routes, wherein interactive modification of process variables is required to obtain design objectives. Included is a provision for a subroutine where parts can be low-temperature hot isostatically pressed to a closed porosity condition, decanned, and hot isostatically pressed again, usually at higher temperatures. This option can be employed when the powder/container interaction (melting, alloying, contamination, etc.) is unacceptable at the preferred higher HIP temperature. This technique has been used, for example, for niobium alloys that are initially hot isostatically pressed at 1205 °C (2200 °F) in low-carbon steel containers, decanned, and hot isostatically pressed at 1595 °C (2900 °F) to circumvent an iron-niobium eutectic reaction at 1360 °C (2480 °F).

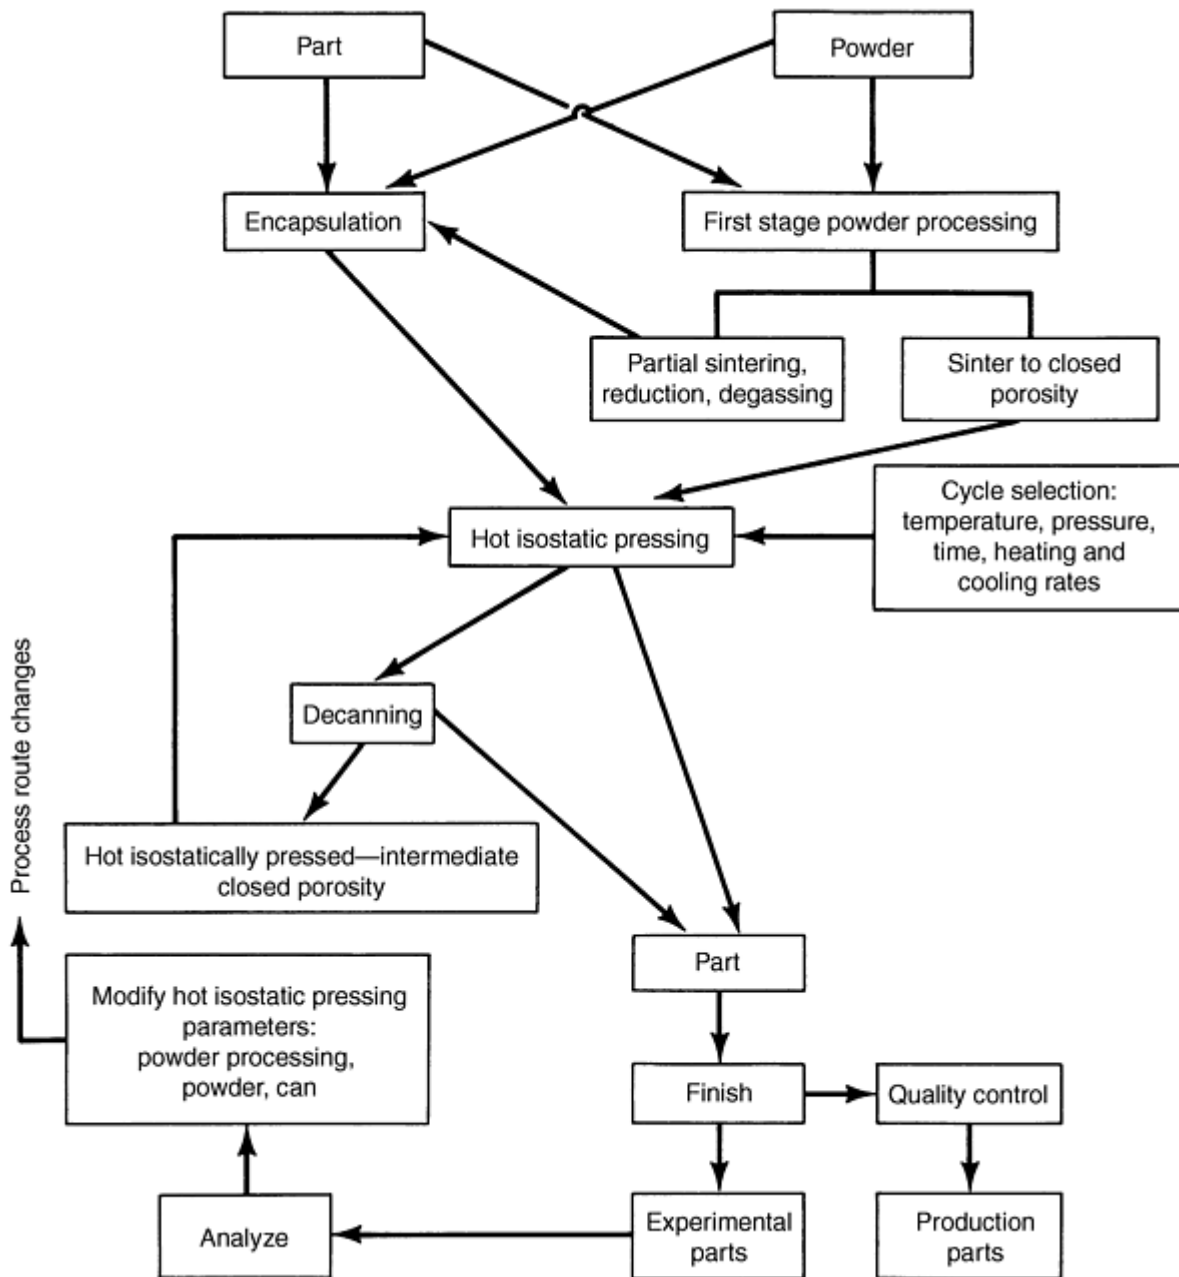

Fig. 8 Flowchart for P/M manufacture of metal parts by HIP

Part Size. The upper size limitation for densification of encapsulated parts is governed primarily by the processing unit uniform temperature working zone diameter and length. Tool steel billets as large as 86 cm (34 in.) in diameter and 300 cm (120 in.) long have been fully densified by HIP. Nickel-base superalloy P/M turbine disks greater than 1 m (3.3 ft) in diameter have been successfully densified. For sheet metal encapsulation of P/M parts weighing more than approximately 20 kg (44 lb), attachment of handling lugs is recommended. For large-diameter parts (greater than 0.5 m, or 1.6 ft in diameter) and weights greater than 100 kg (220 lb), sheet metal bending stresses due to enclosed powder weight must be considered. Careful consideration must be given to the support of large parts in hot isostatic press tooling to prevent bending during heating prior to complete densification. For small net-shape parts (up to 1000 g, or 35 oz), particularly with thin sections, tooling that permits separate setting of each part is often required.

Production of small (less than 10 kg, or 20 lb) net-shape parts by HIP using encapsulation techniques is not generally economical because of the cost of container fabrication and leak checking. This applies particularly to P/M steel alloys. Exceptions include experimental parts and manufacture of specialty parts in P/M refractory metals, composites, and precious metals, where metal cost is a controlling factor. Small net-shape parts (less than 0.5 kg, or 1 lb) are best

manufactured by containerless HIP, particularly for tool materials, provided satisfactory process procedures can be developed.

Worldwide HIP Capacity. It is estimated that there are nearly 1000 operational HIP units worldwide (Ref 6). Approximately 50 to 75% of these systems are research and development or laboratory units. About 35 to 40% of all operational HIP units are in the United States, with perhaps 75% of these being research and development units; Japan is currently home to around 300 operational HIP units, two-thirds of which are research and development/laboratory units; Western Europe houses about 165 units, probably 60+% of which are research and development/laboratory units; and there are between 30 and 95 units in Asian countries other than Japan. Eastern Europe may have as many as 85 HIP units, the majority of which (~80%) are production units.

The principal manufacturers of hot isostatic presses are ABB-Autoclave Systems, Inc. of Columbus, OH, and ABB of Vasteras, Sweden; Engineered Pressure Systems, Inc. (formerly National Forge); and Kobe. Together, these three companies have clearly dominated world HIP equipment production (and commercial HIP equipment technology development) in the 1990s. From 1990 to the present, ABB, EPSI, and Kobe have together sold no less than 162 HIP units worldwide.

Several other companies build HIP units, among these probably the most prominent being ABRA, American Isostatic Presses, Conaway, and Vitek. ABRA is a Swiss firm incorporated in 1988. Both American Isostatic Presses and Vitek are relatively new and small firms, and both have sold several units. Conaway is a second- or third-generation descendant of Conaway Pressure Systems, Inc., the company mainly responsible for one of the major technical innovations in HIP during the late 1970s and early 1980s--namely, the introduction of the self-contained, laboratory size "MiniHIPPER." Conaway today seems to be focused on the development of rapid, very-high-pressure HIP processing technology, an example of which is the Quick HIP system at Michigan Technological University.

General Process Parameters

Hot isostatic pressing of P/M material generally produces fully dense material with successful process parameters usually biased toward the shortest process time, using pressures within the equipment rating large enough to accommodate the parts being processed. Strict grain-size control also may be required for P/M parts subjected to subsequent isothermal forging or other hot-working operations.

Process Cycle. Several types of hot isostatic pressing cycles can be used. These vary primarily in the magnitude and sequence of pressure and temperature application, as shown in Fig. 9. Additional variations are possible with staged heating and cooling operations.

Fig. 9 Typical process cycles. Source: Bodycote IMT, Inc.

A type I cycle is carried out by cold pressurization to approximately one-fourth to one-third of final process pressure (T equals approximately 1100 to 1200 °C, or 2000 to 2200 °F), isolation of the pressure vessel, and heating to process temperature. Pressure rises due to increased gas temperature under constant volume constraint. This process constitutes a typical cold-loading cycle and is particularly useful for geometry control of large net shapes in sheet metal encapsulation.

Type II cycles involve heating workpieces to process temperature while maintaining a low vessel pressure (up to 7 MPa, 1000 psi). Pressurization is often accomplished by equalization from storage cylinders and pumping. This type of processing is equivalent to a hot-loading cycle and is used for glass-encapsulated powder and other fragile containers to prevent breakage.

Type III cycles involve full pressurization, followed by heating, while process gas is bled back to storage to maintain pressure within the equipment rating. This cycle tends to enhance recrystallization of powder particles through plastic deformation at the lowest possible temperature.

A type IV process cycle, with the accelerated cooling capabilities of HIP equipment, is the most cost-effective processing mode in terms of reduced process time for a cold-loading cycle. Pumping and heating occur concurrently to a level where sufficient pressure exists within the system to attain the required final pressure when the process temperature is achieved.

Selection of process parameters, such as temperature, time, and heating and cooling rates, to achieve material property and dimensional requirements usually is verified by processing through a matrix and testing. Guidelines to process temperatures for HIP of P/M parts can be obtained from published literature. Rapid diffusion and power-law creep, in which deformation rate is proportional to applied stress raised to a power (n), occur in most cases near these temperatures. General temperature guidelines indicate that metal powders can be densified at 100 MPa (15 ksi) pressure in 2 to 4 h, as indicated:

- *Nickel-base alloys*: 1100 to 1200 °C (2000 to 2200 °F)
- *Iron-base tool steels*: 1050 to 1200 °C (1950 to 2200 °F)
- *Titanium-base alloys*: 850 to 950 °C (1550 to 1750 °F)
- *Aluminum powders*: 480 to 530 °C (900 to 1000 °F)
- *Copper-base alloys*: 750 to 850 °C (1400 to 1550 °F)
- *Molybdenum and niobium fine powder*: 1200 to 1650 °C (2200 to 3000 °F)

Generally, the maximum pressure of the equipment (usually 100 MPa, or 15 ksi) should be used, unless intentionally porous parts are desired. This approach minimizes process time, but scale-up requirements must be considered to avoid requiring pressures not available in larger hot isostatic pressure vessels.

Process times for most powders listed above are 2 to 4 h at 100 MPa (15 ksi). This processing time is based on temperature after soak-through. Because of capacity and transfer lags, particularly for large parts weighing more than 25 kg (55 lb), workpiece temperature must be measured by closely coupled thermocouples (Ref 3). Figure 10 shows a recommended thermocouple installation within a HIP unit to eliminate overriding heat transfer effects from the hot high-pressure gas. Final-stage densification depends primarily on diffusion because pores shrink to radii where the applied-pressure driving force is insignificant compared with surface tension effects (Ref 4).

Fig. 10 Workpiece thermocouple installation for HIP cycles. This design is intended to minimize transfer and lag errors in timing P/M cycles. Source: Bodycote IMT, Inc.

Evaluation of the time parameter effect on densification must be done on the basis of a structure-sensitive mechanical property, such as notched stress rupture. High-magnification microscopy of grain boundaries in polished sections, if grain-boundary structure is critical for the particular application, also discloses residual pores. For an alternate approach to process parameter selection, see Ref 5 for mechanism maps of HIP.

Special constraints on process parameter selection may relate to controlled grain-size requirements, avoidance of powder/container interactions, and solid-state phase transformations. Micron-sized (0.1 to 1.0 mm) powders (usually precompacted and partially sintered) can be densified at approximately 100 to 200 °C (180 to 360 °F) below coarser (100

mm mean particle size) powders at equivalent pressure and time. This effect is derived from greater contribution of grain-boundary sliding during creep deformation. It is useful in processing of refractory metal powders.

Principles and Process Modeling of Higher-Density Consolidation

W.B. Eisen, Crucible Research; J.C. Hebeisen, Bodycote IMT, Inc.

Modeling of HIP

Modeling of the HIP process has tried to define mathematically consolidation, and its objective has been to either predict the properties or the shape of the finished product. This work has been going on for more than 20 years, and the starting points for most models have been either microscopic, in which constitutive equations are based on the interaction of particles under high stress, or macroscopic, in which yield criteria were developed for the powder, treating it as a porous material continuum. A third technique, confined to shape prediction, results in an empirically derived model based on an analysis of actual production experience over an extended period of time. This section reviews all three of these methods and shows the current status and capabilities of all models.

Table 1 lists the nomenclature used in this section on HIP modeling. However, readers should be aware that often different symbols are used in literature for some properties or parameters. Another case is the material property parameters in constitutive equations developed by different authors. In some cases, the terms are identical, but have different mathematical definitions. In some cases, they are unique with their own mathematical description.

Table 1 Nomenclature used in equations

Symbol	Definition
α	function of relative density, used in yield function with J_1
β	function of relative density, used in yield function with J_2
ϵ	strain
$\dot{\epsilon}$	strain rate
$\dot{\epsilon}_0$	material property in power-law creep equation
$d\epsilon_{eq}$	equivalent matrix strain increment
θ	temperature
$\delta\lambda$	nonnegative constant
σ	stress
$\sigma_1, \sigma_2, \sigma_3$	principal stresses
σ_{av}	average stress
σ_m	hydrostatic stress
σ_{eq}	equivalent stress
σ_0	material property parameter in creep equation
σ_y	yield stress of material
τ_s	shear stress
ϕ	function of relative density, used with hydrostatic stress in stress-strain equations
b	material constant used in various yield functions. May have different specific meanings
f, f_1, f_2, f	function used in various yield functions. May have different specific meanings
k	thermal conductivity of fully dense product

k_D	thermal conductivity as an exponential function of relative density
l_i	characteristic initial dimension of compact
l_f	characteristic final dimension of compact
m	material constant in various yield functions
n	power-law creep exponent
A	power-law creep coefficient
D	relative density of the powder at any time
D_0	initial relative density of the powder
\bar{D}	densification rate
F	yield function
J_1	$\sigma_1 + \sigma_2 + \sigma_3$, first invariant of the stress tensor
J_2	$[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]$, second invariant of the deviatoric stress tensor
P	pressure
P_{eff}	effective (contact) pressure on each powder particle
P_{lim}	external pressure that will cause yielding
Q	activation energy for creep
R	radius
R_0	universal gas constant
T	temperature
V_i	initial volume of powder container
V_f	final volume of powder container after HIP

Empirical Models

The earliest models or estimates of size change were based on the starting packing density (fraction of theoretical) of the powder and on the estimate that shrinkage was the same in all directions. Total volumetric shrinkage was calculated according to the following analysis:

$$\frac{V_i - V_f}{V_i} = 1 - D_0 \quad (\text{Eq 1})$$

Assume that the volume can be approximated by the cube of the linear dimension:

$$l_i^3 = V_i \quad (\text{Eq 2})$$

$$l_f^3 = V_f \quad (\text{Eq 3})$$

The shrinkage is the same in all directions (isotropic behavior):

$$\frac{l_i^3 - l_f^3}{l_i^3} = 1 - D_0 \quad (\text{Eq 4})$$

$$\frac{l_f}{l_i} = D_0^{1/3} \quad (\text{Eq 5})$$

The final dimension is the initial dimension times the cube root of the initial relative density. In other words, isotropic shrinkage or the shrinkage of each linear dimension is equal to $(1 - D_0^{1/3})$.

From these equations, the initial dimensions, that is, the starting shape of the powder needed to end up with specific final dimensions, can be approximated if one knows the starting density and the desired finished dimensions. The assumption of isotropic shrinkage has limited validity. If a spherical container is hot isostatically pressed with no thermal gradient present, shrinkage is uniform, but all other starting shapes do not densify uniformly in all directions. This is, however, a satisfactory starting point when the initial packing density is greater than 0.65 and if an additional machining allowance is used to produce a near-net shape. A large allowance produces a satisfactory part all the time. This may be an uneconomical solution, however, because the additional weight of powder for the allowance may make the process too

expensive. Shrinkage corrections can be made based on experience for nonspherical geometries, and one company, Crucible (Ref 7), has developed a model based on a continuing analysis of production data on near-net-shape parts. This is a significant refinement over the isotropic calculation and works very well when a complex part can be divided into simple cylinders, rectangular prisms, hollow cylinders, or spheres. The important variables in this model are starting density, aspect ratio, cylindrical area/end area, and the absolute value of the outside diameter. Because this concept involves the construction of the starting container based on an analysis of existing data, it may be thought of as an "expert system." Crucible's design procedure (using their shrink bus software) is shown in Fig. 11.

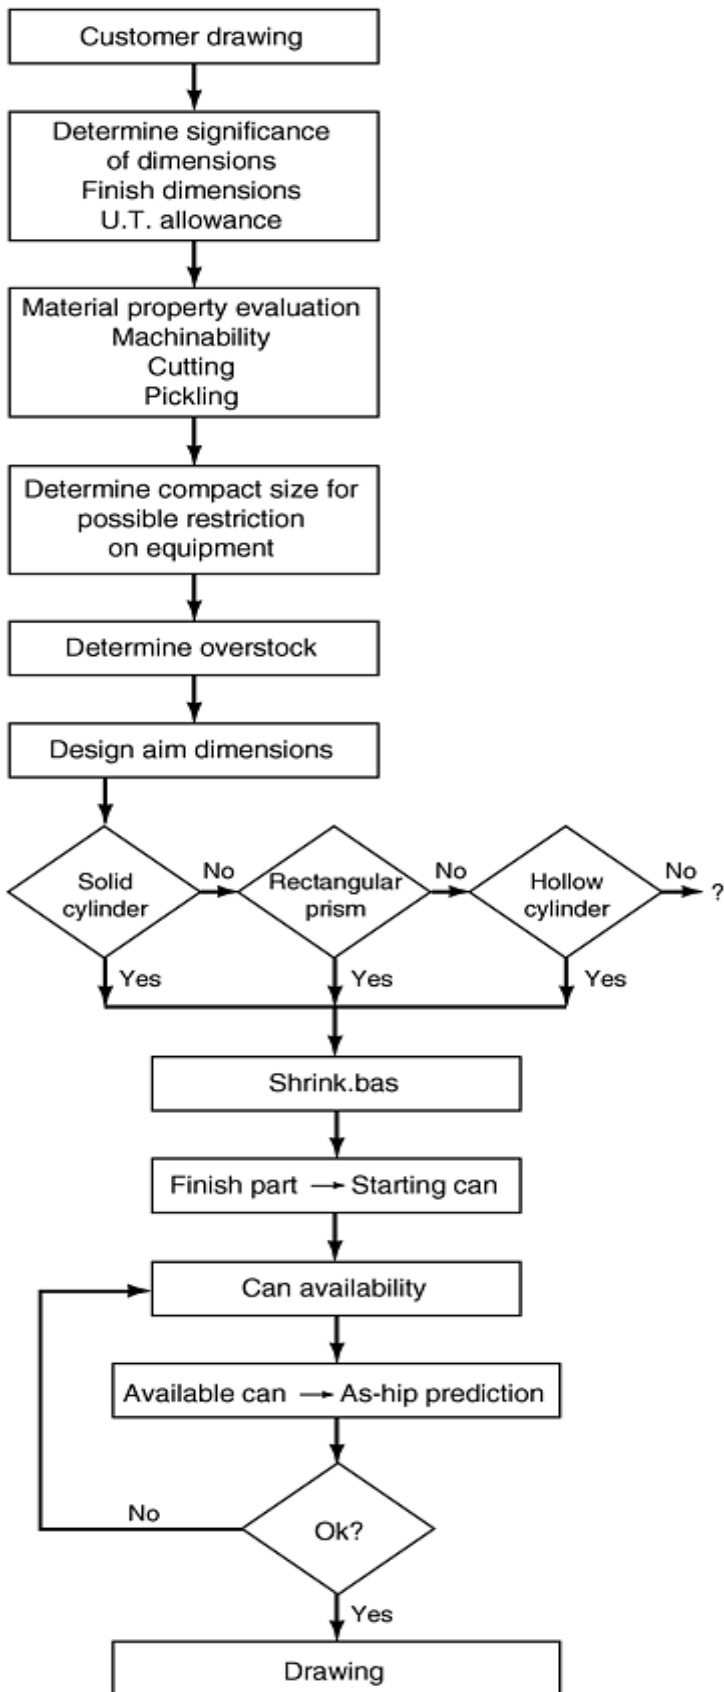

Fig. 11 Crucible design procedure. From Ref 7

This practice has been in use for more than 10 years. Statistical analyses of production data show good repeatability on the same part, but there are some serious limitations to this model as shown by the question mark to the right of the hollow cylinder diamond in Fig. 11. It works well with thin-walled containers and with relatively simple shapes, but

initial attempts to predict how curved surfaces would shrink were incorrect. There are two other known empirical models. The Swedish Institute of Production Engineering described their work (Ref 8) using factors similar to Crucible's, also based on the analysis of production data. The third work is that of Powdermet Sweden which, like Crucible, is in the near-net-shape business. It was reported that they evaluated a finite element model, but are designing containers based on their production experience (Ref 9). A more fundamental understanding of the mechanics of densification and the effect of HIP cycles on shape change beyond the empirical models is needed to get more accurate shape control after HIP on complex parts.

Microscopic Models and Mechanisms

Mechanistic models of the microscopic mechanisms in the HIP process was pioneered by Ashby et al. (Ref 5, 10, 11, 12, 13) in the early 1980s and is based on the interaction among powder particles during the consolidation process. Ashby and his collaborators did most of the early work on this subject and opened up many avenues for further study by later investigators. They divided the entire consolidation process into three stages, based on powder packing and how the porosity is located relative to the powder particles. Stage 0 describes the density reached by the packing of the loose powder. Stage 1 describes the early stages of densification (relative density less than 0.9) when the porosity is still connected. Stage 2 describes the final densification (relative density greater than 0.9) when the residual porosity is in the form of small holes. A schematic of these two stages is shown in Fig. 12.

A particular particle (shaded) contacts a number Z of its neighbors in small contact areas, a .

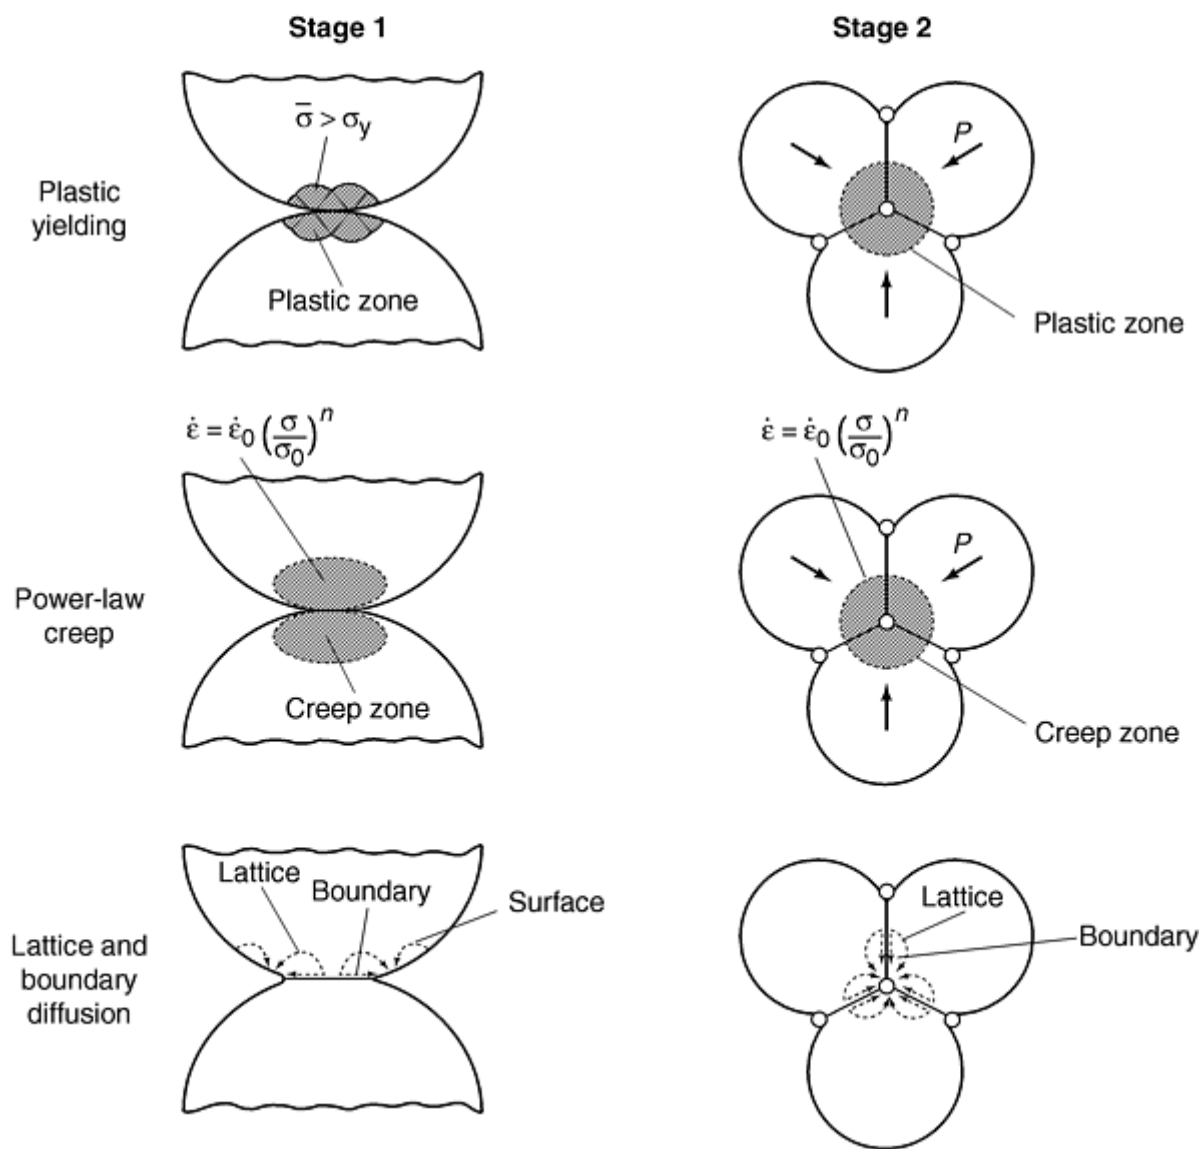

Fig. 12 Ashby stage 1 and stage 2 densification. From Ref 13

Although this work assumes that the powder consists of spherical particles of a single size, other authors have attempted to determine densification rates with spherical particles (Ref 14, 15, 16, 17) of nonuniform size distribution. Ashby recognized that the mechanism of densification depends on the temperature and pressure at any given time in the HIP cycle and derived equations in each stage for plastic yielding, power-law creep, Nabarro-Herring creep, and diffusion. For the complete derivation of all the equations used for each of these mechanisms, see Ref 16. This section presents the final results of this derivation.

Plastic Yielding Densification. Yielding occurs during the initial stage provided the effective pressure, P_{eff} , on the particle is equal to or greater than three times the yield stress of the material. The external pressure that just causes yielding is:

$$P_{\text{lim}} = 3D^2 \frac{D - D_0}{1 - D_0} \sigma_y \quad (\text{Eq 6})$$

Because yielding is a time-independent mechanism, the densification rate will be infinite if the effective pressure is greater than the limiting pressure for yielding. Likewise, the rate will be zero at effective pressures below the limiting pressure for yielding.

Power-Law Creep Densification. Densification also occurs by creep deformation. The constitutive equation for a solid exhibiting power-law creep is:

$$\dot{\epsilon} = \dot{\epsilon}_0 \left(\frac{\sigma}{\sigma_0} \right)^n \quad (\text{Eq 7})$$

σ_0 , and n are material properties; $\dot{\epsilon}$ and σ are the equivalent strain rate and stress, respectively.

In Stage 2, the densification rate becomes:

$$\dot{D} = \frac{3}{2} \left(\frac{\dot{\epsilon}_0}{\sigma_0^n} \right) \frac{D(1-D)}{([1 - (1-D)^{1/n}]^n)} \left(\frac{3}{2n} P \right)^n \quad (\text{Eq 8})$$

Although densification in the latter part of Stage 2 does occur as Nabarro-Herring creep and diffusion, the relative changes in both density and geometry due to these mechanisms are usually small compared to plastic yielding and power-law creep. Equations have been developed for all these mechanisms and can be found in Ref 11 along with the derivations.

HIP Maps. The major use for these equations has been in the construction of HIP maps. These HIP diagrams identify the dominant mechanism that is responsible for densification in a particular temperature/pressure region and can be used as a tool to qualitatively predict densification rates and consolidation times as functions of pressure and temperature. The maps are constructed by evaluating the contribution of each densification mechanism and summing them to give the total densification rate. Like every mechanistic model, the map requires material property data. Data for many materials as well as how to construct and use these HIP maps are available from Ashby's software program, HIP 6.0 (Ref 18). The user manual describes in detail how to construct maps and analyze data from them. The output of this program is in one of three forms: temperature versus relative density, pressure versus relative density, or pressure versus temperature.

A typical HIP map is shown in Fig. 13. It is a density versus temperature map of a tool steel starting with a relative density of 0.69 at a constant pressure of 100 MPa. The three times are 5, 30, and 180 min. The power-law creep exponent used is 7.5, which is the value from Ref 18. Because creep is the dominant mechanism in this consolidation, the densification rate is very sensitive to the power-law creep exponent. If 7.5 is not the correct value for this material an error will occur in the densification rate. Actual experimental data (Ref 19) indicate that full consolidation in large diameter parts takes place at about the rate that is predicted if the exponent is 3.5. This is the first indication that the correct material property parameters may be a major cause for inaccuracies in any HIP model.

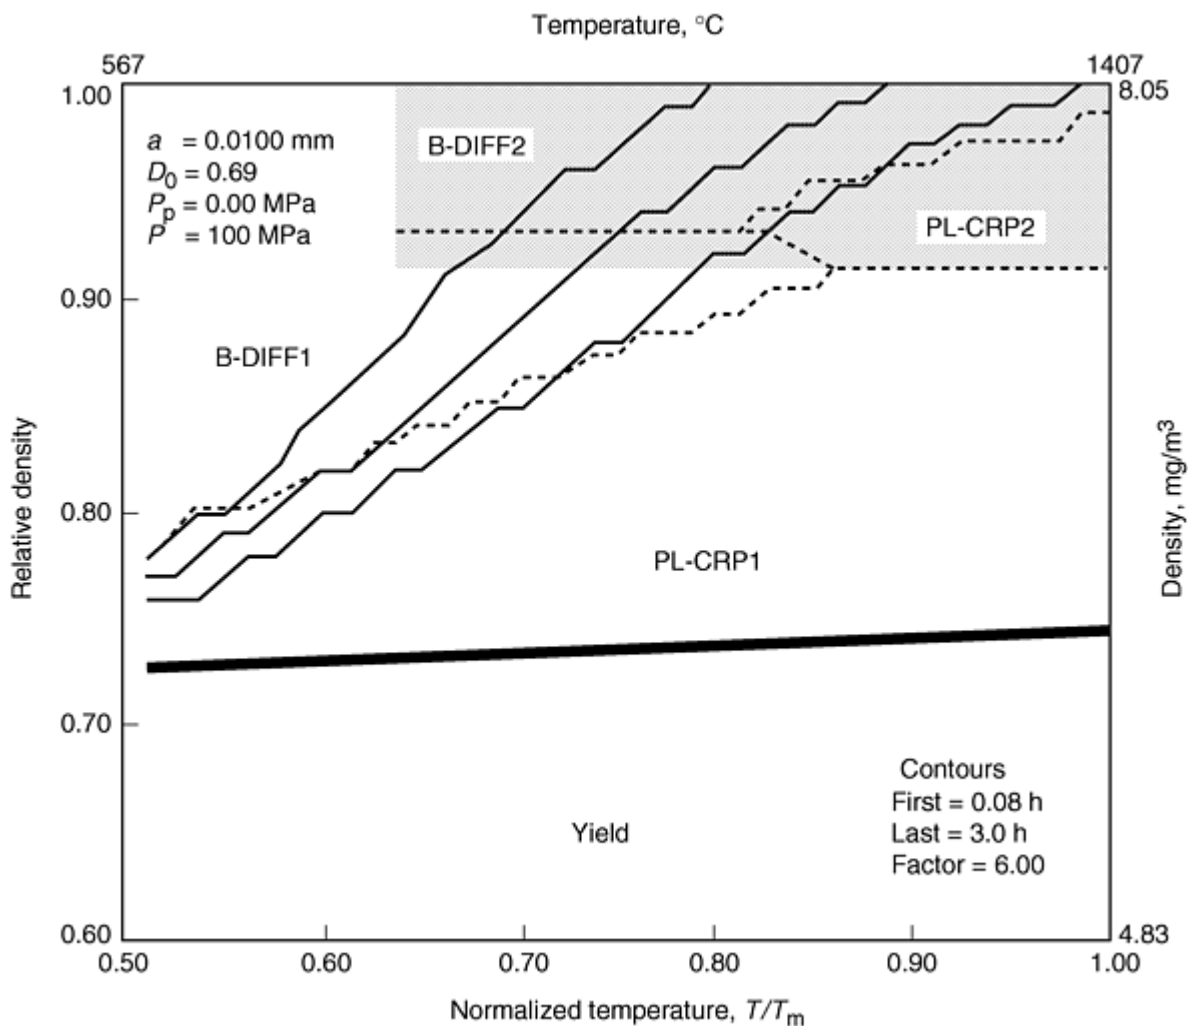

Fig. 13 Tool steel HIP diagram, creep exponent = 7.5. From Ref 18

Two points should be made: (1) although these maps do not provide a quantitative picture of what happens during a cycle, they are very useful in providing qualitative guidelines for densification changes at various times at either a given temperature or pressure, and (2) the dominant mechanism of densification is readily identified. One large advantage of HIP maps is that data can be input and the program run in about 1 min, so a great deal of information can be learned in a short amount of time by the creation of several maps.

Summary. Although the best use of the microscopic model is in qualitative evaluations, it has been used to determine shrinkage and size change during HIP on small cylindrical containers (up to 100 mm long by up to 200 mm in diameter) (Ref 20). This work showed that temperature gradients in the powder during HIP could cause densification fronts that are a major reason for unusual or anisotropic shape change. This same effect was also shown by Aren and Navara (Ref 21) who determined the effect of different geometries on densification. The contributions, significance, and use of the microscopically developed models can be summarized:

- Information about microscopic details of the HIP process enabled mathematical equations to be developed that established the mechanisms of densification in the different temperature/pressure regions of the process.
- Much of this work has provided education for those unfamiliar with the HIP process and has served as a means to qualitatively examine the process on an industrial scale.
- Computer programs for personal computers exist that can help to evaluate the effect that different HIP cycles may have on densification kinetics. These HIP maps have provided a basis for much of the knowledge of how metal powder is consolidated.

- The need to combine heat transfer and densification equations to quantitatively describe the HIP process was recognized.

Macroscopic Models of HIP

Developments Prior to about 1990. The earliest attempts to develop a macroscopic model were the work of Kuhn and Downey (Ref 22) and Green (Ref 23), who proposed a plasticity theory for porous metals. They independently developed yield criteria and stress-strain relationships for these materials. Both of these theories suggest that the yield criterion is a function of the first invariant of stress, J_1 , and the second invariant of the deviatoric stress, J_2 . The relationship is expressed:

$$F = (\alpha J_1^1 + \beta J_2)^{1/2} \quad (\text{Eq 9})$$

where α and β are functions of the relative density. They also defined the stress-strain relationship:

$$d\varepsilon_i = d\lambda(\sigma_i - \phi\sigma_m) \quad (\text{Eq 10})$$

where ϕ is a function of relative density, $d\lambda$ is a nonnegative constant, and σ_m is the hydrostatic stress.

Shima and Oyane (Ref 24) built on this work and rewrote Eq 9 as follows:

$$F = \left[\frac{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 + \sigma_1)^2}{2} + \left(\frac{\sigma_m}{f} \right)^2 \right]^{1/2} \quad (\text{Eq 11})$$

where f represents the degree of influence of the hydrostatic stress component, σ_m , on the onset of yielding of porous bodies and is a function of relative density. Their expression for the yield criterion for porous materials as well as stress-strain relationships is:

$$\sigma_{eq} = \frac{1}{D^m} \left[\frac{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 + \sigma_1)^2}{2} - \left(\frac{\sigma_m}{f} \right)^2 \right]^{1/2} \quad (\text{Eq 12})$$

$$d\varepsilon_i = d\lambda [\sigma_i - (1 - \frac{2}{9}f^2)\sigma_m] \quad (\text{Eq 13})$$

f and m in Eq 12 were determined by simple compression and tension tests and are given by:

$$f = \frac{1}{2.49}(1 - D)^{0.514} \quad (\text{Eq 14})$$

$$m = 2.5 \quad (\text{Eq 15})$$

$$d\lambda = \frac{3}{2} \frac{1}{D^{2m+1}} \frac{d\varepsilon_{eq}}{\sigma_{eq}} \quad (\text{Eq 16})$$

These basic equations were applied to the analysis of closed-die compression, and the calculated pressure-relative density relationships for sintered copper agreed well with experimental results. Although this work did not deal with the HIP process itself, it has served as the basis for virtually all subsequent continuum models. The functions, f and m , in Eq 12 appear in similar forms in work done since this pioneering effort. These functions must be determined experimentally for each particular material.

The work of Shima and Oyane served as the basis for studies done by Soh, Nohara, and Nakagawa (Ref 25) and Nohara, Nakagawa, Soh, and Shinke (Ref 26). These investigators carried out uniaxial compression tests on MERL 76, a nickel-base superalloy and ended up with a comparison between the predicted shape change for an axisymmetric turbine disk and the actual shape change after a HIP cycle, as shown in Fig. 14 and 15. This particular HIP cycle is somewhat unusual because temperature is kept constant for a long time and then raised in a single step. This practice tends to eliminate temperature gradients during the HIP cycle. In most commercial cases, however, temperature and pressure increase together and thermal gradients do exist. How to calculate them and deal with them is a problem that still challenges all researchers who are working on the computer modeling. Work done in Ref 25 and 26 assumed a linear relationship between thermal diffusivity and relative density. This work was sponsored by Kobe Steel and has led to the finite element program, HIPNAS, which has been used in Japan.

Fig. 14 HIP cycle for MERL 76 disk. From Ref 25

Fig. 15 Final shape of MERL 76 disk. From Ref 25

Another important contribution to the understanding of the consolidation process was the work of Abouaf et al. (Ref 27) (early 1980s). This work also recognized that deformation or consolidation involved both plastic flow and time-dependent creep and from this developed a viscoplastic model. The form of Abouaf's constitutive equations are very similar to those of Shima and Oyane, but have an additional creep deformation term. The density-dependent functions were determined with simple compression tests at different temperatures on partially dense materials, while the creep parameters were determined on fully dense material tested at different temperatures. This is a technique that is currently used on most models to determine material properties.

Thermal characteristics were determined experimentally, and their results show an exponential relationship different from the Japanese investigators. Theoretical work of Argento and Bouvard (Ref 28) expressed diffusivity as an exponential function of relative density, but work done in 1997 (Ref 29) on the nickel-base alloy 625 using the laser flash technique confirmed the assumption of the Japanese investigators that the relationship is linear. There is yet no full agreement on how thermal diffusivity correlates with relative density. Because density does change during consolidation, this relationship has an important bearing on any calculation, and the lack of specific agreement on this relation adds to the difficulty of developing an accurate mathematical model.

A comprehensive review by Doraivelu et al. (Ref 30) defined a new yield function for porous bodies. The basis for their work was the large discrepancy between the experimental and theoretical dependence of compressive yield stress on relative density. Again, the yield function is tied in to the first invariant of the stress tensor and the second invariant of the deviatoric stress component. Their yield function is expressed only as a function of relative density:

$$F = \left[(2 + D^2) J_2' + \frac{(1 - D^2)}{3} J_1^2 \right]^{1/2} \quad (\text{Eq 17})$$

This is in a form similar to Eq 9 and 11 and gives yield curves very close to those. This work also summarizes all previously developed expressions for yield curves proposed by several different researchers as shown in Fig. 16. Qualitatively all are similar, but quantitatively there are obvious differences. No HIP simulations came from this work, but three-dimensional yield surfaces were calculated by software developed from this mathematics by Brigham Young University.

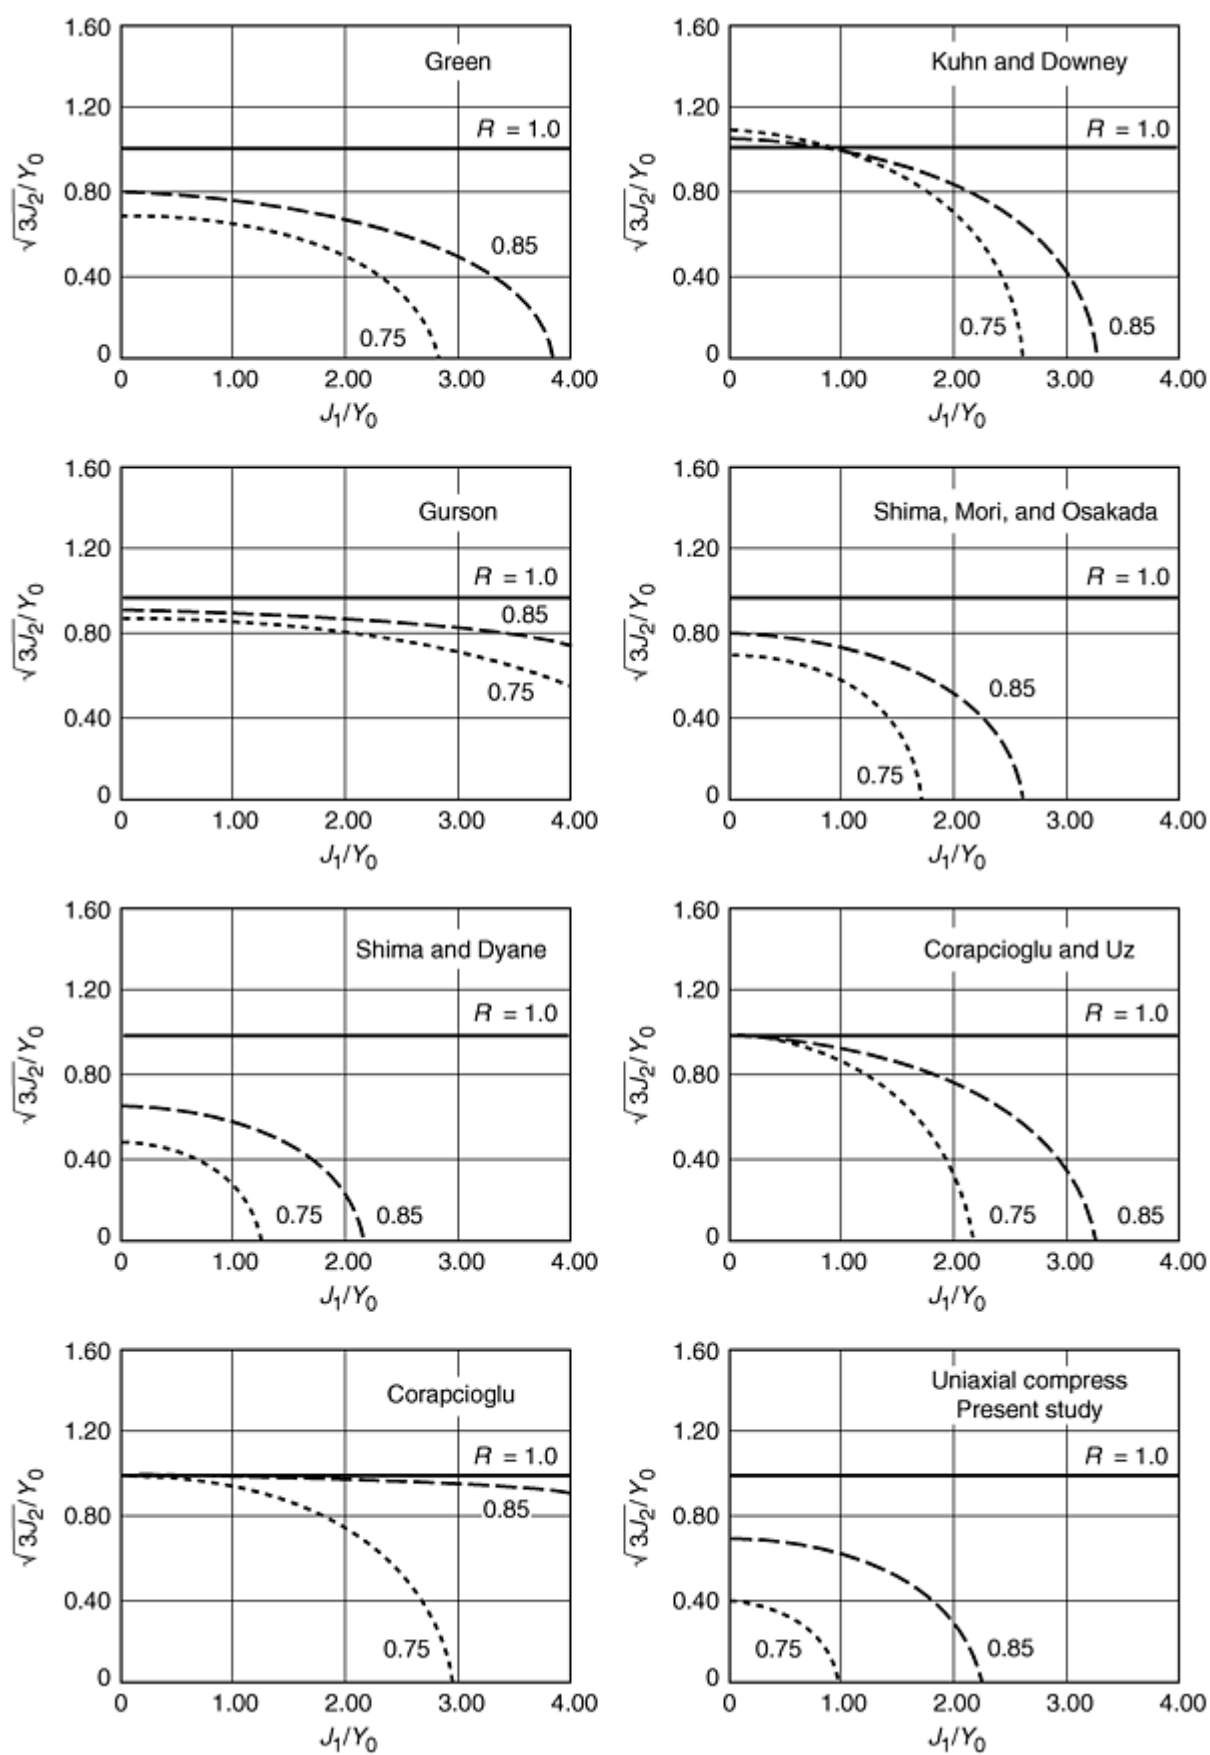

Fig. 16 Yield functions proposed by various researchers. From Ref 30

Current Developments in HIP Modeling. Consolidation mathematics began to be integrated into computer code to create simulation models starting approximately 1990. The status in 1997 can be summarized:

- Constitutive equations based on plasticity and creep deformation have been developed for porous materials. All are of similar form and have functions in them dependent on relative density and material property parameters.
- Because yield strength of both the fully dense and the partially dense material are both functions of temperature as are the creep properties, it is necessary to develop the equations for heat transfer during the densification process so that the mathematical descriptions for deformation (consolidation) and heat transfer can be coupled into a single finite element code.
- Commercial models have been confined to relatively simple shapes, and insufficient data have been presented to show the quantitative relationship between the predicted and actual dimensions on any hardware to know whether any of the models are quantitatively accurate.

The utility of a model should be defined in terms of its capability to predict actual size and shape change during HIP, so that under perfect conditions using the model will eliminate the need for production trials. Work that is either a continuation of that already described or from new sources has recognized this. While there have been efforts from other investigators, specific attention will be paid to the results from four groups, because these are closest to realizing the goal. These four groups are LNT in Russia, CEA/CEREM in France, and MATSYS and CTC in the United States. LNT's model is plastic, while the other three employ a viscoplastic model. Each of these models are briefly described.

From a practical engineering and design approach, however, each of the HIP models suffers from lack of validation for any but the simplest of parts. The true test of the accuracy of any model can only be done on a relatively large and complex production part with curved surfaces and different cross sections. If any of these models is to gain the confidence of the production facility that wants to use it, additional validation experiments must be run. Moreover, the expected precision of size change predictions must be quantitatively defined if parts producers are to rely absolutely on the results predicted by the simulation alone. To make complex parts, either net or near-net shape, the designer must produce a prototype as a first iteration and then use the analysis of the results of that trial to make production hardware. Current HIP models for design systems can only work when some trial part is an integral part of the manufacturing process because the simulations are just not accurate enough to do the job alone.

LNT Model of HIP. Computer simulation of HIP started at the All Russia Institute of Light Alloys (VILS), which is now at the Laboratory of New Technology (LNT) in Moscow. Their work (Ref 31, 32, 33, 34) was initially tied into the use of superalloy powder for as-HIP near-net-shape parts. The objective is to shorten the time it takes to manufacture a complex part from powder, and its model uses plastic yield criteria only. However, LNT research recognizes the existence of errors in both the mathematics of the constitutive equations as well as in the determination of material property parameters that are used in the model. Because of these errors, researchers believe the results of a simulation alone cannot be used directly in the manufacture of hardware. Their yield criterion is:

$$\frac{\theta_2}{f_1^2} + \frac{\sigma_{av}^2}{f_2^2} + \tau_s^2 \quad (\text{Eq 18})$$

where f_1 and f_2 are functions of density, σ_{av} is the average stress, τ_s is the shear stress, and θ is the temperature.

The LNT methodology is to determine yield curves and apply them to the manufacture of actual parts (Fig. 17). Temperature and pressure are raised together in a HIP cycle, and samples, S_1, S_2, \dots, S_n , are obtained by interrupting the cycle. Relative densities of each sample are checked, and the compressive yield strength of each is determined. This gives the yield strength of the material at different densities at a specific temperature and gives yield strength as a function of relative density because subsequent HIP cycles have the same temperature, pressure, and time relationship as the test cycle. Their method assumes that the relative density in the simulation will change at the same rate as the samples used to measure yield strength. Temperature gradients do not exist. The variables f_1 and f_2 and the yield strength values are calculated and are implemented into a finite element code to simulate shrinkage. The next step is to design a capsule (container) and make a demonstrator part and compare the final actual geometry with that of the simulation. Because errors are expected, the model is then "fine-tuned" until the simulation accurately fits the dimensions of the demonstrator part. Finally, the model is used to determine the starting geometry for a production part. This is a practical engineering

approach to a complicated problem, and LNT researchers use modeling in combination with the manufacture of a prototype part. Figure 18, which shows their flowchart for container design, divides the entire problem into four subproblems: modeling (simulation), parametric identification, capsule design, and stochastic analysis.

Fig. 17 LNT HIP cycle for calibration. From Ref 18

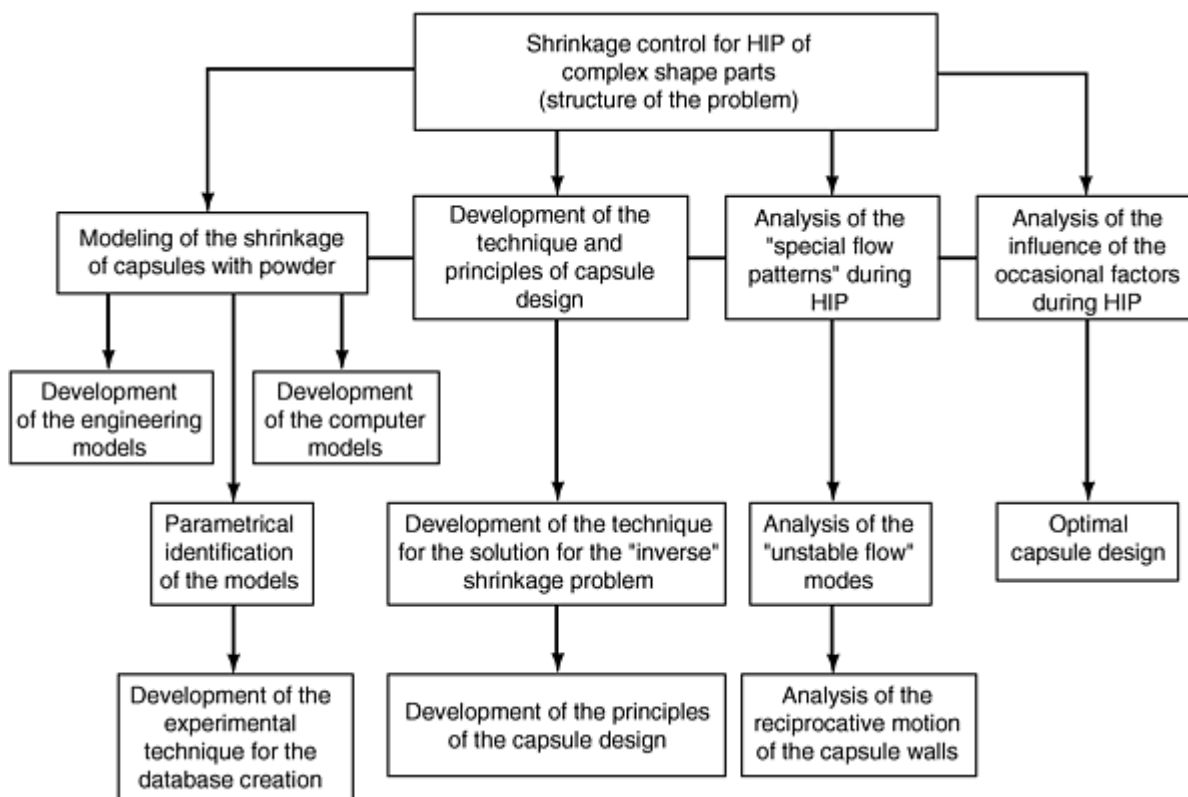

Fig. 18 LNT flowchart for container design. From Ref 32

MATSYS Model of HIP. A second commercial finite element model of HIP was started under an Intelligent Processing of Materials initiative funded by ARPA. The HIP modeling was carried out by BDM (now MATSYS) and this viscoplastic model has been described in detail elsewhere (Ref 35, 36, 37). This work recognizes the different stages of consolidation as interpreted by Ashby and shown in Fig. 12, but defines them in terms of the relative density in each stage rather than in the geometry of the pores between powder particles:

- *Stage 1*: relative density is less than or equal to 0.75.
- *Stage 2*: relative density is greater than 0.90.
- *Transition region*: relative density is between 0.75 and 0.90.

Using these three ranges, they define yield curves in stage 1 based on the work of Fleck, Kuhn, and McMeeking (Ref 37) and in stage 2 based on the work of Gurson (Ref 38). In the transition region where relative density is between 0.75 and 0.90, they introduced a new concept, a yield function that is a weighted average of the two functions and dependent on the relative density at any given time:

$$F = \frac{D_2 - D}{D_2 - D_1} F_1 + \frac{D - D_1}{D_2 - D_1} F_2 = 0 \quad (\text{Eq 19})$$

where F_1 is the yield criterion in stage 1, and F_2 is the yield criterion in stage 2.

Constitutive equations were also developed for deformation due to power-law creep in stage 1 and stage 2 with the transition region handled as in Eq 19. The models were implemented by determining the densification due to these two mechanisms, summing them, and calculating the size change that resulted. A third mechanism, diffusional creep has been added to their calculation for densification change. The determination of which mechanisms are active during densification is tied into the experimental method for calculation of material property parameters.

This method is quite different from that used by other model developers and is based on actual densification rates as experimentally determined using eddy-current sensors first described by Kahn, Mester, and Wadley (Ref 39). By measuring in real time the impedance of a small cylinder filled with powder during a HIP cycle and measuring density after the run, these two variables can be correlated so that the signal from the eddy-current sensor during a subsequent HIP cycle gives a dynamic measurement of actual density. Material property parameters in the densification equations are determined by initially estimating them in the densification change equations and comparing the calculated density changes with the actual density changes of the small samples. Nonlinear optimization techniques are then used to match the output of the model with the actual density changes. The end result of this match gives accurate determinations of the material parameters. Figure 19 is a plot of the actual sensor data superimposed over the creep densification mechanism densification rate for γ -titanium aluminide. There is an excellent fit between the two up to a relative density of about 0.90, but above that there is an obvious mismatch between the two curves, indicating that power-law creep is not the only densification mechanism. Figure 20 corrects this mismatch by using diffusional creep above a relative density of 0.90 to get a much better fit.

Fig. 19 BDM calculated versus sensor shrinkage for TiAl. Estimation of γ -TiAl properties. Power-law creep is the active densification mechanism during stage 1.

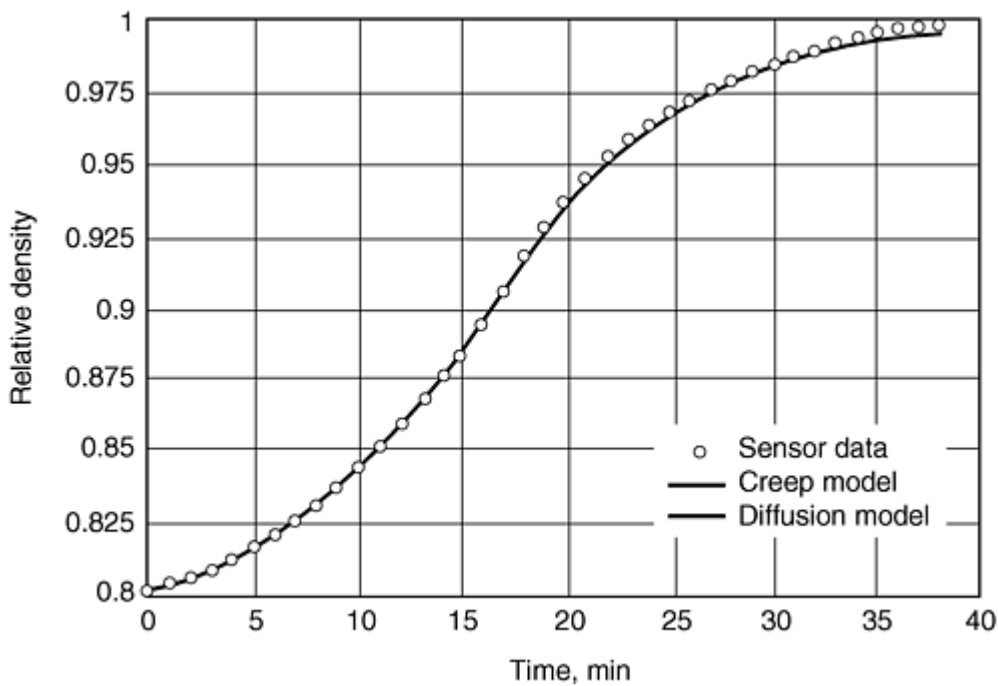

Fig. 20 BDM calculated versus sensor shrinkage for TiAl. Estimation of γ -TiAl properties. Power-law creep is active during stage 1. Diffusion is active during stage 2.

CTC Model of HIP. A third model, developed by Concurrent Technologies Corporation (CTC), is the offshoot of work started by Trasorras et al. (Ref 40) at Carnegie Mellon University. The specific goal of this U.S. Navy sponsored program at CTC is to develop a program that can accurately predict the final dimensions of a hot isostatically pressed component. Trasorras defined two different deformation processes: deformation of the powder aggregate idealized as a continuum and deformation of the individual particles. His model accounts for the plastic deformation of the powder aggregate as a

whole, the stress response of the powder aggregate, heat transfer properties of the powder aggregate, and evolution of the matrix material state. This work uses both plastic yield and power-law creep as densification mechanisms and is thus another viscoplastic model. Most of the experimental work on this model has been done with commercially pure titanium (Ref 41, 42, 43, 44). Trials using the CTC computer model shows it can be used in place of actual production trials (Ref 44). The trial was with a titanium part. The first trial of the model matched the actual production part in qualitative terms, but it did not meet the desired shape. The starting container shape was changed to determine what initial shape would produce the finish customer dimension. On the third computer trial, the simulated container produced the desired finished part shape. This system has been upgraded to coordinate solid modeling with mesh generation and finite element analysis. The methodology is similar to that of LNT with the only difference being the use of an actual part by CTC as opposed to a demonstrator part by LNT to "fine-tune" the model.

CEA/CEREM Model of HIP. Work by CEA/CEREM in Grenoble, France, is based on the Abouaf viscoplastic model. In this work (Ref 45, 46) an equivalent stress is defined as:

$$\sigma_{\text{eq}} = \left[fJ_1^2 + \frac{3}{2} bJ_2^2 \right]^{1/2} \quad (\text{Eq 20})$$

This form is similar to Eq 12, where f and b are functions of the relative density, D , and are material dependent. When the relative density equals 1, $f(1) = 0$ and $b(1) = 1$, this satisfies the von Mises criterion for incompressibility of a fully dense material. The equivalent stress and strain rate are also related through the creep law:

$$\dot{D} = A \exp\left(-\frac{Q}{R_0\theta}\right) \sigma_{\text{eq}}^n \quad (\text{Eq 21})$$

The values of A and n are calculated using fully dense samples, while f and b are determined with porous samples with relative densities ranging from 0.77 to 1.0. Experimental work with T316LN powder was done to determine these functions (Ref 47, 48).

These investigators also have proposed a function in which thermal conductivity is an exponential function of relative density:

$$k_D = k \left(\frac{D - D_0}{1 - D_0} \right)^{1.46(1 - D_0)} \quad (\text{Eq 22})$$

where k is thermal conductivity. The results of this work have been incorporated into a multi-materials finite element modeling code, PRECAD/M, that allows the simulation of HIP of axisymmetric and three-dimensional parts. The finite element software was taken from a commercial package and modified by CEA/CEREM specifically to handle the problem of dimensional change during HIP. Data were presented to show the comparison between initial and deformed geometry in a part made with Ti-6Al-4V powder with a solid core (Ref 46).

Validation tests of the different models by different collaborators have also been run for actual HIP cycles on production type parts, where beginning and final dimensions are reported so that the precision of the model can be evaluated (Ref 49, 50, 51). This work was done with 316L stainless steel powder from a single source so that the variable of powder type and size is kept constant. Simulation results were reported by three investigators in a 1997 workshop with the following conclusions:

- Jeon and Kim (Ref 49) using the models of Abouaf and McMeeking concluded that it is not feasible to produce near-net shape parts under HIP when the part has an asymmetric shape.
- Eisen, Bouaziz, and Dellis (Ref 50) compared the prediction of the Crucible empirical model and the CEA/CEREM two-dimensional model using two different HIP cycles (one with a very rapid heat up and pressurization, the other with a slower ramp up for temperature and pressure) with the actual results. They found that the predictions of both models were qualitatively but not quantitatively accurate and

that either model could be used for near-net-shape prediction. Errors (ratio of simulated final value minus measured final value to initial value minus measured final value) on the three major dimensions ranged from 4 to 32% for the Crucible model and from 7 to 42% for the CEA/CEREM model. They also showed that the isotropic predictions using Eq 5 gave an accuracy very close to actual results. On this basis, they hypothesized that in small parts and even in large parts that are heated slowly enough to minimize temperature gradients, isotropic shrinkage can be used as a first approximation.

- Dellis, Bouaziz, Baccino, and Moret (Ref 51) used a three-dimensional simulation on this same part and compared it to the actual shrinkage. Their error on the three main dimensions ranged between 1 and 10%, which is a significant improvement over the two-dimensional and empirical model. This three-dimensional model required a fine-mesh grid and took 72 h of central processing unit time compared with 4 h for the two-dimensional simulation.

It is also possible, however, that current models may not be accurate because the mathematics do not describe what is actually happening during the consolidation process. Work of DeLo and Piehler (Ref 52) using thin-walled containers holding Ti-6Al-4V powder that was hot isostatically pressed consolidated concluded that the vast majority of densification and shape change occurs early in the HIP cycle before steady state-temperature and pressure are achieved. They attributed particle motion as the reason for an underestimation of densification. It has also been suggested that because temperature and pressure are increased together in most HIP cycles, power-law creep may be the predominant mechanism during consolidation and that the plastic yielding contribution could be ignored. A model using power-law creep as the sole densification mechanism might work as well as any viscoplastic model.

Hot Isostatic Pressing of Metal Powders

J.J. Conway and F.J. Rizzo, Crucible Compaction Metals

Introduction

HOT ISOSTATIC PRESSING (HIP) is a process involving the use of high-pressure gas isostatically applied to a part or workpiece at an elevated temperature performed in a specially constructed pressure vessel. When consolidating metal powders in pressure-tight, sealed compacts, the HIP process plastically deforms the powder, which closes up porosity and achieves 100% theoretical density in the part. Thousands of fully dense HIP P/M compacts (equivalent to >10,000 tons) are commercially produced each year. This includes net shapes, near-net shapes, and a variety of mill forms for subsequent thermomechanical processing. Monolithic and bimetallic or clad parts are part of the near-net shapes that are supplied in many different conditions such as: HIP, HIP plus heat treated, HIP plus thermomechanically processed, and so forth. The majority of individual parts are made as near-net shapes. Other parts are made as net shapes, or with some net surfaces and other surfaces that need finishing to match mating parts or to meet some other critical parameters. The elevated temperature in HIP ranges from approximately 480 °C (896 °F) for aluminum alloy powders to 1700 °C (3092 °F) for tungsten powders. Most of the commercial HIP activity is with steel and nickel alloys, which are commonly hot isostatically pressed between 1100 °C (2012 °F) and 1205 °C (2201 °F). High-density argon gas is the most common pressure medium used in the process, although other gases such as helium or nitrogen can also be used. Pressures ranging from 20 to 300 MPa (3 to 45 ksi) are possible with 100 MPa (15 ksi) being the most common.

The HIP process was invented at Battelle Memorial Institute in 1955 as a method to diffusion bond dissimilar materials where Zircaloy was clad to uranium oxide nuclear fuel elements (Ref 1, 2). As the technology evolved, applications other than diffusion bonding were discovered, namely consolidating encapsulated powder, porosity healing inside castings, and densification of presintered components. In the 1960s, HIP technology (sometimes referred to as gas pressure forging) was used to consolidate beryllium metal powder, refractory metal powder, ceramic powder, and cemented carbides. Not until the 1970s, however, did the HIP process expand to an industrial scale. For example, high-volume hot isostatic compaction of high-speed tool steel was achieved in the United States (Ref 3) and Sweden by 1972. By the late 1970s, the United States Air Force Materials Laboratories funded work to develop HIP technology to manufacture titanium and superalloy components for aircraft engines. This application currently represents the highest technology level of the process. Powder metallurgy tool steels represent the highest production tonnage.

Some of the current applications of HIP P/M parts include:

- *Tool steel billets* (for mill processing) for hot and cold working tools and dies
- *Nickel and titanium alloys* for high-temperature components on aircraft and marine gas turbine systems
- *Nickel alloys* in the oil and gas and petrochemical industries for corrosion-resistant components on wellheads and piping systems
- *Nickel alloys* in the nuclear power industry for corrosion-resistant components in reactors
- *Titanium and cobalt alloys* in the biomedical industry for prosthetic implants
- *Refractory metal alloys* for high-temperature service
- *Cemented carbides* for superior wear-resistant parts
- *Composite aluminum materials* for lightweight structural components

Although HIP technology is commonly used for sealing porosity in castings and P/M sintered compacts, this article focuses on the consolidation of metal powder and the diffusion bonding of dissimilar materials.

Hot Isostatic Pressing of Metal Powders

J.J. Conway and F.J. Rizzo, Crucible Compaction Metals

Process Selection

During the design phase of a particular component, the end user must select a material and process that will best suit the requirements of the application given the constraints of economics, availability, and time. There are several different processing routes available to designers, among them are ingot metallurgy (I/M) and powder metallurgy (P/M).

Ingot metallurgy processing involves casting molten metal into molds, solidifying at relatively slow cooling rates (0.1 °C/s), and subsequently converting to the final product form by thermomechanical processing. The as-cast ingot exhibits chemical compositional variations, porosity, and a nonuniform microstructure containing equiaxed and columnar grains. Postcasting processing (e.g., heat treatment, thermomechanical processing, etc.) helps to homogenize the materials and somewhat ameliorate these anomalies. However, in some cases, conventional ingot metallurgy restricts the material from attaining its fullest potential in terms of properties.

The P/M processing route enables materials to achieve higher alloyed compositions without encountering segregation. Once fully densified by HIP, the P/M material has a fine grain size with an equiaxed microstructure. This uniform microstructure with a consistent composition leads to isotropic mechanical and physical properties. Not only do the properties have less variation than those properties found in I/M products, but the mechanical properties are often enhanced due to the fine grain size and the fine dispersion of precipitates available for strengthening. Better properties extend product life cycles or allow lesser grade materials to be used in more stringent applications. In addition, machinability is enhanced due to the uniformity and fine microstructure of P/M materials.

One example where the P/M route was selected over ingot metallurgy is René 95, which initially started as a cast-and-wrought (C/W) nickel-base superalloy in 1972. This highly alloyed material used for rotating disks in jet engines is prone to microsegregation, which during forging (even under careful controls) ultimately causes severe cracking and an undesirable microstructure (Ref 4). Later, the process was modified to use HIP P/M (Ref 5) and more than 100,000 of these parts are in aerospace service today.

Another example of the beneficial use of P/M versus I/M is in highly alloyed tool steels (Ref 6, 7). Through the years, producers of these materials have increased the content of carbide-forming elements such as molybdenum, tungsten, and vanadium to achieve increased wear resistance. Increasing alloying additions has led to increased segregation, which has resulted in lower product yields and lack of toughness. Due to the fine nature of the carbides in the P/M product and their high volume fraction, the wear resistance and toughness are greatly improved over I/M-produced tool steels.

HIP versus Other Powder Metallurgy Methods. Once powder metallurgy is established as the preferred processing route, other factors influence proper selection of a compaction process, namely:

- Properties required to meet component service requirements
- Size, shape, thickness, and complexity of the part

- Tolerances and surface finish requirements
- Cost, availability, and lead time

Because mechanical performance improves with increasing density (Fig. 1) (Ref 8), applications requiring maximum properties generally employ HIP for larger-sized parts instead of pressing and sintering (Fig. 2). By utilizing the combination of high temperature and pressure, HIP can achieve a particular density at lower pressure when compared to cold isostatic pressing (CIP) or at lower temperature versus sintering. In addition to the processes described in Fig. 2, there are processes other than HIP that can be employed to achieve near-full or full density, each with their inherent advantages and disadvantages. Cold isostatic pressing combined with some subsequent thermal process (e.g., sintering, HIP, extrusion, etc.) can provide full density for most materials. The CIP approach can be used when it is metallurgically advantageous to begin densification prior to exposure to elevated temperature. Pressure-assisted sintering (PAS) involves the simultaneous application of pressure and heat to a powder mass typically created by hot pressing and pressurized sintering. Sinter plus HIP (containerless HIP) involves sintering a partially dense compact produced by die compaction or CIP and applying heat to sinter in an autoclave with subsequent pressure for the HIP phase. Sinter plus HIP has been used for tungsten carbide, silicon carbide, and silicon nitride for high-performance applications. Consolidation by atmospheric pressure (CAP) involves applying heat to a glass-enclosed, vacuum-tight compact to consolidate powder that has been chemically treated with a sintering activation agent. Rapid omnidirectional compaction (ROC), or fluid-die process, involves using a conventional forging press and a pot die to compact powder in a cavity of usually a thick-walled shaped "fluid" container. The Ceracon process (CERAmic CONsolidation) involves taking a heated preform and consolidating the material by pressure against a granular ceramic medium using a conventional forging press. Consolidation of metal powders via extrusion can be performed by using either a blocker die or extruding loose powder to full density (see the article "Extrusion of Metal Powders" in this Volume).

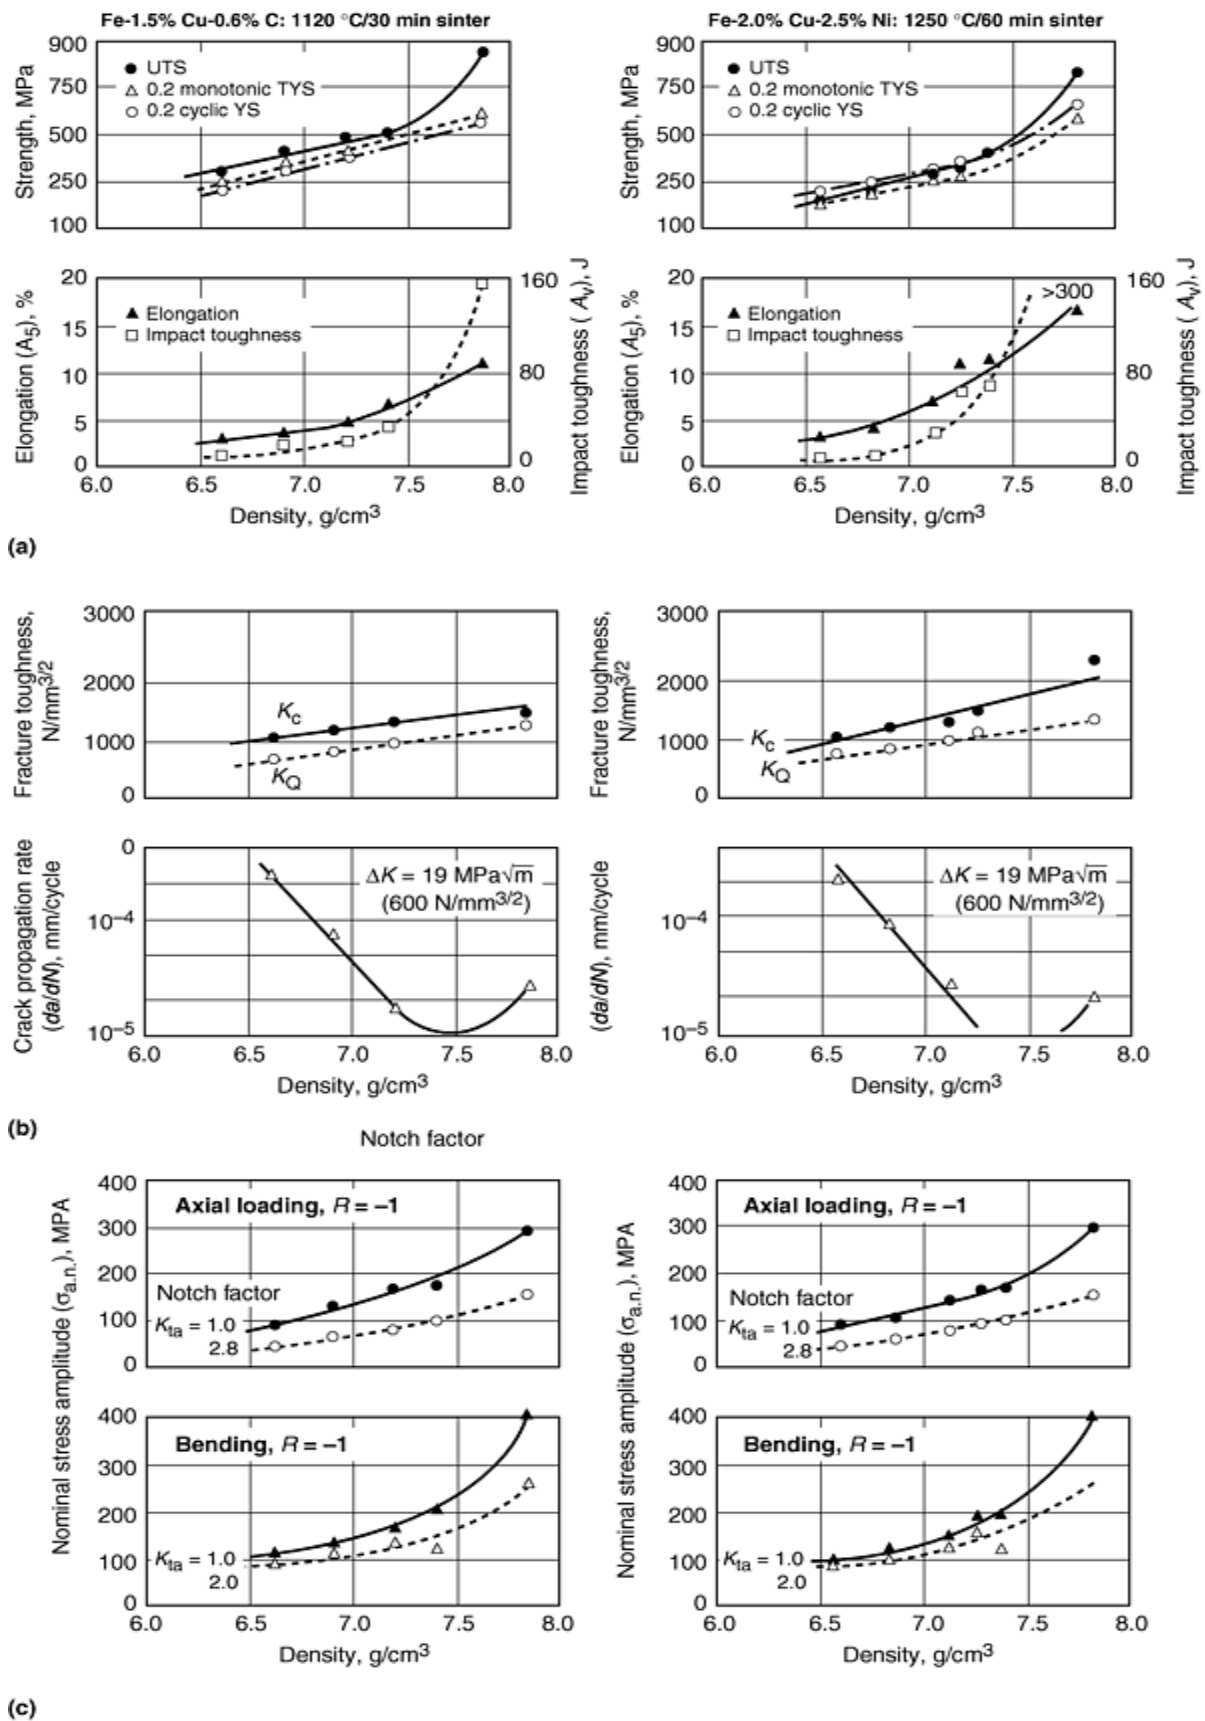

Fig. 1 Effect of density on mechanical properties of two P/M steels (Fe-1.5%Cu-0.6%C and Fe-2.0%Cu-2.5%Ni). (a) Strength, elongation, and impact toughness. (b) Fracture mechanical properties. (c) Nominal stress amplitude for 50% fatigue failure at 2×10^6 cycles. UTS, ultimate tensile strength; TYS, tensile yield strength; YS, yield strength. Source: Ref 8

Fig. 2 Three variables that dictate the P/M approach are size, density, and performance (as a percentage of wrought). This behavior corresponds to ferrous-base P/M systems, but is representative of many P/M materials. P/S, press and sinter; reP, press, sinter and repress; P/S + F, press and sinter and forge; CIP + S, cold isostatically press and sinter; HIP, hot isostatic press; HIP + F, hot isostatic press plus forge. Source: Ref 9

Although these processes show promise, each has limitations. Some do not achieve full density (e.g. CIP and PAS). Others require subsequent processing (e.g., CIP and CAP), while others have not been scaled to production levels (e.g., Ceracon, ROC, and CAP). The HIP process is currently the most commercially viable method to produce fully dense P/M material. In excess of 10,000 tons of HIP P/M material is produced annually, far exceeding all of the other techniques.

When end users select the HIP P/M processing route to manufacture their parts, it is typically due to the following characteristics, which are desired for the final application:

- Full density of highly alloyed materials that usually cannot be produced by I/M processing
- Near-net-shapemaking capability
- Fine grain size
- Isotropic physical and mechanical properties
- Improved mechanical properties
- Extended life cycle
- Cost-effective components
- A range of possible part sizes from 1 to >10,000 lb
- Combinations of the above

Although cost of HIP P/M parts are often higher than the competing I/M or press-and-sinter P/M produced parts, HIP P/M can be an affordable method to increase part performance, reduce equipment weight (e.g., stronger material therefore thinner cross sections, etc.), maximize material usage by producing near-net shapes, or realize cost savings by increasing life cycles, eliminating downtime, and reducing maintenance and replacement costs. In general, the main cost elements for the HIP P/M process are the prealloyed, gas-atomized powder, the container (and container tooling if needed), HIP vessel efficiency (e.g., maximizing the number of parts during a single HIP run of the autoclave, Fig. 3), and postconsolidation processing. The combined considerations for customer requirements and the process cost elements determine if HIP P/M processing can be used for a given application. To properly assess each application, the end user should make a comparison with other production processes such as casting and forging. This should involve a total engineering evaluation that includes acquisition cost, finish part manufacturing cost, and component life-cycle cost.

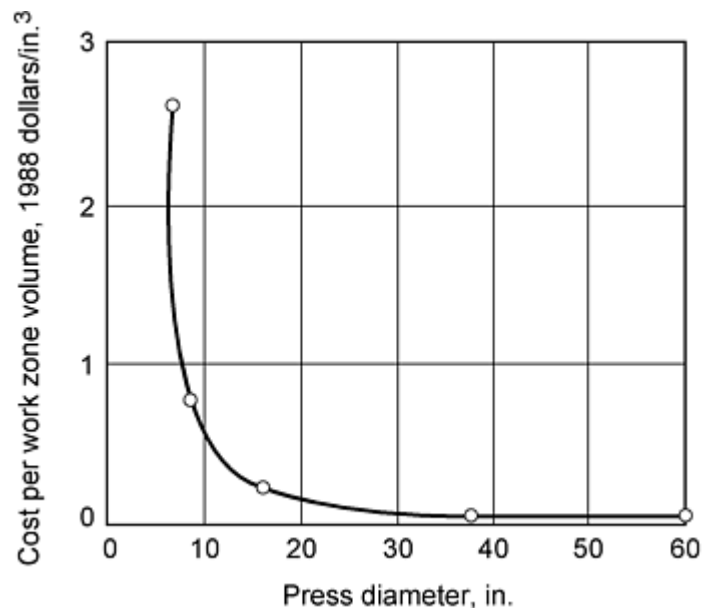

Fig. 3 HIP processing cost as a function of press size. The cost per unit work-zone volume to run a HIP cycle depends on the size of the HIP unit. Increasing the diameter of the work zone reduces the cost, but above 0.8 to 1 m diameter, further gains are small. Still larger HIP units are built to handle specific products. Source: Ref 10

Hot Isostatic Pressing of Metal Powders

J.J. Conway and F.J. Rizzo, Crucible Compaction Metals

HIP Technology

Whether it is consolidating powder in an encapsulated compact, bonding two surfaces together, or healing a casting or sintered compact, HIP is a process to remove porosity. The following describes the mechanisms and stages of pore closure for metal powders and HIP diffusion bonding of two surfaces.

Consolidation of Encapsulated Powder. As will be described in more detail later, powder particles are randomly packed inside a container that encapsulates the powder during the HIP process. Powder used for HIP is typically spherical with a broad particle size distribution. This is better for achieving high packing density when compared to irregularly shaped particles and/or monosized particles. With monosized particles or powder with narrow particle size distributions, there are no small particles to fill the interstices, thus decreasing packing density. However, even with the ideal size distribution, there will always be some percentage of void space due to the spherical morphology (Fig. 4) of the powder and possibly the presence of hollow particles (Fig. 5) that may have formed during the powder-making process.

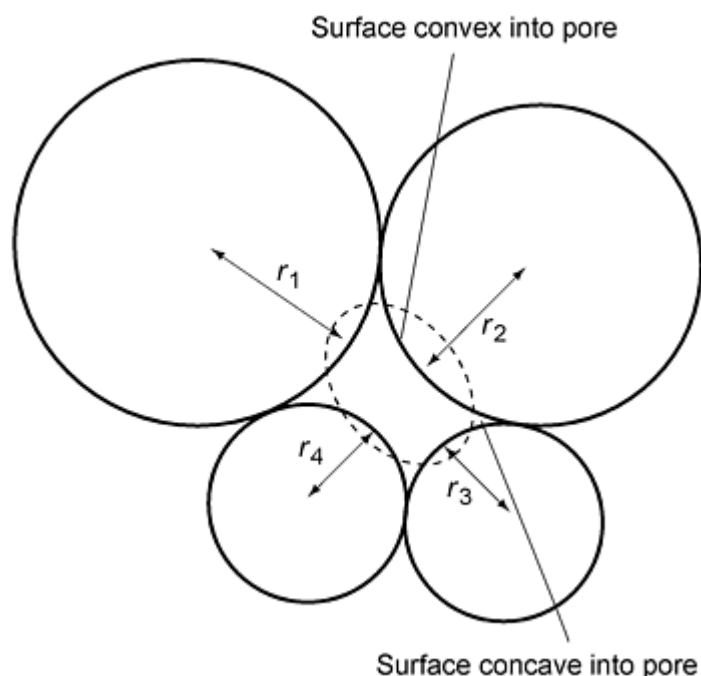

Fig. 4 Pore with varying radii of curvature around the surface. The broken curve shows the pore surface after some spheroidization has taken place by redistribution of material from convex surfaces to concave. Source: Ref 1

Fig. 5 Pores in -80 mesh Astroloy powder particles produced by argon gas atomization. Courtesy of Industrial Materials Technology, Inc.

To describe the consolidation of metal powders and thus the removal of pores, it is generally believed that the HIP process is similar to sintering where three physical mechanisms (Ref 11) are present, namely:

- Powder consolidation
- Neck growth

- Final densification

Powder in compacts prior to HIP is packed at a relatively low density (e.g., 60 to 80% of theoretical density). During the powder consolidation phase, powder is considered a cohesionless granular material where particles can slide freely without particle deformation. Particle rearrangement occurs, and some macroscopic deformation is observed. Once a particular density is attained and particle rearrangement discontinues, necks grow at the contacts between particles. At this stage, particles are beginning to bond, but the porosity is still interconnected. Various mechanisms describe this phenomenon as follows:

- Plastic deformation of the particles by dislocation
- Power-law creep or dislocation creep
- Nabarro-Herring creep or volume diffusional creep
- Coble creep or grain boundary diffusion creep

During final densification, the material may be considered a solid containing isolated pores connected by grain boundaries. The mechanisms controlling the final densification stage is the same as those controlling neck growth (Ref 11). A more detailed description of the mathematics is given in the article "Principles and Process Modeling of Higher-Density Consolidation" in this Volume and elsewhere (Ref 11, 12, 13, 14).

Interface/Diffusion Bonding. Hot isostatic pressing technology was initially developed as a method to diffusion bond two dissimilar materials. Unlike fusion methods (e.g., welding, brazing, etc.), diffusion bonding depends on atomic transport across two mating surfaces to remove bond line pores. Fusion processes involve melting, which can cause segregation or solidification cracking. Unlike consolidation of a powder compact, components undergoing HIP diffusion bonding deform very little macroscopically. However, microscopically there is localized plastic flow across the bondline with the size of the initial pore being a function of the surface roughness (Fig. 6). Depending on the mismatch in physical and mechanical properties of the two materials, pores at the interface will spheroidize due to surface energy considerations. Afterward, previously described mechanisms take over until final densification is reached (Ref 1).

Hot Isostatic Pressing of Metal Powders

J.J. Conway and F.J. Rizzo, Crucible Compaction Metals

Process Description

The interaction of the HIP process and equipment must be understood to help explain the technology. There are two basic types of autoclave used for HIP. The first is known as a hot-loading cold-wall vessel where the parts to be densified are heated to the HIP temperature external to the high-pressure chamber. The second type is known as a cold-loading cold-wall vessel where the parts and furnace enter the high-pressure chamber at room temperature and are sealed in place. The heating and pressurizing of the parts and the vessel are then done according to a preprogrammed set of parameters.

A typical HIP cycle for a hot-loading cold-wall HIP unit is as follows:

1. The powder-filled compacts would be placed on fixturing designed to hold the load at elevated temperatures. Some compacts can be self- fixtured by attaching a lifting device to the container.
2. The compacts and fixtures are placed into a furnace and heated to the desired temperature at a controlled rate or progress through a series of preheat and high-temperature furnaces to a hold point. Because the thermal conductivity of loose powder is much less than that of fully dense material, long hold times are necessary to ensure the entire cross section of the largest compact in the load is thoroughly heated and ready for HIP.
3. Once heated, the compacts and fixture are lifted from the furnace and placed into the pressurizing vessel. The load may be protected with insulating material during the transfer to prevent cooling prior to placement in the HIP unit.
4. The lid is placed on the vessel and sealed.
5. A pressure valve is opened, and gas at high pressure is released from a reservoir into the densifying chamber until there is equalization in both tanks. The vessel is held at these conditions for a set period of time, which is usually short, and thus lends itself to high production rates.
6. The gas is pumped from the densification chamber back into the storage reservoir, and the connecting valve is closed.
7. The lid is removed from the HIP chamber, and the load is removed.
8. The load is cooled to room temperature either in air or in another chamber (e.g., a furnace) at a predetermined rate to protect the parts from undesirable reactions or microstructural phase transformations.

A typical HIP cycle for a cold-loading cold-wall autoclave is as follows:

1. The powder-filled compacts are placed on fixturing designed to withstand the load weight and elevated temperature to which it will be subjected. This is usually done at a station that can also accommodate the furnace. To maximize efficiency, the load is built in a duplicate base heater while the vessel is actively running a cycle.
2. The furnace is placed over/around the compacts and the base heater. The entire load is lifted and placed into the HIP vessel as a module. The base heater engages outlets in the bottom of the vessel, and the process is ready to start. The vessel is closed by putting the lid in place and sealing it properly via threads or a yoke.
3. The vessel is then evacuated and purged with inert pressurizing gas sufficient to remove all the traceable remnants of air and/or moisture from the vessel.
4. High-purity gas, usually argon, is discharged into the vessel from the gas storage tanks until the pressure is equalized.
5. The compressor is turned on, and vessel pressure is increased via pumping until the hold pressure is reached. For most cycles, heating takes place during high-pressure purging, contributing to the pressurization. In fact, gas expansion is responsible for the largest contribution to the high pressure.
6. The load is heated to the desired holding temperature previously determined and based on material properties and so forth at some predetermined rate. The duration of the hold is based on the nature and size of the load.
7. After the cycle completes the established hold conditions, the load can be cooled in three ways. First, the furnace can be turned off, and the entire system will cool naturally to a temperature low enough to protect the furnace elements and to enable the load to be handled safely. This rate will vary with vessel size and with the amount and configuration of the load. Second, the furnace can be programmed to cool slowly to prevent a material problem such as unwanted excess residual thermal stresses. Third, the furnace can be rapidly cooled by circulating new cooler gas to replace the high-temperature gas in the vessel (Ref 15). This process can be used to improve cycle turnaround time or affect a quench of the material in the HIP unit. Regardless of cooling cycle type, the gas can either be vented to the air or recycled for future use.
8. The HIP charge is removed from the vessel when the temperature is appropriately low. Another charge built during the cycling of the furnace charge replaces it in the vessel, and this process repeats itself.

The cycle times for a given vessel depend on the load and the size of the autoclave. However, a typical floor-to-floor time for medium- to large-size vessels is a matter of minutes in hot-loading units and 24 h or less in cold-loading units. The cycle time in a hot-loading unit is generally a matter of minutes. These run usually 30 min or less. However, to achieve maximum benefit from this type of system, the preheating furnace capacity must be extensive. The charge will generally require 12 to 24 h of heating before it is ready to be introduced into the HIP unit. Nearly all of the autoclaves used extensively in the HIP P/M industry are the cold-loading cold-wall style because they can achieve a more reproducible cycle, which is necessary for near-net shape processing. The hot-loading cold-wall wall vessels are used where high volume is needed and the product is a compact or preform for reprocessing.

Selection of Specific Cycle Parameters. Generally, HIP of P/M material produces fully dense material in the shortest process time, using pressures within the rating of equipment large enough to accommodate the parts being processed. Control of the fully densified microstructure may also be required for HIP P/M parts, especially if they will be subsequently hot worked. For most materials, the temperature of HIP is the primary controlling factor and is usually at least 70% of the melting point of the material. With most materials, the HIP temperature is specified by the end user because of its effect on the subsequent microstructure and properties of the product.

There are potentially an infinite number of HIP cycles available, and the rate of heating and pressurizing the vessel is of primary importance to the shape of the parts being produced. Work by Evans and Malley (Ref 16) showed that by varying how heat and pressure are applied, the shape of a simple cylinder can vary dramatically. All cycles can be classified into three basic categories: (1) heat up first and then pressurize, (2) pressurize first and then heat, or (3) heat and pressurize simultaneously. How the load of parts reaches the hold parameters determines the shape of the parts. This means that reproducibility of the HIP cycle is most important to the reproducibility of any given part and is a key variable in obtaining a desired shape.

Hot Isostatic Pressing of Metal Powders

J.J. Conway and F.J. Rizzo, Crucible Compaction Metals

Consolidation of Encapsulated Compacts

When metal powder is consolidated via HIP, encapsulation is required to act as a barrier between the high-pressure gas and the powder to provide the differential force required to create the plastic deformation of the powder. Powder is typically placed in a container or envelope made of metal or glass to a specified shape larger than final desired size. There are three main components to producing a HIP-encapsulated P/M part, namely: powder manufacturing and processing, container manufacturing, and compact manufacturing.

Powder Processing

Powder Manufacture. Although crushed/irregular, mechanically alloyed, and hydride/dehydride powders can be used for HIP processing, prealloyed, spherical powder produced via gas atomization is most commonly used throughout the HIP industry. The primary advantage of spherical powders is their high pre-HIP packing density (e.g., 60 to 80% or greater of theoretical density) and relatively low variation in packing, which provides repeatable packing density in production. As the initial packing density increases, the probability of predicting final fully dense shape is higher, thus the more reproducible the HIP P/M process becomes.

For HIP P/M parts, the most commonly used powder-making process is inert gas atomization, which entails creation of powder by impinging high-pressure inert gas on a molten metal stream to disintegrate the metal into tiny liquid droplets. Due to surface tension considerations, the liquid droplets form spheres that rapidly solidify into powder particles at a rate of 10^4 to 10^8 °C/s (Ref 17). This rapid solidification provides a powder particle with superior chemical homogeneity not possible with conventional ingot metallurgy. In general, several alloy systems can be gas atomized successfully, namely those based on iron, nickel, cobalt, niobium, titanium, aluminum, copper, silver, and so forth with the molten metal containment (i.e., refractory or skull melt) being the limiting factor.

In addition to gas atomization, spherical powder can be produced by other methods that utilize centrifugal force as the energy mechanism to break up liquid metal. The rotating electrode process (REP) and the plasma rotating electrode process (PREP) are two such methods. During REP, the face of a rotating bar is melted by a direct-current electric arc maintained between the electrically negative tungsten tip and the positive alloy bar (Ref 18). The liquid metal is centrifugally ejected from the outer edge of the rotating bar and solidifies in flight as spherical particles, which are collected in a sealed chamber. While REP is normally used to produce iron-base powders, applications requiring superior cleanliness (e.g., titanium, nickel alloys, etc.) can be produced by PREP. During PREP, the plasma torch uses a dc arc to melt the rotating bar with a water-cooled tungsten cathode that is protected by helium gas to minimize erosion (Ref 18). Another mechanical atomizing technique is the rotating disk process where a molten metal stream is impinged on a rapidly spinning disk. As with the first two processes, the liquid metal is spun off the disk and centrifugally atomized into spherical droplets, which solidify in flight. Particle cooling can be enhanced by blasting the emerging particles with a stream of helium (Ref 19). Centrifugally produced powder typically has a narrower particle size distribution and lower packing density than gas atomized powder.

Another process that is commonly used to make titanium powder is the hydride/dehydride process. Titanium sponge is charged with hydrogen and thus embrittled. The particles are mechanically crushed and dehydrided to yield fine powder particles. This powder is not as pure as that made by the PREP or inert gas atomization, nor is it spherical. However, it

can be used to make HIP components. Powder of other refractory metals such as molybdenum and niobium can also be made in this way. It is also possible to make alloys of these elements using this process.

Powders can also be made by crushing and grinding ingot material. This process is usually used for highly alloyed materials and is not ideal for HIP P/M because of the inherently low packing density associated with this manufacturing method. These powders are often used with the HIP cladding process because they can be highly alloyed to achieve a specific property such as wear and/or corrosion resistance. These powders have a tendency to be extremely nonhomogeneous.

Powder Particle Size Classification. Classification may involve separating powder by particle size, typically via vibratory screening. Air classification through specially designed cyclones has also been employed. Bulk screening processes involve feeding raw powder onto the vibratory screener. Two exit ports from the screener are connected to separate collection bins to segregate the oversize and undersize fractions. The prime powder (usually the undersize) is used to manufacture HIP P/M parts, and the other fraction (usually the oversize) is reprocessed through melting.

Powder blending is performed to homogenize the particle size distribution. Hot vacuum blending is used to remove adsorbed gases from the surface of powder particles. Uniform particle size distribution is essential to HIP P/M near-net shape parts to minimize distortion during the consolidation step of the process. If a near-net shape is not being produced, then blending of the powder is not an essential step in the process and is often omitted. For some applications, blending can be used to achieve the desired chemistry of the end product. This can be as drastic as blending of elemental powders to make the entire composition or blending prealloyed powders that are close in chemistry as a refinement to meet a requirement for a specification. Blending for chemistry reasons is not considered a high-quality process and would not be utilized for technically demanding applications. After blending, powder is ready for loading into containers for HIP.

Container Manufacture

Container Design. There are a number of methods used to make both simple and complex shapes by the HIP P/M technology. The HIP component designer usually works with the end user to establish dimensional parameters that will meet the requirements of the application and still be compatible with the capability of the HIP process. The designer of the HIP container considers all the factors and then makes his decision on container type and material to give the best chance of successfully meeting the needs of the user. Figure 7 (Ref 20) displays a typical algorithm that designers of cylindrical HIP cans will employ. There may also be some consideration for metallurgical factors as well. As an example, section size of a part may be critical for cooling from heat treatment. These factors must be included in the part/container design process.

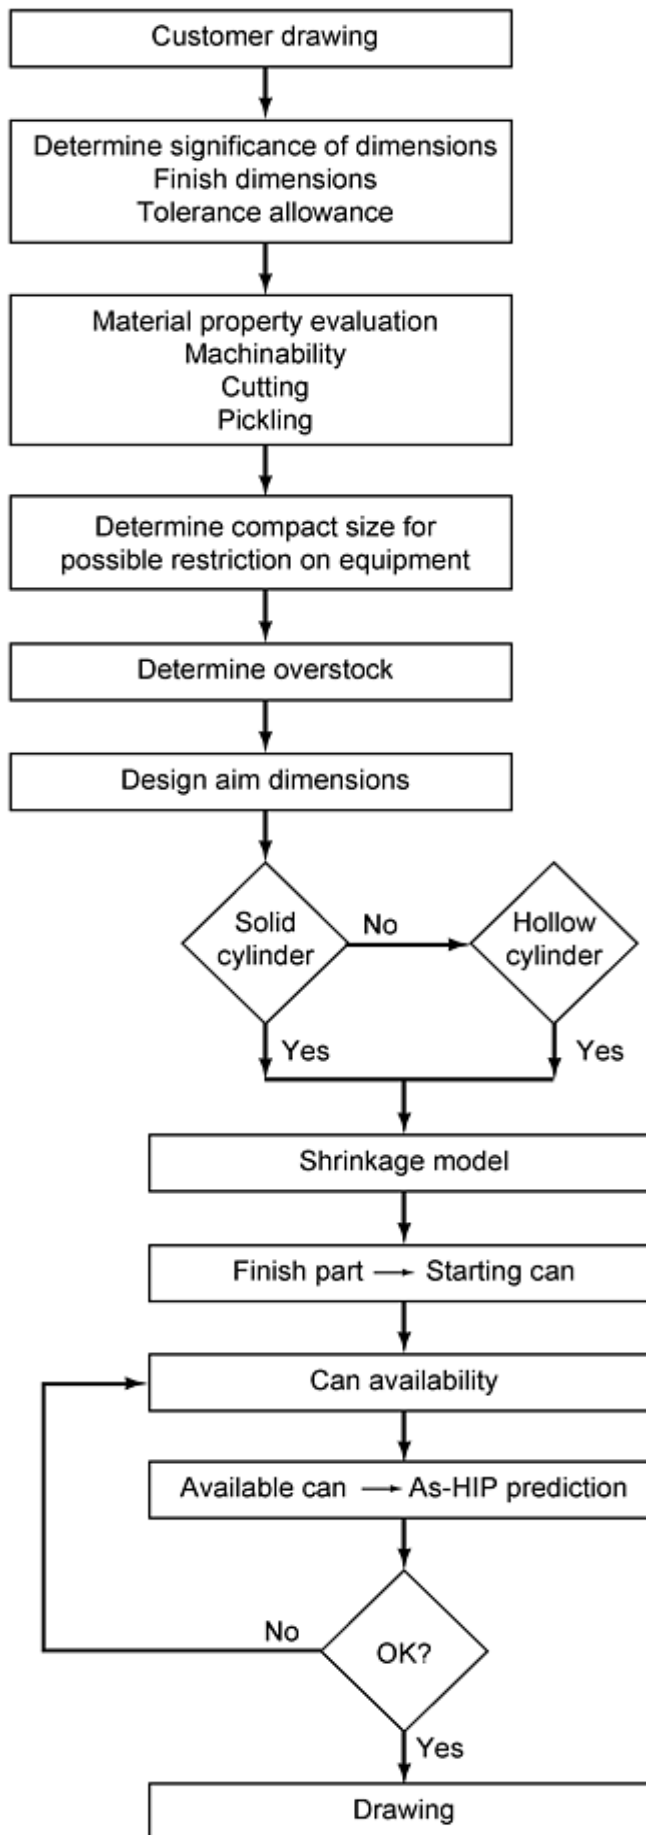

Fig. 7 Container design methodology for cylindrical shapes. Source: Ref 20

The basic requirements of the container are that it must:

- Be strong enough to maintain shape and dimensional control prior to and during processing
- Maintain leak tightness against the low and high pressures (typically up to 100 MPa, or 15 ksi) during evacuation, sealing, and densification
- Remain inert and plastic under applied temperature and pressure conditions
- Not contaminate the powder
- Be compatible with the material to be compacted and exhibit minimal integration with the powder by diffusion processes
- Be readily removable by machining, grinding, chemical dissolution, and so forth.

Currently, metal encapsulation is the most widely used containerization method for both experimental and production scale HIP P/M parts. In most cases, metal containers in the form of sheet, tubing, pipe, and so forth are used. Container components machined from heavy mill products (e.g., plate or bar) is not advised because pinhole piping originating from steel ingot solidification occurs frequently and persists through mill operations. This can result in a defective container that is likely to leak during the HIP cycle. Nickel and copper can be used, but thermodynamic reduction of sheet metal grain boundaries and weld metal oxides can occur in high-pressure argon during processing. Sheet materials commonly used for metal powder encapsulation include 1010, 1018, and 1020 low-carbon steel, extra-low-carbon-killed steel, type 304 austenitic stainless steel, commercially pure titanium, and Ti-6Al-4V alloy. Thicknesses less than 0.75 mm (0.030 in.) are impractical because of limited tensile ductility, whereas appreciable plasticity without through fracture may be required in certain container configurations that stretch or bend during the shrinkage that occurs during HIP. Special tooling (e.g., shear spinning tools) can be necessary to form the desired container shape. Large solid shapes, such as shown in Fig. 8, usually are produced with sheet metal containment. For shapes with internal cavities, sheet metal encapsulation with internal inserts that can be removed by machining or chemical etching is used (Fig. 9). Figure 10 illustrates the magnitude of the shrinkage a cylindrical compact experiences during HIP.

Fig. 9 HIP P/M shapes with internal cavities. Source: Ref 21

Fig. 10 Cylindrical billet can. (a) After HIP. (b) Before HIP. Source: Ref 22

The fill, evacuation, and seal tube attachment to the powder container is designed to prevent can buckling and tearing in the transition area. Thick-walled fill tubes are preferred, typically 19 mm outside diameter by 3 mm ($\frac{3}{4}$ in. outside diameter by 11 gage) for compacts weighing 5 to 200 kg (11 to 440 lb) and 9.5 mm outside diameter by 2.3 mm ($\frac{3}{8}$ in. outside diameter by 13 gage) for smaller compacts. A thick-walled tube prevents buckling under the applied HIP pressure and facilitates metal flow during the forge welding crimping step.

A successful metal container weld design is the "matched-lip" style (Fig. 11), which accommodates severe deformation during consolidation and minimizes potential leaks. Applied process pressure creates a self-sealing action and eliminates shear loads on the weld. The small volume of accessible weld metal also permits repair by grinding and rewelding. When the matched-lip design is impractical, suitable fillet and butt welds can be employed so long as the welds are capable of passing radiographic inspection per ASME Section VIII (Ref 20).

Fig. 11 Typical can corner designs. (a) Recommended design. (b) Poor design. Source: Ref 22

Low-carbon steel parts made from plate or bar (free-machining grades are not recommended) may be used for can interior shapes or cavity-forming components. As compact weight increases, container sheet gage should be increased to provide structural support during pre-HIP operations. Usually 14 gage (1.9 mm, or 0.07 in.) sheet is adequate for parts weighing approximately 200 kg (440 lb) and 12 gage (2.7 mm, or 0.1 in.) sheet is suitable for parts weighing approximately 1000 kg (2200 lb).

The presence of "continuous path" oxides in the metal container walls or welds can lead to subsequent leakage during densification and result in a nonusable product. Powder/container metal combinations must be evaluated or tested for detrimental interactions at processing temperatures. Binary phase diagrams can be consulted for potential low-temperature melting reactions. Commercially pure titanium encapsulation of refractory metals (molybdenum, niobium, tantalum, and tungsten) permits processing of these alloy systems between 1400 and 1650 °C (2250 and 3000 °F) without problems. However, any iron-containing capsules can only be used with titanium powders if the HIP temperature is kept below approximately 1000 °C (1830 °F). Solid-state reactions between can and powder include interdiffusion alloying and carbide formation.

In some boron- and carbon-containing materials (e.g., cemented carbide) thermodynamic activity of these elements may approach unity, leading to powder/container system melting points approximated by binary phase diagram eutectics. For example, the iron boron eutectic melts at 1149 °C (2100 °F). The latter case precludes steel canning of tungsten carbide/cobalt powder and HIP above approximately 1100 °C (2010 °F), because tungsten carbide/cobalt contains approximately 6 wt% C.

Glass that softens at the HIP temperature can be used as a container (e.g., Vycor glass for nickel alloys) (Ref 1). Glass containers can be fabricated by glass blowing or casting a slurry of ground glass to the required shape, drying, and then firing the shape. Typically, glass is used for high-temperature HIP cycles (e.g., refractory alloys, ceramics, etc.) where metal containers do not have the required properties. Currently, glass molds are not used extensively in production of HIP P/M components. Glass mold technology is described in detail elsewhere (Ref 23).

Another choice for container material is porous ceramic. The ceramic mold process (Ref 24) can produce solid net shapes with a complex geometry. The ceramic container is produced via the same principles as the investment-casting lost-wax process. A wax pattern is produced either by machining (usually experimental quantities) from wax billets or by wax injection molding in precision-machined tooling. A series of ceramic coatings are applied to the wax patterns and air hardened. The mold is then dewaxed and fired to leave the shape of the desired finished part expanded appropriately to accommodate the HIP shrinkage. Because the ceramic container is porous, it cannot be used directly as a container for HIP. The mold is filled with powder and placed into a secondary container and surrounded with a pressure transmitting medium (e.g., sand) and sealed except for an evacuation stem for outgassing. Once the entire assembly is outgassed, the secondary container stem is crimped and the compact is densified by HIP (Fig. 12). The ceramic mold process is particularly advantageous for production of complex precision shapes with compound curved surfaces and reentrant configurations.

Fig. 12 Schematic diagram of ceramic mold process for producing fully dense P/M shapes. Source: Ref 24

Design Methodology. At first glance, the design of the HIP container would seem to be one of isotropic expansion of the finish shape given a particular packing density (Ref 25). However, in practice, it is rarely observed that a photographic reduction of the original shape is obtained (Fig. 10). Factors that can influence the dimensional distortion during HIP are:

- Stiffness of the container
- Thickness and variations in thickness and geometry
- Local variations in powder density
- Types and positions of welds
- Heating and pressurization rates during HIP consolidation
- Formation of densification fronts due to nonisothermal conditions of the powder (Ref 11, 26)

This dimensional anisotropy can be difficult to predict given the complex interrelationships between the properties of the powder and container materials as a function of temperature, density, and part geometry.

The designer of HIP cans starts with an end user drawing of the required part and a bill of material listing specifications to be met. The next step is to design a net or near-net shape to protect the dimensions of the part with considerations of machining allowance, powder/container interaction, bowing (particularly in thin sections), end effects, integral sample material allowance, and other secondary processing as described in Fig. 7 (e.g., nondestructive testing, machinability, ability to straighten, heat treatment, etc.). Once this is established, an aim configuration is determined with material allowances as required.

The container design may include several components fabricated from various techniques (e.g., shear spinning, stamping, hydroforming, etc.) and eventually put together to yield a capsule for loading. Because powder occupies only about 70%

of the available volume inside the container, a considerable amount of shrinkage occurs. The science/art of designing a container must account for the packing density and the symmetry or lack thereof to achieve an acceptable part. During the initial production of a particular component, preproduction trials and/or iterations of the full-size shape may be necessary to determine the shrinkages empirically. However, this iterative approach is frequently costly and time consuming.

Through the years, HIP P/M part manufacturers have employed engineering intuition and previous experience to develop the starting can design. At this time, other approaches are being developed and used, namely, empirical and continuum mechanics/finite element modeling. Some of these are briefly described here.

Empirical Models. A large percentage of the HIP P/M compacts produced are either simple or hollow cylinders. An empirical model for these shapes was developed several years ago (Ref 26) by analyzing dimensional data from before and after HIP for a variety of cylindrical shapes. To eliminate the effects of the HIP cycle, alloy systems, and container thickness, the analysis focuses on cylinders made from nickel-base alloys consolidated in similar HIP cycles with a certain can thickness range. Best fit curves were generated for axial and radial shrinkage as a function of aspect ratio (length to diameter) and surface area ratio (area of cylindrical component to area of the lateral ends) as shown in Fig. 13. Based on these data, a computer program was generated to provide either the starting container dimensions to make a finished near-net shape or predict post-HIP dimensions given a specified starting container (Ref 26).

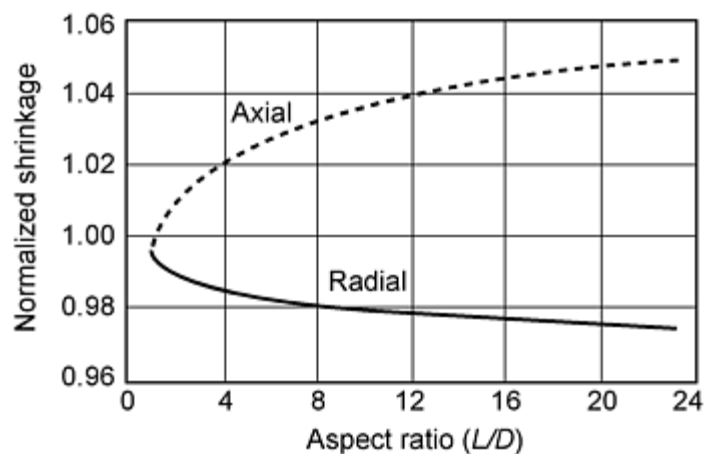

Fig. 13 Normalized shrinkage on solid cylinders (normalized shrinkage = actual shrinkage/isotropic shrinkage). Source: Ref 20

Engineering Models. One promising approach to perform a direct process simulation via the use of computer models is to combine a constitutive model of continuum mechanics equations solved by a finite element computational method. Several approaches ranging from simple plastic to compressible, viscoplastic constitutive models have been investigated as described in the article "Principles and Process Modeling of Higher-Density Consolidation" in this Volume. Even though some of these mathematical models are utilized in production, none has matured into a reliable modeling system for arbitrary geometries and HIP cycles.

Container Fabrication

Tooling and Container Component Fabrication. Once the design has been established, the metal container is fabricated. This is not a trivial step because the container must be producible in an economical fashion or the finished part cannot be manufactured. The most economical and easily formed container material is low-carbon steel; however, other materials (e.g., stainless steel, nickel alloys, titanium, etc.) can also be used. The process is constrained by existing metalforming techniques (e.g., metal spinning, hydroforming, stamping, hand forming, casting, machining, etc.) with each having its inherent advantages and limitations.

Tooling for the HIP P/M process refers to that which may be used to fabricate the container components. Usually, the quantity of parts to be made dictates the precision and cost committed to the tooling for HIP P/M containers. Large numbers of parts (1000 or more) would employ stamped containers. Anything less than this would be determined on a case-by-case basis. Cost of tooling must be amortized over the quantity of parts produced, so more expensive and more

precise tooling can be cost effective only for sizable production runs. Because HIP P/M is most often used as a near-net shape process with small quantities of parts, container tooling is not made to be as precise as other processes where net shape is important.

Cleaning. Contamination of encapsulated powders will result, unless dirt, oxides, metalworking lubricants, and rust preventatives used to fabricate container components are removed. See *Surface Engineering*, Volume 5 of the *ASM Handbook* for cleaning procedures applicable to various metals. Proper cleaning, storage, and handling procedures immediately prior to any welding operation are necessary to prevent dirt entrapment or contamination on can surfaces.

Powder metallurgy alloys that are particularly sensitive to contamination (titanium, nickel-base alloys, and refractory metals) require controlled humidity and stringent cleanliness for final can preparation, assembly, welding, and filling. Electropolishing of stainless steel container components and nonchlorinated solvent cleaning (usually acetone, methylethylketone, or methanol) of titanium container components represent typical cleaning processes for specialized applications. Carbon steel sheet metal containers should be supported carefully to prevent distortion during welding. Similar precautions are recommended for the outer sheet metal container used in a ceramic mold process.

Welding. A matched-weld-lip container configuration is designed to promote directional plane front solidification with good liquid metal feeding in the solidifying weld metal. Certain oxides (iron, nickel, and copper) can be reduced at high temperature in a high-pressure argon environment. This process may produce leaky containers during HIP if oxides extend through weld metal or container wall materials. Use of stainless steel filler metal for carbon steel container repairs is recommended because chromium oxides essentially are stable under processing conditions up to 1200 °C (2200 °F) in argon. Gas tungsten arc welding of nickel containers with stainless steel filler metal is also advised.

Containers for loose powder are assembled, welded, leak tested, and filled in sequence. Containers with interior spacers (mandrels), powder/solid composites (e.g., clad components), or precompacted and sintered P/M compacts can be filled with at least one cover removed. This procedure results in an extensive assembly weld area that cannot be leak tested in the vacuum mode because of the slow response time of helium through the interior of the filled container. Consequently, careful removal of loose powder from the weld area is necessary and use of precision and reproducible (preferably machine) weld techniques is required to prevent leakage. Leak tightness of HIP containers is a major process consideration.

Electron beam, gas tungsten arc welding, and stick welding are used for final container assembly. Argon dry box and electron beam welding are used for titanium alloy containers because nonoxidizing conditions are required. Gas tungsten arc welding with and without filler is used for carbon steel and stainless steel containers. Carbon steel containers may require a final reduction anneal after weld assembly, and some clad parts may need to be preheated prior to welding because of substrate material considerations or section size differences. Because weld metal is essentially a solidified casting, shrinkage and gas porosity are the fundamental causes of leakage at welds.

Leak Testing. Containerized HIP of metal powders can only be achieved successfully with leak-free containers. Location of leaks in a fully assembled container by use of valid leak-testing procedures and subsequent repair are fundamental requirements of HIP P/M technology. Leak detection is based on characteristics of helium and argon flow through small capillaries when compared at 1 atm (0.1 MPa) and 1000 atm (100 MPa) total pressure. Flow characteristics of a cylindrical capillary have been described by Guthrie and Wakerling (Ref 27):

$$Q = 1/L [C_1P^2 + C_2P + C_3 \ln (1+C_4P)] \frac{P_1}{P_2} \quad (\text{Eq 1})$$

where Q is the flow rate, cgs units; P_1 and P_2 are the exterior and interior pressure, cgs units; C_1 , C_2 , C_3 , and C_4 are constants; and L is the capillary length, cm. For $P_2 = 0$ (evacuated container interior) and P_1 large:

$$Q = C_1P_1^2/L = \pi D^4 P_1^2 / 256 \eta L \quad (\text{Eq 2})$$

where η is the gas viscosity and D is capillary diameter, both in cgs units. This applies strictly in the viscous flow region, when Reynolds number (Re) is <1200:

$$Re = DV\rho/\eta < 1200 \quad (\text{Eq 3})$$

where V is the gas velocity, cgs units; and ρ is the gas density, cgs units.

Equation 2 indicates the relationship of container design, manufacturing, and leak testing. Leakage flow is proportional to the exterior pressure squared. Whereas leak testing is conducted with pressure differences across the container wall of one to several atmospheres, HIP typically uses 1000 atm (100 MPa). Thus, a leak occurring just below the detectability limit of a selected method permits leakage flow rates 10^6 times greater during HIP. Consequently, sensitivity of the leak-detection method is of utmost importance.

Capillary length (L) can be identified with container wall thickness, and with all other variables being constant, a capillary leaks ten times faster through a 0.25 mm (0.01 in.) wall than a 2.5 mm (0.1 in.) wall. The self-sealing, matched-weld-lip design is advantageous because capillary path length through the weld increases rapidly as weld flanges deform and solid-state bonding occurs. The fourth power dependence of leakage flow rate on capillary diameter indicates the necessity for procedures to eliminate weld porosity.

Leakage flow rates for helium at 1 and 10 atm and for argon at 1000 atm (100 MPa) for a set of capillary leak sizes and D/L parameters that could occur in practice are given in Table 1. This illustrates the major problem in leak testing of HIP containers: the leakage flow rate of argon through a capillary hole at 1000 atm (100 MPa) process pressure is approximately 10^5 times greater than the flow rate during a 1 atm (0.1 MPa) leak-testing procedure such as use of the helium mass spectrometer in the vacuum mode (i.e., evacuated container and/or atmospheric helium surrounding container exterior). This flow-rate difference defines a requirement for maximum sensitivity of the leak-testing method that is satisfied only by use of the helium mass spectrometer method in the vacuum mode.

Table 1 Leakage rate as determined by capillary (hole) diameter, gas type, and pressure

Capillary length $L = 0.1$ cm

Capillary diameter (D), μm	Leakage rate, cm^3/s , for:		
	Helium at 0.1 MPa (1 atm)	Helium at 1 MPa (10 atm)	Argon at 100 MPa (1000 atm)
0.001	3.8×10^{-16}	3.8×10^{-14}	3.3×10^{-11}
0.01	3.8×10^{-12}	3.8×10^{-10}	3.3×10^{-7}
0.1	3.8×10^{-8}	3.8×10^{-6}	3.3×10^{-3}
1.0	3.8×10^{-4}	3.8×10^{-2}	3.3×10^{-1}

Note: Leakage rate is inversely proportional to the capillary length; that is, if the capillary length is twice as long, the leakage rate will be half as much. For example: if $D = 0.1 \mu\text{m}$ helium pressure = 1 MPa, and $L = 0.3$ cm, then leakage rate = $(3.8 \times 10^{-6}/3) \text{ cm}^3/\text{s} = 1.3 \times 10^{-4} \text{ cm}^3/\text{s}$. Source: Ref 22

Figure 14 illustrates a typical setup for a HIP container that is connected to a commercial helium mass spectrometer for leak testing in the vacuum mode. The effect of argon in powder compacts is estimated here to emphasize the importance of using only leak-free containers for powder encapsulation. Total leakage (in argon at standard temperature and pressure, assuming constant leak conditions and no appreciable pressure rise inside the container) for 1000 and 10,000 s flow times is given in Table 2. Distribution of this "leaked" argon within compacts of various sizes permits estimates of argon contamination in parts per million (ppm) by weight, as shown in Fig. 15.

Table 2 Total argon leakage flow at standard temperature and pressure

Capillary (hole) length $L = 0.1$ cm

Capillary diameter (D), μm	Leakage flow, cm^3 at a leakage time of:	
	1000 s	10,000 s
0.001	3.8×10^{-8}	3.8×10^{-7}
0.01	3.8×10^{-4}	3.8×10^{-3}
0.1	3.8×10^0	3.8×10^1

Note: Leakage flow is inversely proportional to capillary length; that is, if the capillary length is twice as long, the leakage flow will be half as much. For example, if $D = 0.1 \mu\text{m}$, argon pressure = 100 MPa (1000 atm), leakage time = 1000 s, and $L = 0.3$ cm, then leakage flow = $3.8 \times 10^0/3 \text{ cm}^3 = 1.3 \times 10^0 \text{ cm}^3$. Source: Ref 22

Fig. 14 Leak testing setup. Acceptance criterion: Q (flow rate) $< 10^{-9}$ standard cm^3/s . (a) Test piece evacuated and hooded with helium atmosphere to determine overall leakage rate. (b) Test piece evacuated; helium jet probe used to locate leak. Source: Ref 22

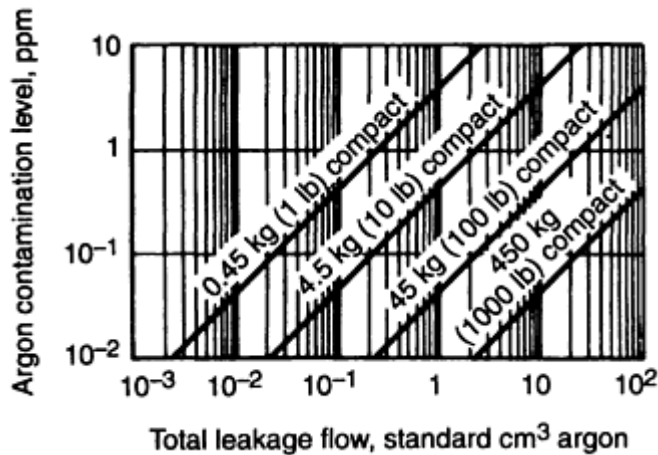

Fig. 15 Argon contamination level versus total leakage flow for various compact sizes. Source: Ref 22

Contained argon, although compressed during early powder densification stages in the HIP cycle, can limit end-point densification by "pressure balance" within small remaining pores. Regrowth of pores in subsequent heat treating operations, with related adverse effects on properties, can occur at levels as low as $0.1 \text{ mL}/\text{m}^3$ (0.1 ppm) for tool steels and 1 to $5 \text{ mL}/\text{m}^3$ (1 to 5 ppm) for superalloys. Leaks representing argon contamination at the 10 to $100 \text{ mL}/\text{m}^3$ (10 to 100 ppm) level generally prevent full densification, and larger leaks usually result in partial or no HIP densification.

Compact Manufacture

Loading. Filling of powder into the hermetically sealed, preshaped metal container can be performed in air, under inert gas, or under vacuum conditions, with the latter to aid in the removal of adsorbed gases. In some cases, powder is still loaded in open air as it was 25 years ago; however, most processing today is containerized to protect the product and prevent inhalation of the metal powder by operators (Fig. 16). Advanced filling systems have been developed to ensure clean, dry handling of powder for critical aerospace applications. Magnetic particle separation, screening, outgassing, and settling have been incorporated into these systems. In a production operation, there is a need for more sophisticated load stations that are automated to achieve maximum productivity. These are usually enclosed systems capable of operating with inert gas or vacuum conditions inside the container and the system. Some loading facilities are also capable of hot dynamic outgassing during the filling operation. If effective, this type of load station will prevent the need for subsequent outgassing once the compact is filled. Figure 17 illustrates a commercial degassing and capsule filling station.

Fig. 16 Illustration of Modeen loading station

The loading process must be performed in a manner to meet the desired packing density of the powder to obtain the proper post-HIP shape. Vibration to settle powder (i.e., packing) is usually employed to get the uniform distribution of powder throughout the inside volume of the container. This is important for good shape definition and for reproducibility among parts of the same configuration. It is also possible to load powder into the container first, and then by use of a large-amplitude low-cycle vibration pack the powder in the compact. This process is sometimes called "thumping." Organic materials such as rubber tubing are not recommended in the powder flow path as they are an obvious contamination source.

Fig. 17 Commercial degassing and capsule filling station Particular attention should be paid to completion of container filling practice. An incompletely filled container results in loss of shape control and may result in collapse and tearing of the container under external process pressure. Compacted powder in the fill tube provides integral contiguous material for testing and evaluation of the part. Figure 18 illustrates recommended and poor loading.

Fig. 18 Container filling practices. (a) Poor practice. (b) Recommended practice. Source: Ref 22

Outgassing. The functional requirement of encapsulated powder vacuum/hot outgassing is to remove the atmosphere and water vapor (free and absorbed) from the packed powder bed to prevent formation of particle surface oxide and nitride films, which reduce workability and/or mechanical properties of the subsequent consolidated product. Behavior of powder in a heating/vacuum cycle (at temperatures up to approximately 400 °C, or 750 °F), for the purpose of defining process specifications, can be determined by thermogravimetry, combined with limited range mass spectrometry techniques. Vacuum outgassing does not remove gas entrapped in hollow powder particles originating from inert gas atmosphere atomization operations. Evacuation time for a packed powder bed can be estimated using viscous and molecular flow concepts. Elevated temperature is used to raise gas pressure within a bed and to promote desorption of water vapor. Packed metal powder beds are poor thermal conductors; therefore, an excessively high heating rate and temperature gradient in the compact during outgassing can result in redistribution of gas by chemisorption and reaction in the outer zone before all the gas is pumped out of the bed. This can occur because the center of the bed evolves gas at "low" temperature, which diffuses and reacts with the outer "high"-temperature portion of the bed before it leaves the compact.

The required practical end point for degassing a powder-filled hot isostatic pressing container can be estimated from the residual bed pressure (assuming air composition), which contributes oxygen and nitrogen levels ten times less than the

base level of the powder. Based on powder packing density, temperature, bed pressure, and ideal gas laws, parts per million by weight is given by:

$$\text{ppm} = 1.32 Pf[(1 - \rho'/\rho)/\rho' RT]M \quad (\text{Eq 4})$$

where P is bed pressure, $\mu\text{m Hg}$; ρ is full density of metal, g/cm^3 ; ρ' is apparent (tap) density of powder, g/cm^3 ; f is fractional composition of gas, oxygen = 0.21 (air); M is molecular weight, g/mole ; R is gas constant, $82.06 \text{ cm}^3\text{-atm/K}$; T is absolute temperature, K .

For $T = 600 \text{ K}$, oxygen in air ($f = 0.2$) $\rho = 8.0 \text{ g/cm}^3$, and $\rho' = 5.2 \text{ g/cm}^3$ (65% packing density):

$$\text{ppm}_0 = 1.8 \times 10^{-4P} \quad (\text{Eq 5})$$

and for $\text{ppm}_0 = 1$:

$$P \cong 5.5 \times 10^3 \mu\text{m Hg} = 5.5 \text{ mm Hg} \quad (\text{Eq 6})$$

The normal oxygen level of commercial superalloy powders ranges from 10 to 50 mL/m^3 (10 to 50 ppm) by weight. Thus, relatively high finishing evacuation pressures are acceptable in some cases. Other alloys, particularly refractory metals, may be more sensitive to residual gas. Carbon steel containers can be through oxidized in an air bake-out furnace with prolonged exposure. Container wall thickness, therefore, should be increased with increasing size and weight. For steel containers, grit-blast descaling is recommended after powder degassing. Stainless steel containers offer greater oxidation resistance during powder degassing and do not require descaling.

Loss of part dimensional control in large compacts (greater than about 25 kg, or 55 lb) also can occur during degassing, because the sheet metal container heats faster than the contained packed powder. New empty space is created inside the can at the bottom, into which powder flows from top areas. An oversize diameter at the bottom and uneven top geometry result from this type of powder movement during can heating without applied pressure. This particular problem also can occur in hot-loading HIP operations.

At the completion of the outgassing cycle, the fill/outgas stem is torch heated to approximately $982 \text{ }^\circ\text{C}$ ($1800 \text{ }^\circ\text{F}$) and sealed by use of a crimping tool. This leaves the powder-filled container sealed under vacuum and ready for consolidation by HIP. Loss of powder during evacuation and degassing (after can filling) can be prevented by inserting a stainless steel wool plug or a metal plug and partial crimping (Fig. 19).

Fig. 19 Insertion of plugs to prevent loss of powder during evacuation. Source: Ref 22

Consolidation by HIP. The HIP of powder compacts is performed to consolidate the powder metal by plastic deformation to 100% of theoretical density. Details of the various HIP systems and cycles are discussed in previous sections of this article. In a cold-loading system (most commonly used for near-net-shape work), powder-filled compacts are fixtured and loaded into the autoclave (HIP) vessel. Pressure and temperature are increased at preprogrammed rates until the desired HIP hold parameters are reached. At the completion of the hold, the vessel is depressurized and the furnace is turned off. The fully dense parts are removed from the fixturing and sent to the next step in the process.

The upper size limitation for densification of encapsulated parts is governed primarily by the processing unit uniform temperature working zone diameter and length. Tool steel billets approximately 60 cm (24 in.) in diameter by 300 cm (120 in.) long and larger have been fully densified by HIP. Nickel-base superalloy P/M turbine disks greater than 1 m (3.3 ft) in diameter have been successfully densified. For sheet metal encapsulation of P/M parts weighing more than approximately 20 kg (44 lb), attachment of handling lugs is recommended. For large-diameter parts (greater than 0.5 m, or 1.6 ft, in diameter) and weights greater than 100 kg (220 lb), sheet metal bending stresses due to enclosed powder weight must be considered. Careful consideration must be given to the support of large parts in HIP tooling to prevent distortion during heating prior to complete densification. For small net-shape parts (1 to 1000 g, or 0.03 to 35 oz), particularly with thin sections, tooling that permits separate setting of each part is required.

Production of small (less than 10 kg, or 22 lb) net-shape parts by the HIP P/M process is not generally economical because it is labor intensive and the container fabrication costs are high. This applies particularly to the manufacturing of individual tools from P/M tool steels. Exceptions include experimental parts and manufacture of specialty parts in P/M refractory metals, composites, and precious metals, where metal cost is a controlling factor. Small net-shape parts (less than 0.5 kg or 1 lb) are best manufactured by containerless HIP, particularly for tool materials, provided satisfactory process procedures can be developed.

Postconsolidation Processing. After HIP consolidation, the compact fill stems are removed, and the components are dimensioned. The material in the fill stem is checked for density and microstructure. Failure to meet set criteria for any of these characteristics is cause for rejection of the compact. Many parts are further processed through heat treatment, container removal via chemical dissolution or machining, NDT, and mechanical testing prior to certification and shipment to the end user.

Because the HIP P/M process generally provides a near-net shape, the powder part manufacturer usually supplies a semifinished product. This could include material in any one or a combination of the following conditions:

- As-HIP
- HIP plus heat treated
- Rough machined
- NDT qualified
- A preform for thermomechanical processing
- HIP plus thermomechanically processed

The end users determine in what condition they want to receive their parts and specify all requirements such as dimensions, surface, thermomechanical history, properties, and so forth.

Hot Isostatic Pressing of Metal Powders

J.J. Conway and F.J. Rizzo, Crucible Compaction Metals

Applications

The ability of HIP to produce near-net shapes has been a primary impetus behind the development of HIP P/M parts. Conventional manufacturing methods for materials with high alloy content have low process yields and typically utilize only 10 to 30% of the material purchased in the final product; the remainder becomes scrap during machining. Hot isostatic pressing to near-net shape improves material utilization significantly during part manufacturing and finish machining. A hot isostatically pressed near-net shape part normally loses only 10 to 20% during final machining. The inability to provide nondestructive inspection of complex near-net-shape parts for certification has somewhat inhibited application of this technology, particularly for turbine engine applications.

High-Speed Tool Steels. The development of gas-atomized prealloyed steel powders in the 1960s (Ref 3) led to HIP P/M tool steels. This represented the first production application of HIP for a relatively low-cost material. Hot isostatic pressing improves the microstructure of tool steels by preserving the fine grain size and carbide distribution present in the atomized powder through the consolidation process. Increased homogeneity of the fine carbides throughout the material is an added benefit. Superior tool properties result from the improved microstructure. Shape stability during subsequent heat treatment is superior in HIP material. Grindability, wear resistance, and uniformity of hardness also are improved. Additionally, cutting performance of high-speed tool steels is improved by this processing treatment, due to the increased toughness related to fine austenite grain size. New high-alloy-content steels with enhanced material properties can be produced. High-speed tool steels are generally consolidated in billet form. A HIP high-speed steel compact is shown in Fig. 20.

Fig. 20 Large-sized cylindrical high-speed steel billet. Courtesy of Crucible Materials Research Center

Nickel-Base Superalloys. Starting with development in the early 1970s, nickel-base superalloys have evolved into one of the best applications for the P/M HIP technology. More than 5000 tons (4545 metric tons) of superalloy components are currently operating in commercial and military aircraft turbine engines. Hot isostatic pressing of forging preforms represents a significant portion of the current production, but there are approximately 100,000 as-HIP parts in service as well. The use of HIP P/M consolidation for superalloys is economically attractive because of its near-net-shape capabilities. High-alloy-content superalloys can be produced with attractive properties. Superalloys strengthened by a large volume fraction of second-phase γ' undergo severe segregation during ingot solidification. Such ingots would be virtually unworkable by conventional hot-working techniques for large-size parts. The division of the melt into small powder particles during atomization eliminates macrosegregation, and microsegregation is reduced because of high cooling rates during particle solidification. Hot isostatic pressing of these powders produces a homogeneous microstructure that improves mechanical properties and hot workability.

Superalloy powders are typically made by inert gas atomization or REP. Care must be taken in processing to avoid the presence of stable nonmetallic compounds on the surface of the powder particles because they can be detrimental to the properties of consolidated products. The article "Powder Metallurgy Superalloys" in this Volume discusses the properties of many nickel-base superalloys made via the HIP P/M process. A comparison of HIP properties with other forms is given in Table 3.

- (a) AC, air cooled. Processing: -150 mesh powder, extruded at 1070 °C (1900 °F) to a reduction of 7 to 1 in area, isothermally forged at 1100 °C (2012 °F) to 80% height reduction.
- (b) Processing: -150 mesh powder, HIP processed at 1120 °C (2050 °F) at 100 MPa (15 ksi) for 3 h.
- (c) Processing: cross-rolled plate, heat treated at 1218 °C (2225 °F) for 1 h.

Heat treatment after HIP can have significant effects on material properties as shown in Table 4. Material response to post-HIP treatment depends on the processing conditions. Near-net-shape parts also may be subject to distortion during post-HIP heat treatment. If complex shapes are required, the ceramic mold process is suitable, particularly for static parts. If a carbon or stainless steel container is used for powder consolidation, a 0.5 mm (0.02 in.) diffusion zone may surround the part. This does not cause a problem in the final part because HIP envelopes usually exceed this dimension. Hot isostatic pressing conditions are alloy dependent. Processing temperatures may be keyed to the γ' solvus temperatures for purposes of grain size control in nickel-base superalloys.

(c) 1080 MPa (157 ksi) at 600 °C (1110 °F).

(d) 50% water-soluble polymeric compound, 50% water

Oxide-dispersion-strengthened superalloys also can be consolidated by HIP. Prior to processing, alloy powders, additives, and oxide dispersoids are put in a high-attrition ball mill and mechanically alloyed. This ensures fine grain size and uniform oxide distribution throughout the powder. Hot isostatic pressing produces fully dense material with these microstructural features maintained.

Titanium-Base Alloys. Powder production for titanium and titanium alloys requires special setups because of the reactivity of titanium. The hydride/dehydride process is the most common way to make titanium powders, but the particles resulting from this process are not spherical and thus do not work well for near-net-shape processing. The early method used to make spherical titanium powder was the REP. This was later supplanted by PREP to reduce contamination. Either of these processes depends on the ability to manufacture bar product of the alloy being made into powder. In the late 1980s, an inert-gas-atomizing technique was developed for titanium and its alloys (Ref 30). By the use of inert atmosphere or vacuum induction skull melting, the titanium alloy is brought to the molten state. The liquid is then poured through a metallic nozzle into a high-pressure gas stream. The metal breaks up and resolidifies as spherical titanium particles. The powder is collected in a cyclone system designed to cool the powder to prevent sintering.

There are any number of applications for titanium and titanium alloy powders. In the late 1970s and through the 1980s, the Air Force Materials Laboratory supported many programs to develop near-net shapes for military uses (Ref 31). For many reasons, this work never resulted in an ongoing production process, even though there is still some experimental work being performed currently. All of the meaningful earlier work was conducted with PREP powder. When the gas-atomized powder became available, it was used for all subsequent activities. At that time, the emphasis changed to applications needing titanium aluminide powders. Because these can be easily made by the skull-melting/gas-atomization process, the bulk of the experimental work is currently being performed in this area. The powders are now being used to manufacture metal-matrix composites and intermetallic-matrix composites. The advantages of these products are their light weight, high strength, oxidation resistance, and creep resistance at high temperatures.

Cemented Carbides. Tungsten-carbide/cobalt tools are the premier example of containerless HIP to achieve full density by removing residual porosity. Superior transverse rupture strength results from HIP. The wear performance of cutting tools at high speeds is not significantly improved, however, because this behavior is governed by the hardness of the material rather than by its fracture properties. Low cobalt content (3%) alloys can be produced by HIP to give enough toughness for use in drawing dies.

Fully dense cemented carbide can be finished to give a perfectly smooth surface, which is required for high-quality rolls, dies, mandrels, and extrusion tools. Generally tungsten-carbide/cobalt tool materials are manufactured by CIP and sintering of blended powders, followed by HIP. Typical conditions for HIP are 1290 °C (2350 °F) at 100 MPa (15 ksi) for 1 h. Cemented carbide parts produced using HIP are shown in Fig. 21.

Fig. 21 Tungsten-carbide/cobalt parts produced by HIP. Source: Ref 22

Refractory Metals. Consolidation of refractory metals by HIP is a two-step process. Processing these materials to net and near-net shape promotes conservation of these critical resources. Niobium alloy C-103 (Nb-10Hf-1Ti-5Zr) has been successfully hot isostatically pressed using a duplex cycle. Hydride/dehydride and PREP powders are consolidated in a plain carbon steel container filled with powder at 1260 °C (2300 °F) at 100 MPa (15 ksi) for 3 h. The container is then removed in a nitric acid solution and further chemically milled in a nitric-hydrofluoric acid solution to remove the alloy/container interaction layer. The material is finished in a HIP step at 1590 °C (2900 °F) at 100 MPa (15 ksi) for 3 h to a final density in excess of 99% of theoretical. Room-temperature and high-temperature (1650 °C, or 3000 °F) tensile strength and ductility properties compare favorably to wrought alloy properties. The ductile/brittle transition temperature is higher (-18 °C versus 160 °C, or 0 °F versus 320 °F, for standard products) in the HIP material due to increased oxygen content. Gas content of the hydride/dehydride material results in poorer weldability than the PREP powder. Hydrogen embrittlement also occurs in the

hydride/dehydride alloy C-103. Vacuum baking at 870 °C (1600 °F) for 2 h eliminates embrittlement, and the alloy will fail in a ductile manner in tensile and Charpy tests.

Near-net shape forward bowls manufactured by consolidation of C-103 in the duplex HIP cycle are shown in Fig. 22. The diameter of the bowls was within 0.13 mm (0.005 in.) of final dimensions. The P/M net shape weighed 0.8 kg (1.8 lb). This, compared with rough forging weighing 1.7 kg (3.8 lb) and a final part weighing 0.6 kg (1.4 lb), illustrates the material savings achieved by HIP to near-net shape.

Fig. 22 Niobium forward bowls hot isostatically pressed to shape. Source: Ref 22

Included is a provision for parts to be low-temperature HIP to a closed porosity condition, decanned, and re-HIP usually at higher temperatures. This option can be employed when the powder/container integration (melting, alloying, contamination, etc.) is unacceptable at the preferred higher HIP temperature. This technique has been used, for example, for niobium alloys that are initially hot isostatically pressed at 1205 °C (2200 °F) in low-carbon-steel containers, decanned, and re-HIP at 1595 °C (2900 °F) to circumvent an iron-niobium eutectic reaction at 1360 °C (2480 °F).

made from an austenitic stainless steel. Large manifolds with integral outlets hot isostatically pressed from a superduplex stainless steel have also been put in service in an offshore oil rig in the North Sea (Ref 32). In addition to the other benefits of a HIP P/M approach, the manifold can be fabricated in far less time and avoid costly welding processes. An analysis of the cost factors showed a greater than 20% savings over a similar manifold produced from fabricated cast and wrought components (Ref 32).

Stainless Steels. One of the most prominent applications of the HIP P/M technology is in the area of stainless steels. Both duplex and austenitic steels have been used extensively as P/M near-net shapes in the oil and gas and petrochemical industries. For example, valve bodies, fittings, and large complex manifolds for piping systems have been successfully produced in a cost-effective manner via HIP processing. Figure 23 (Ref 32) shows some of the typical fittings that have been made from 254 SMO material. Figure 24 (Ref 32) is a valve body that weighs more than 2 tons and was

Hot Isostatic Pressing of Metal Powders

J.J. Conway and F.J. Rizzo, Crucible Compaction Metals

Interface/Diffusion Bonding

Not only can HIP be used to consolidate loose powder, it can also be used to create a component of multiple bonded materials. Diffusion bonding by HIP can be performed on solid-to-solid, powder-to-solid, and in some cases, powder-to-powder surfaces. As with powder/metal container combinations, material compatibility must be evaluated to ensure no low-temperature melting reactions occur at the HIP temperature. If this does occur, interlayers can be used to alleviate this problem.

HIP Diffusion Bonding versus Other Joining Processes. As stated previously, HIP technology was initially developed as a method to diffusion bond two materials together. Table 5 shows various attributes of joining two materials when comparing diffusion bonding with fusion methods (i.e., welding and brazing). The major advantages of diffusion bonding are no melting of the parent metal and therefore no segregation or cracking problems, very little dimensional distortion, and stronger bonds due to the elimination of a low-melting-point filler.

Table 5 Diffusion bonding in comparison with other joining processes

	Fusion welding	Diffusion bonding	Brazing
Contacting method	Autogenous fusion, autogenous fusion and pressure, pressure and autogenous fusion	Pressure (no fusion)	Contact fusion, contact fusion and pressure, pressure and contact fusion
Bonding	Cohesive	Adhesive, diffusion	Cohesive, adhesive
Heating	Local	Local, total	Local, total
Temperature	Melting point of parent metal	0.5-0.7 of melting point of parent metal	Somewhat above melting point of braze
Surface preparation	Less exacting	Careful	Less exacting
Fit-up	Lenient	Precise	With capillary gap
Materials	Metals, alloys	Metals, alloys, nonmetals	Metals, alloys, nonmetals
Joint formation	Gradual	Simultaneous	Simultaneous, gradual
Edge preparation	Yes	No	Yes
Joining of dissimilar materials	Limited	Unlimited	Unlimited
Stepwise conduct of process	Limited	Unlimited	Unlimited
Susceptibility to solidification cracking	Strong	None	Weak
Porosity	Shrinkage, blowholes	None	Blowholes, shrinkage, diffusion
Overlapping with heat treatment	No	Unlimited	Limited
Warping	Heavy	None	Light
Principle types of	Butt, lap	Flat (butt, lap, tapered plug in	Butt, lap

joint	socket, between cylinders, spherical, curvilinear)		
Joining in hard-to-reach places	Limited	Unlimited	Limited
Product precision	Low	Fairly high	High
Disassembly of joint	No	No	Yes
Vibration survival	Low	Very high	High
Corrosion resistance	Satisfactory	Fairly high	Low
Strength	Close to that of parent metal	That of parent metal	That of braze
Air pollution and radiation emission	Yes	No	Yes

Source: Ref 1

When HIP diffusion bonding is compared with conventional diffusion bonding, there are several advantages, namely (Ref 1):

- Conventional diffusion bonding uses uniaxially applied pressure, which limits the geometry of the joint. For HIP, complex, shaped surfaces can be bonded together.
- Applied pressure must be low to prevent macroscopic plastic deformation with conventional diffusion bonding. For HIP, the plastic deformation is on the microscopic scale and therefore can be performed at a higher temperature.
- Powder and porous bodies can be simultaneously densified to a substrate with HIP diffusion bonding.

Encapsulation Methods. As with consolidating P/M compacts, components for HIP diffusion bonding must be encapsulated to ensure a differential pressure exists to create the driving force for bonding. One method is to simply weld the contact area between the two parts. Another is to seal only the contact area with a container component. Yet another is to encapsulate part or all of the substrate. Figure 25 shows the steps used to HIP diffusion bond a powder material with a solid substrate material (Ref 21).

Fig. 25 HIP diffusion bonding of powder to solid. Source: Ref 21

HIP Parameters. The choice of HIP parameters is usually based on metallurgical and economic consideration. Diffusion bonding is typically enhanced by increasing temperature and pressure. The temperature will generally be 50 to 70% of the melting point of the lowest-temperature material in the system. The pressure shall be sufficient to close up all pores along the bond line as well as internal pores and pores created by interdiffusional pores (i.e., Kirkendall effect). The time at temperature should be kept to a minimum to decrease cost and potentially avoid any deleterious effects from formation of brittle intermetallics, excessive grain growth, and secondary recrystallization.

Use of Interlayers. An interlayer is sometimes used between surfaces to prevent the formation of deleterious brittle compounds and/or alleviate stresses due to thermal expansion mismatch. As described previously, interlayers must be compatible with each material that it contacts. The thickness must be sufficient enough to accommodate cooling stress and not so thick that the bond strength is decreased by the presence of a thick ductile interlayer. A 100 μm thick Ni-Cu-Ni interlayer was successfully used as a carbon diffusion barrier between BG42 tool steel and 17-4 stainless steel and a cobalt-base alloy and 17-4 stainless steel, thus maintaining a martensitic structure up to the interface (Ref 33). Another interlayer application was the use of refractory metal and ceramic interlayers during the fabrication of as-HIP foil of highly alloyed material (e.g., titanium, nickel, and niobium alloys) (Ref 34).

Applications. There have been several applications of bimetallic components that have utilized the HIP diffusion bonding process. Examples include:

- Corrosion-resistant alloy 625 clad to the interior of F22 steel (Fig. 26)
- Wear/corrosion resistant alloy (MPL-1) clad to 4140 steel (Ref 21)
- Alloy CPM 9V clad on the exterior of 4140 cylinders (Ref 20)
- Twin extrusion barrel internally clad with CPM 10V against 4140 steel (Ref 21)
- CPM 10V clad to low-carbon steel for segmented screws used inside the plastic extrusion barrel (Fig. 27)

Fig. 26 Low-alloy steel HIP clad with alloy 625 for corrosion resistance

Future Developments

Applications using HIP technology have evolved from diffusion bonding of dissimilar materials to consolidating encapsulated powder and sealing microporosity in castings. Hot isostatic pressing technology is continuing to grow with diversification into new areas. These areas include equipment improvements, mechanistic modeling of material undergoing HIP, and new applications of HIP.

Refinements of Batch Processing. One equipment refinement that is generating interest is "quick cool" or "HIP quenching." After the HIP cycle hold, furnace cooling on a cold-walled vessel can take several hours with cooling rates of about 100 °C to 200 °C/h depending on the vessel and size of the load. By utilizing a flow device (Ref 15) and the introduction of cold gas into the hot gas, the convective cooling is dramatically increased. One portion of the gas is forced to the outside of the thermal barrier for cooling while the other portion is circulating inside. To achieve the desired cooling rate, the proportion of the hot and cold gas can be computer controlled. The major driver of this technological improvement is to increase productivity, which ultimately increases capacity and decreases costs. In addition, there may be metallurgical enhancements of some materials, thus potentially eliminating some downstream processing steps.

HIP Modeling and Microstructure Prediction. As described in the article "Principles and Process Modeling of Higher Density Consolidation" in this Volume, there has been much work devoted in the 1990s (Ref 13) to predicting dimensional changes during hip via continuum mechanics/finite element modeling. To predict shrinkage changes, an understanding is needed of the anisotropy of consolidation brought about by the complex interrelationships between the properties of the P/M and container materials as a function of temperature, density, and part geometry. With the development of the constitutive equations for the particles and powder aggregates to predict shrinkage, the underlying mathematics now exist to also predict microstructure of the HIP product (Ref 11, 12, 35). With computational power continually increasing at an affordable rate and material property characterization available from hot triaxial compaction tests (Ref 36), the ability to predict grain size (Ref 37) and other microstructural features (Ref 12, 38) may soon be possible.

HIP Modeling and Closing Porosity in Spray Formed Billets. To compete with ring-rolled products, there has been some interest in producing large nickel-base superalloy rings via spray forming followed by HIP (Ref 39, 40). For this process, metal is nitrogen-gas-atomized onto a low-carbon steel substrate to form a partially dense preform (typically, >90%). The resulting microstructure is determined by amount of liquid in the spray before impact and amount of liquid on the top surface of the deposit. As the amount of liquid is increased, an increase in deposit yield is observed (i.e., atomizing into a swamp); however, these slower solidification rates typically lead to a coarser grain size. If a finer grain

size is required, the amount of liquid is decreased, but this typically increases the amount of unusable overspray that cannot be recycled due to increased nitrogen content concerns. Hot isostatic pressing of the preform increases the density to nearly 100% density with some interconnected surface porosity present.

Extrusion of Metal Powders^{*}

B.L. Ferguson, Deformation Control Technology, Inc.; P.R. Roberts, American Superconductor Corporation

Introduction

EXTRUSION is a relatively recent addition to metalworking as noted in a historical survey of extrusion and the development of the process (Ref 1). Notably, the inventive genius of Alexander Dick and the increasing availability of steels that could withstand higher working temperatures opened the way for the hot extrusion of copper alloys and laid the foundation for modern extrusion. Pearson and Parkins (Ref 1) and Lange and Stenger (Ref 2) have written comprehensively on the history, development, application, and mechanics of extrusion; these are recommended texts that provide an excellent background for understanding the process.

There are two main types of extrusion mechanisms, (a) direct and (b) indirect or inverted, as shown in Fig. 1. In direct extrusion, the ram pushes a workpiece forward through a die, causing a reduction in cross-sectional area of the workpiece. Conversely, in indirect extrusion, the workpiece remains stationary relative to the container and there is no friction between the workpiece and container. Both methods may be used to extrude metal powders, although direct extrusion is more widely practiced.

Fig. 1 Basic methods of extrusion. (a) Direct extrusion. (b) Indirect extrusion.

Powder extrusion provides a method to obtain a useful shape or form that may not be readily achieved by other means. It has been used to make seamless tubes, wires, and complex sections that would be difficult or impossible to fashion by any other process. Pioneering work in the extrusion of metal powders was conducted in the late 1950s to produce controlled ductility in beryllium, dispersions of nuclear fuels and control rod materials, and dispersion-strengthened aluminum (Ref 3).

The extrusion of metal powders occupies a special niche in extrusion technology for many reasons, which include:

- The ability to form shapes by extrusion from materials that are difficult or impossible to process by casting or working
- Improved properties and performance because of microstructural refinement and minimization of segregation that results from powder processing
- The dispersion of one species in another from the extrusion of powder mixtures
- The ability to form wrought structures from powder without the need for sintering or other thermal treatments
- Reduced extrusion pressures and wider temperature and ram velocity ranges for powder extrusion than for extrusion of cast billets

This article concentrates on direct extrusion processing where metal powders undergo plastic deformation, usually at an elevated temperature, to produce a densified and elongated form having structural integrity. Three main approaches to extrusion of powders are shown in Fig. 2. In the first instance where the principal material is poured loose into the extrusion container, the particle size is normally large. Lenel (Ref 4) mentions that this process is used to extrude magnesium alloy pellets (particle size 70 to 450 μm). A hot container supplies heat to the pellet charge, and extrusion is performed with no atmosphere protection.

Fig. 2 Hot extrusion methods for metal powders

The second method, shown in Fig. 2, relies on the use of a compacted billet as the extrusion workpiece. Precompaction is useful because a workpiece shape that can be handled is produced, supplying a form that is much easier to use and control in a manufacturing environment than loose powder, and compaction increases the density of the workpiece in comparison with that of loose powder. The higher density reduces the ram stroke and decreases the container length needed to produce the required extruded length. In this method, a powder that compacts readily is used; this type of powder has particles that are rough and jagged with multiple asperities and ragged protrusions, or a flake form. In loose form, such particles have low packing efficiency and a correspondingly low density, for example, 35 to 50% of theoretical. However, these particles can be pressed into a partially consolidated billet shape with densities of 70 to 85% of theoretical. This form is referred to as a "green" compact, and it has sufficient "green strength" to endure handling. Where greater resistance to crumbling during handling is needed, the porous compact may be sintered before extrusion. However, sintering is not a required processing step, and many materials are extruded without this additional processing. Alternatively, hot pressing may be used instead of cold pressing to produce the extrusion workpiece.

A more elaborate approach to powder billet preparation is that shown in the third variation in Fig. 2 and in more detail in Fig. 3, where powder is first partially densified directly in a can. This can may then be evacuated and sealed, as shown in Fig. 4, or it may be left open to the atmosphere. Canning is employed for the following reasons (Ref 5):

- Isolation of the principal material from the atmosphere and extrusion lubricants (clean extrusion technique)
- Isolation of toxic materials such as beryllium and uranium for safe handling
- Encapsulation of spherical and other difficult-to-compact powders to produce a billet form
- Improved lubricity and metal flow at the die interface by proper selection of the can material
- Isolation of the principal material from the extrusion die and region of highest shear, which is an important consideration for materials with limited ductility
- The ability to position powder and solid components within the can to produce unique and complex

shapes (this is a variation of the filled billet extrusion technique that is discussed below)

Fig. 3 Packing of powder in metal can

Fig. 4 Evacuation and sealing of powder extrusion billet. (a) Billet with evacuation tube leading to vacuum pump. (b) Billet with sealed tube

When purity must be maintained, canning of the powder, including evacuation and sealing as shown in Fig. 4, is an essential step. Billet preparation for critical applications, such as gas turbine engine components, requires that filling and evacuation be performed with great care and refined practice. Procedures may include clean-room container preparation and assembly, total isolation of powder from ambient air, evacuation at slightly elevated temperatures to drive off adsorbed gases from particle surfaces, and leak checking of sealed containers. The extruded product must be free from both prior particle boundary decorations and nonmetallic inclusions that degrade mechanical properties, especially fracture toughness and fatigue resistance.

With this introduction to the basic powder extrusion processes, it is pertinent to review briefly the mechanics of extrusion and to examine specific extrusion practices for the production of wrought material from powder stock.

Mechanics of Powder Extrusion

Typical pressure curves for direct and indirect extrusion of a conventional billet are shown in Fig. 5. Initially, pressure increases linearly with ram displacement as the billet upsets to fill the container and reaches a maximum value as the workpiece begins to flow through the die; this is known as the breakthrough pressure. Steady state is achieved as the ram advances. For direct extrusion, the pressure falls as the ram stroke continues, reflecting the decreasing frictional resistance as the contact area between the billet and container decreases. For indirect extrusion, the extrusion pressure is fairly constant because there is no relative movement and thus no friction between the billet and container. At the end of the stroke, a sharp rise in pressure may occur because of the increasing resistance to radial inflow of the residual billet material. This latter effect may be overcome by placing a follower of some disposable material between the billet and ram to ensure that the billet clears the die.

Fig. 5 Extrusion pressure as function of ram travel

Extrusion pressure is a function of material flow stress, temperature, friction, strain rates, and deformation. Sachs and Eisbein (Ref 6) proposed an extrusion constant K such that:

$$P = K \ln R \quad (\text{Eq 1})$$

where P is the required extrusion pressure, R the extrusion ratio A_i/A_f , which is the ratio of initial cross-sectional area to final cross-sectional area, and K the extrusion constant for the material.

The extrusion constant K combines flow stress, friction, and redundant work into one parameter. While K is dependent to some extent on particular extrusion practices, reported extrusion constant values may be broadly applied as an aid to the design of useful extrusions. Extrusion constant values for a variety of engineering materials are shown as a function of temperature in Fig. 6. These curves were compiled from many runs on various extrusion presses (Ref 7).

Fig. 6 Extrusion constant versus temperature for some engineering alloys

It is clear from Fig. 6 that K decreases with temperature, and it follows that hot extrusion requires lower extrusion pressure than cold extrusion. The effect of temperature on K is similar to the relationship between flow stress and temperature. For cast billets, K increases as the ram speed is increased, which reflects the relationship between flow stress and strain rate. Dieter (Ref 8) mentions that a tenfold increase in ram speed results in a 50% increase in the required extrusion pressure, as a general rule for cast/wrought billet stock.

In evaluating the dependency of extrusion pressure on temperature and strain rate, adiabatic heating, heat generated by friction, and conductive heat transfer must be taken into account. Proper extrusion speed and temperature are usually determined by experience, following general guidelines shown schematically in Fig. 7. This figure shows the relationship between pressure and temperature on deformation level and between strain rate and temperature on allowable deformation

level. Together these relationships define an allowable range of processing conditions. With improved mathematical modeling capabilities, analytical methods may be used to verify selected extrusion conditions by computer simulation.

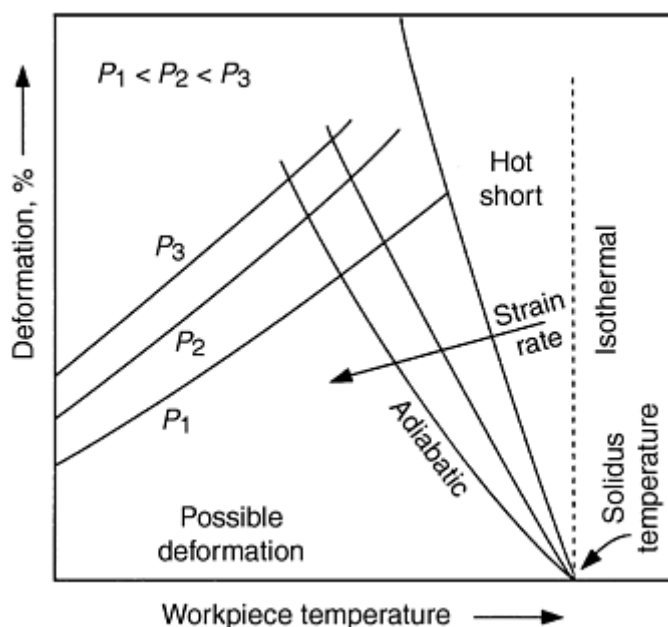

Fig. 7 General effects of pressure, strain rate, and temperature on allowable deformation. Source: Ref 8

The discussion up to this point has only dealt with extrusion of cast/wrought billets. Extrusion of powder is mechanically different from extrusion of cast material. First, the billet stock for powder extrusion is usually compacted powder, with a density of ~ 75 to 85% of theoretical, or loose powder, with a density of 55 to 65% of theoretical. The presence of porosity and unbonded particulate changes the deformation mechanics significantly from that of cast/wrought material (Ref 3, 4, 5, 9, 10, 11, 12, 13, 14, 15, 16).

Pressure versus ram displacement curves are shown in Fig. 8 for the extrusion of cold compacted Al-Mg-Si (as supplied) powder billets at two ram speeds (Ref 13). For comparison, a pressure versus displacement curve for a similar cast material is also shown. The initial pressure buildup is considerably different for powder and cast billets. Pressure increases linearly for a solid billet as it upsets to fill the container. For a powder billet, the pressure rise during the upsetting stage is both nonlinear and more gradual than for a cast billet. During this pressure buildup, the powder is being compacted to nearly full density. While densification is substantially completed before the onset of extrusion, powder particles remain poorly bonded and mechanical strength is low. The material does not attain measurable strength and ductility until it has traversed through the extrusion die and been subjected to a sufficient level of shear deformation. Shear deformation results in the formation of metallurgically sound bonds between particles and produces a "wrought" product.

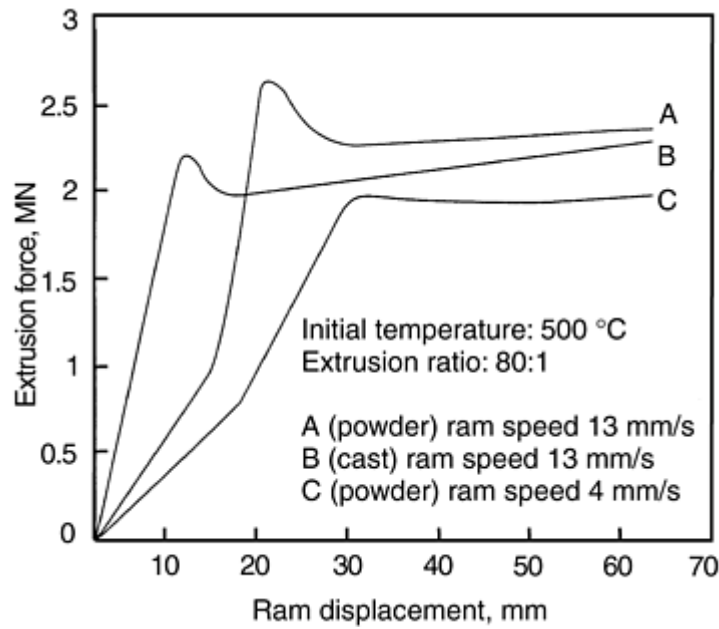

Fig. 8 Load versus displacement curves for extrusion of Al-0.33Mg-0.12Si (final) alloy powder (containing alumina) and cast billet. Source: Ref 12

In practice, back pressure or resistance must be provided initially to aid densification of the powder in the billet nose before the extrusion. Therefore, a solid nose or a pad is placed in front of the powder billet. The pad may also provide a measure of lubrication. Extrusion of green compacts without such assistance to densification has resulted in gross surface cracking (Ref 9). For loose powder, the pad is incorporated in the container design.

Experimental results for extrusion of compacted billets have shown that the extrusion pressure is less dependent on ram speed for powder than for cast material (Ref 9). Therefore, strain rate is of less importance in powder extrusion than in extrusion of cast materials. The major reason for this is thought to be the overwhelming influence of porosity and the formation of particle bonds during powder deformation as opposed to the importance of flow stress on extrusion pressure for cast/wrought material. However, the breakthrough load for powder extrusion remains a function of strain rate and increases as ram speed increases (Ref 13).

Theoretically, the pressure P needed to extrude a billet through a die has three components:

$$P = A + B \ln R + C \quad (\text{Eq 2})$$

where A is related to redundant work, $B \ln R$ is the homogeneous work of deformation, C is the work needed to overcome friction, and R is the extrusion ratio.

For cast billets, Eq 2 is generally normalized by the material shear yield strength Y , as follows:

$$P/Y = a + b \ln R \quad (\text{Eq 3})$$

For powder billets, Eq 2 does not hold because the yield strength of the material changes dramatically as it flows through the extrusion die. For extrusion of powder, Eq 4 is preferred:

$$P = a' + b' \ln R \quad (\text{Eq 4})$$

In Eq 4 the term a' relates to redundant work and b' relates to homogeneous work. Table 1 contains experimentally determined constants a' and b' for extrusion of several aluminum powder alloys and cast aluminum at various reduction

ratios. The ratio a'/b' indicates the relative importance of redundant work, and it is clear that redundant work is much more significant in powder extrusion than in extrusion of cast stock. For powder extrusion, the redundant work term includes the process of forming cold welds between particles, breaking welds, and rewelding, while particle deformation is occurring. Sheppard proposed that the high proportion of redundant work in extrusion of powder contributes to the formation of sound particle bonds and eliminates the need for subsequent sintering (Ref 9, 10, 11, 12, 13, 14, 15). A minimum level of extrusion reduction must be exceeded in order to produce sound bonds, with 9 to 1 being a typical minimum reduction ratio for extrusion of spherical powders.

Table 1 Extrusion pressure and reduction ratio relationships based on $P = a' + b' \ln R$

Powder, wt%	Extrusion relationship	a'/b'
Al-3.6Mn-0.95Al ₂ O ₃	$P = 555 + 252.5 \ln R$	2.2
Al-2.4Fe-1.09Al ₂ O ₃	$P = 475.5 + 252.5 \ln R$	1.9
Al-1.9Al ₂ O ₃	$P = 277.5 + 252 \ln R$	1.1
Al-0.26Al ₂ O ₃	$P = 187.5 + 252.5 \ln R$	0.74
99.5Al (cast)	$P = 20 + 287.5 \ln R$	0.07

Source: Ref 14

Because the amount of redundant work that accompanies powder extrusion is a function of the number of welds formed, the extrusion pressure component related to redundant work is a function of particle size and size distribution. Fine powder, which has a higher surface area per unit volume than coarse powder and thus forms more welds, requires a higher extrusion pressure than coarse powder (Ref 9, 10).

Sheppard and coworkers have extended the upper-bound analysis to study powder extrusion (Ref 9, 10, 11, 12, 13, 14, 15). A typical deformation zone geometry, as defined by the upper-bound method, and the accompanying hodograph are shown in Fig. 9. This analytical technique is reviewed thoroughly by Sheppard et al. (Ref 9, 11, 12) and Avitzur (Ref 17).

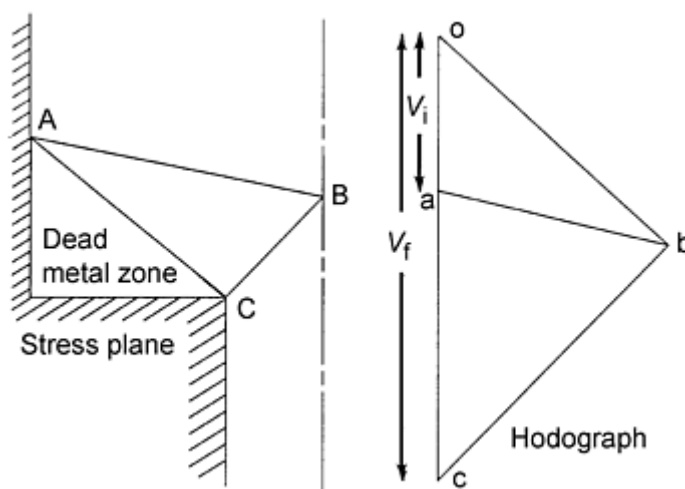

Fig. 9 Typical deformation zone and hodograph for upper bound modeling of extrusion of powder billet. oa , initial velocity V_i ; oc , final velocity V_f . Source: Ref 11

For canned powders, an important consideration is the nature of the flow of material through the die. Modeling studies of material flow during extrusion have been conducted using such diverse materials as colored wax (Ref 18), mixtures of chalk, beeswax, and petroleum jelly with added coloring (Ref 19), and Plasticene (Ref 20). Green (Ref 20) has shown that a good working analogy to hot metal is afforded by such simple substances. Sachs and Eisbein (Ref 6) used small cylindrical tin billets that were sectioned longitudinally, with a grid scribed on the flat surface. The cylinder halves were held together and forced through conical dies of different included angles. The flow patterns were revealed in the

distortion of the grid in a range of partial extrusions, as shown in Fig. 10. When the die is flat (180° included angle), a zone of dead metal forms in the front corner of the press container and flow at the periphery of the billet occurs by shear over a conically defined surface (Ref 6, 17). As the included cone angle decreases from the extreme case of the flat die, flow becomes more streamlined and the ogival characteristic of the transverse grid lines becomes less pronounced. Conical dies are used for the extrusion of canned powder to avoid the formation of a stagnant flow zone and the associated turbulence and shear experienced with flat dies. Conical dies work well with included angles of 90 to 120° , and good streamlined flow is obtained when there is effective lubrication and closely fitting extrusion tooling working in conjunction with the die. Canned extrusions have been limited to the fabrication of simple shapes such as circular sections, tubes, flats, and so forth, because of the necessity for a conical approach to the die land. Advances in analytical modeling of extrusion and in die-making techniques permit the extrusion of more complex cross sections.

Comparison of Extrusion with Cast and Powder Billets. Comparison of analysis results for cast billets with results for powder billets has led to some fundamental conclusions:

- Extrusion of powder is a continuous process of welding particles, breaking welds, and rewelding as particles are rearranged and deformed. Densification is nearly completed in the extrusion container, before actual extrusion. However, the achievement of adequate structural integrity is dependent on shear deformation as the compacted powder is forced through the extrusion die.
- The presence of porosity and unbonded particles in the extrusion billet produce a deformation zone much different from that of the extrusion of a cast billet. The extrusion pressure for powder is much lower than for extrusion of a cast billet of similar composition. This results from the development of final properties in the powder extrusion only after the material has traversed through the deformation zone. Conversely, a cast billet exhibits higher flow stress before extrusion.
- The amount of redundant work is dependent on the surface area/volume ratio of the powder. As the powder particle size decreases, this ratio increases, and a greater number of welds are required for bonding. Consequently, the amount of redundant work increases.

Extrusion of Metal Powders*

B.L. Ferguson, Deformation Control Technology, Inc.; P.R. Roberts, American Superconductor Corporation

Powder Extrusion Practice

Extrusion of canned powder can be considered a special case of filled-billet extrusion. Filled billet refers to an extrusion billet or workpiece that contains more than a single material. For canned powder, there are at least two components, the powder and the can. More typical filled-billet workpieces, discussed below, may have two or more different materials arranged in a geometric array within a container. In the extrusion of a filled billet, it is important that the materials of the various components are metallurgically compatible. A careful review of their mechanical and physical properties will avoid serious pitfalls, such as:

- The formation of eutectic phases
- Gross thermomechanical mismatch at extrusion temperature
- Excessive interdiffusion of can and workpiece material
- Extreme difficulty in removing the can material from the extruded product

These considerations are discussed in more detail by Roberts (Ref 5).

In the treatment of powder-filled billets, a further concern is the relative deformation of the canister and the powder contents during the upset of the billet. The can may buckle in the press container if the resistance of the contents of the container to upsetting is low in comparison with the buckling resistance of the can. The folds that result from buckling will carry through into the extruded rod as a defect. This is shown schematically in Fig. 11 and is discussed by

Loewenstein et al. (Ref 3). The density of the powder and the wall thickness of the can must be balanced to avoid buckling. One solution to this problem is to use a ram that penetrates the canister, densifying the powder without axially loading the canister wall. This is shown in Fig. 12. Alternatively, the powder billet may be precompacted as in Fig. 3 or, more suitable for spherical powders, it may be jolted or vibrated during filling to increase the density of powder packing.

Fig. 11 Folding of metal can with loosely packed powder

Fig. 12 Penetrator technique to avoid folding of can

Because densification is largely completed during the upsetting stage, extrusion of the canned powder can be thought of as coreduction of two materials having a core-sheath relationship. The relative resistance to deformation of the two materials must be balanced in order to avoid severe instabilities in plastic flow and possible fracture of either the sheath (can material) or core (densified powder workpiece). Avitzur has presented an analysis used to predict conditions that cause fracture in either the cladding or the core based on the following parameters (Ref 17, 21):

- Overall reduction ratio
- Extrusion die angle
- Volume fraction of each material
- Relative flow stress of each material friction

Roberts and Roberts (Ref 22) cite examples and conditions for successful coreduction of metals by hot extrusion and cold wire drawing.

The extrusion constant K defined in Eq 1 can be used to design billets for either powder extrusion or extrusions of various arrays of solids within a can. The force required to coextrude a billet containing more than one material can be calculated by a rule of mixtures approach:

$$F = (K_1A_1 + K_2A_2 + \dots K_iA_i) \ln R \quad (\text{Eq 5})$$

where the various K and A terms are the respective extrusion constants and the cross-sectional areas of the components that sum to A , the cross-sectional area of the press container. A general guideline is to balance the required force components by selection of container material (K term) and relative area fractions of workpiece and container (A terms) for the required reduction ratio.

While precise matching of flow stress values is not practical, it serves as a simplified guide. Gross mismatch of flow stress values usually results in unstable metal flow manifested by large variations in component sections along the extruded rod. In extreme cases, discontinuities may occur. Figure 13 shows the results of uneven reduction obtained from the coextrusion of seven cast rods of a cobalt alloy (Coast Metals alloys No. 64, Co-30Cr-20W-1V-5Ni-1C) set in a drilled billet of low-carbon steel. The billet geometry is shown in Fig. 14. The reduction ratio and temperature used for this trial were 12 to 1 and 1065 °C. The cobalt alloy rods were exposed by etching away the steel matrix in hot dilute nitric acid. It is interesting to note that while this attempt to coextrude cast rods in a mild steel matrix was unsuccessful, much better results were obtained when the same cobalt alloy was introduced as -80 mesh (<175 μm) powder.

Fig. 13 Attempt to coreduce cast cobalt alloy rods in low-carbon steel matrix. See Fig. 14.

Fig. 14 Low-carbon steel drilled billet with seven cobalt alloy rods introduced (see Fig. 13). (a) Longitudinal section B-B'. (b) Cross section A-A'

In certain instances, trials have been conducted successfully that violate the simple rule of matching flow stresses. An example involving a thin cladding of 10 carat gold alloy over a thin-walled tube of Inconel 600 with a central core of nickel rod and all contained within a steel can, extruded successfully with proportionate and uniform component sections in the extruded product (Ref 5). Had the components been presented in the same amounts but with a different geometry of distribution, such as in the form of parallel rods of these materials, much less uniform coreduction of section could be expected. The exact influence of component distribution is not well established, and a considerable amount of art is required for proper billet design.

Extrusion of Metal Powders*

B.L. Ferguson, Deformation Control Technology, Inc.; P.R. Roberts, American Superconductor Corporation

Materials Processed by Powder Extrusion

The early development of powder extrusion processes concentrated on the search for materials with improved high-temperature performance and the development of methods for encapsulating and handling toxic materials. The use of an outer skin or container and a particulate workpiece also stimulated metalworkers to examine powder extrusion as a means for forming structural components from difficult-to-work material. These basic uses of powder extrusion still drive the industry. Examples are given below to illustrate the advantages of coupling powder metallurgy with a large deformation process such as extrusion for the production of unique materials.

The most critical applications of extruded powders today involve extrusion of canned material. The primary applications include tooling and aerospace markets, where the materials include tool steels, superalloys, titanium, copper, and aluminum. Common to the products produced from these materials are the requirements for structural integrity and high performance. These attributes are achieved only by proper powder processing and controlled extrusion practices.

It is well established that shear deformation in combination with pressure fractures oxides and other films on particle surfaces and produces sound bonds between particles. For this reason, extrusion of aluminum powders, which have substantial oxide contents, is common practice. On a more subtle scale, extrusion of "clean" powders, for example, with oxygen levels below 100 ppm, relies on the same mechanism to produce particle bonds of high integrity. Here, the environment within the sealed container is critical to the success of the process.

Thus far, little mention has been made of the mechanical properties or microstructure of the extruded products because the process may be used to form a wide variety of materials for many applications. A discussion of the versatility of the extrusion process as it applies to powder follows.

Dispersion-Strengthened Materials. In the ongoing search for materials with improved properties at elevated temperature, sintered aggregates of metals and nonmetals were investigated. This development started at the laboratories of Aluminium Industrie AG in Switzerland in 1946 as an accidental discovery when experiments to make extruded Al-C wires from powders showed much higher strengths than expected. The oxide skin that surrounds each aluminum powder particle inhibits sintering, and the result is a weak, brittle sintered product. However, this skin is easily broken to expose clean metal surfaces that bond metallurgically during extrusion deformation to produce sound products. Furthermore, extrusion tends to fragment and redistribute the oxide.

Subsequently, Irmann (Ref 23) reported details of a commercially manufactured material that came to be known as sintered aluminum product (SAP). Irmann's development of SAP encouraged further research in the 1950s and 1960s. A good account of the processing details and enhanced mechanical properties developed in the original SAP materials is found in Ref 24. Metallic systems with nonmetallic dispersion phases studied intensively included copper, cobalt, iron, nickel, silver, gold, platinum, and lead, using dispersions of oxides, carbides, and nitrides. Zwilsky and Grant (Ref 25) mixed electrolytic copper with fine alumina; pressed, sintered, and extruded rods were swaged; and it was found that recrystallization was affected significantly. A 10% addition of a 0.3 μm alumina to -325 mesh (<45 μm) copper powder so processed was found to suppress recrystallization completely and retain useful hardness up to 1000 °C. Cremens and Grant (Ref 26) mixed very fine alumina with fine carbonyl nickel. Pressed, sintered, and extruded rod stock showed a sevenfold increase over pure nickel for stress rupture at 100 h. In all of these experiments, extrusion was the primary densification process. Ansell (Ref 27) suggested a mechanism whereby the supply of dislocation sources was diminished by extrusion to explain the delay in the onset of creep and the often erratic creep behavior in these early oxide-dispersion-strengthened materials. He further suggested that extrusion or rolling may be essential manufacturing steps for these products.

Oxides of aluminum, magnesium, thorium, and the rare earths, such as yttrium, are generally preferred as dispersion phases because they are hard and stable at high temperatures. Nickel strengthened with a dispersion of thoria is an early example of these products. These early materials have been superseded by more well developed and precisely controlled dispersion-strengthened materials in recent years.

The main methods of producing current dispersion-strengthened metals are mechanical alloying and chemical reaction, for example, internal oxidation (Ref 28, 29, 30, 31, 32, 33, 34, 35). Both of these techniques are based on powder metallurgy as a means of producing a uniform distribution of fine dispersoids, and both involve extrusion as the primary consolidation method. Examples of these materials are presented below.

Commercial grades of oxide-reinforced copper are available (C15715 with 0.3 wt% Al_2O_3 and C15760 with 1.1 wt% Al_2O_3) in wire and rod form produced from extruded bar (Ref 32). Primary applications include spot welding tips that require high electrical conductivity and resistance to deformation at elevated temperature. The oxide in this P/M product is produced by internal oxidation, and it is redistributed during the large area reduction of the extrusion process. At high temperatures, the material extrudes easily, and the extruded bar may be drawn to large reductions in section without intermediate annealing steps. Consequently, the product is fine grained with high strength and yet maintains electrical conductivity close to that of pure copper. The key to achieving a high elevated-temperature strength is the fine size (3 to 12 nm) and uniform spacing (50 to 100 nm) of the alumina dispersoid. The combination of powder metallurgy and extrusion provides these metallurgical features.

In the original aluminum SAP alloys, the oxide content was typically 12 to 15 wt%; high fractions of dispersoid were required because of the relatively coarse and uneven distribution. Commercial dispersion-strengthened aluminum alloys currently available contain a significantly lower dispersoid content, that is, <5 wt%, but these alloys are much more effective than SAP alloys because of the fine size and the uniform distribution of the dispersoid (Ref 29, 30, 31). IN-9021 (Al-4.0Cu-1.5Mg-1.2C-0.75O) and IN-9051 (Al-4.0Mg-0.7C-0.60O) mechanically alloyed aluminum alloys contain oxide and carbide dispersions of less than 5 wt%. Typical processing involves hot consolidation to densify the powder, followed by hot extrusion. Extruded forms may be rolled, swaged, or drawn.

Nickel alloy Inconel MA754 (Ni-20Cr-1Fe-0.3Al-0.5Ti-0.6Y₂O₃) is used for gas turbine vanes and is required to have a strong texture to provide good thermal fatigue and creep resistance (Ref 28, 33). Mechanically alloyed powder, attrited in a high-energy ball mill, is thermomechanically processed via extrusion, hot rolling, and zone annealing to provide a strong <100> grain-axis alignment parallel to the working direction in order to impart the desired properties. The directional working of extrusion and subsequent rolling or plane strain forging produces the microstructure needed to form a large, elongated grain structure during zone annealing to provide directional recrystallization.

Dispersion strengthening of silver by particulate cadmium oxide was developed to produce electrical contacts having improved resistance to arc erosion, low contact resistance, and antiwelding characteristics (Ref 34). While the CdO content may be high in comparison with the dispersoid content in copper (e.g., up to 25% CdO in Ag versus 1% Al_2O_3 in copper), the thermal and electrical conductivities of these materials are excellent. It is common practice to make rod stock in this alloy by pressing, sintering, and extruding coprecipitated or preoxidized powders or powder blends.

Platinum and its alloys, used in special furnace windings, heater tapes, and structural shapes that are required to operate close to their melting points, are fabricated from powder blends with thoria, yttria, or zirconia dispersions (Ref 35).

A dispersion-strengthened titanium powder produced by the plasma rotating electrode process (PREP) was consolidated by extrusion (Ref 36). The chemistry of this alloy was a modification of Ti-6246 with an erbium addition (Ti-6Al-2Sn-4Zr-2Mo-0.1Si-2Er). The rare earth was internally oxidized to Er₂O₃ in a fine dispersion of particles where the maximum size observed was 50 nm. The principal intent of this exercise was to obtain fine dispersoids in a rapidly solidified powder material. It is interesting to note that powder consolidation by extrusion did not compromise the useful metallurgical characteristics developed by rapid solidification processing of this material.

These are some of the many examples of materials that have had their properties significantly extended by dispersions, and extrusion is most often used to consolidate the precursor powder blends into bar form that may then undergo further working. Extrusion serves to densify the product and impart a uniform longitudinal and transverse distribution of the dispersed phase together with the development of preferred orientation in the metal matrix that assists further deformation by wire drawing or other methods for the reduction of cross section.

Superalloys. Extrusion is commonly used to consolidate superalloy powders into billet stock for subsequent forging operations (Ref 37, 38). Typical processing includes containerization of gas-atomized powder, hot compaction by forging to around 94% of theoretical density, and extrusion to full density at a reduction ratio of 5-7 to 1. After can removal and inspection, the extruded bar is sectioned into billets for forging. Extrusion is relied on to produce strong metallurgical bonds between powder particles by virtue of shear deformation and high pressure across particle interfaces. In addition, extrusion produces a fine grain size that facilitates forging. This is especially important in isothermal forging processes.

Superalloy powders are susceptible to carbide formation on particle surfaces because of the presence of strong carbide-forming elements. In high-carbon superalloys, such as René 41, carbides are relied on to provide grain size control and to enhance mechanical properties (Ref 38). In such cases, the extrusion temperatures must be controlled to avoid gross carbide formation before extrusion. High extrusion preheat temperatures result in excessive carbide formation along prior particle boundaries in the extruded form that reduces transverse strength and ductility to unacceptable levels. Furthermore, grain growth is limited to the powder particle size during high-temperature solution annealing, which results in low elevated-temperature properties. The use of a low extrusion temperature reduces the amount of particle-boundary carbide formation significantly. Subsequent solution annealing temperatures can then be controlled to produce either a fine-grained microstructure with more uniform properties or a large equiaxed microstructure with good elevated-temperature properties.

Unintentionally introduced organics are often the source of undesirable prior particle boundary decorations. Low-deformation consolidation processes, such as hot isostatic pressing, do not deform particles sufficiently to rupture surface films and present virgin surfaces for bonding. Extrusion, by virtue of its large deformation, effectively removes the deleterious effect on performance of such contaminants when potentially harmful particle surface films are fragmented and isolated within the product.

In a novel application of superalloy powder filled billet extrusion, a method has been developed that relies on a powder-solid configuration for fabricating thin-weld filler wire that is used for critical repair of turbine engine blades and vanes. Weld wire has been made in the cobalt and nickel alloys listed in Table 2; adjustment of component dimensions and process parameters were derived to provide wire at various diameters. While the technology is proprietary, the basic process is well known. Arrays of tubes filled with clean spherical powder made by PREP are packed within a larger tube that is capped, evacuated, and sealed. Because the billet contains both solid and powders, billet design must compensate for the differential in their packing densities and the effect this will have while the billet undergoes upset and the powder finally comes to full density. PREP powder is preferred because it produces slag-free welds due to virtual absence of nonmetallic contaminants. In addition, PREP spherical powders pack reproducibly to a density of 65% because particles are free of satellites. The number of tubes processed and the high aspect ratio preclude ramming or step compaction for powder fill. The billet is extruded to a diameter calculated to contain the desired wire diameter within the resultant rod. Weld wires are ultimately released from the rod by immersion in a reagent bath that attacks the container matrix but is inert to the weld wire. The cross section of a weld wire extrusion billet is shown schematically in Fig. 15. After extrusion, the rod section contains an array of evenly spaced wires consolidated to full density. The wire sections are not perfectly circular, but the total variation in cross-sectional area from wire to wire and along the length of any wire does not exceed 5%. An example of an extrusion section and some short samples of released wires are shown in Fig. 16.

Beryllium. Extrusion of beryllium serves as an excellent example of processing a toxic, difficult-to-work metal into useful structural shapes. Beaver and Wikle (Ref 39) have reported comprehensive mechanical properties for beryllium. This metal has a hexagonal close-packed crystal structure and shows the development of a considerable degree of anisotropy when hot-pressed compacts are hot worked by extrusion. Most notably, the ductility is enhanced in the working direction. Gelles et al. (Ref 18) described the texture developed by extrusion, which imparts the increased elongation properties in the extruded direction. Basal planes tend to lie parallel to the extrusion axis with the $\langle 1010 \rangle$ crystallographic direction aligned. Fracture occurs by cleavage on the (1120) planes.

The much-improved properties obtained by extrusion have resulted in the application of beryllium tubing in the construction of communication satellites. The combination of low density (1.85 g/cm^3) with a high modulus of elasticity and an elongation in excess of 10% in the longitudinal (extrusion) direction make this an ideal structural material for this application.

Loewenstein et al. (Ref 19) have concluded that while it is possible to extrude beryllium uncanned using a glass lubricant, after the method of Ugine-Séjournet (Ref 40, 41), cracking will occur in any section more complex than a simple round rod, unless considerable precautions are taken, especially in die design. In view of the toxicity of the metal and its proclivity to oxidize, any advantage that might be realized in dimensional tolerance control via bare extrusion would seem to be outweighed by the hazards inherent to this practice.

Normal canning for beryllium powder billet construction is low-carbon steel, and this is readily removed by nitric acid when the beryllium core is to be released. The use of pressed powder rather than cast material as the precursor beryllium charge produces much finer grain size in the extruded product (Ref 4). The grain refinement attained contributes to the improved ductility in the extruded product. A detailed review of beryllium extrusion practices is given by Loewenstein (Ref 42).

Ferrous Alloys. Although powder extrusion is intrinsically an expensive process, benefits in improved homogeneity and a more direct route from melt to a wrought, consolidated structure are realized for a number of materials that, until recently, have been wedded to conventional practice involving casting and extensive hot working. An example is the manufacture of fully dense stainless steel tubes for critical service, such as in the production of urea carbamate. Two stainless steel compositions, referred to as 724L and 724LN, are manufactured by Nyby Uddeholm AB, Torshalla, Sweden, and the compositions are given in Table 3 (Ref 43). Inert gas atomized powder is canned in mild steel, with a packing density of 70% of theoretical being achieved. The powder billets are cold isostatically pressed to densify the powder further to 85 to 90% of theoretical density. These are then extruded at 1200 °C using a glass lubricant to reduce friction. Tubing is fully densified for extrusion ratios at or above 4 to 1. The use of powder extrusion to produce tubing and pipe seems to be a logical extension of the technology developed to produce rolled sheet directly from stainless steel and other powders.

Table 3 Stainless steel compositions (wt%) extruded into tube by Nyby Uddeholm AB

Some high-speed steels and tool steels have been fabricated into rod form via extrusion of powders in order to overcome segregation and alloy limitations encountered during ingot metallurgy processing. These powders possess fine uniform grain sizes and provide improved homogeneity when consolidated. Spherical powders from gas atomizing are canned, and the container is evacuated, outgassed, sealed, and then extruded, as in Fig. 4. Water-atomized powders may be cold pressed and sintered and then extruded, as in Fig. 2. Typically, these materials are extruded at 1100 to 1200 °C, and extrusion pressures of 620 to 690 MPa are required (Ref 44). The improved properties and microstructures justify the expense of hot isostatic pressing or extrusion, and in many cases savings are achieved when the extensive and energy-intensive operations of rolling and forging from large ingot sections are bypassed (Ref 45).

Composite Materials. Powder metallurgy coupled with extrusion offers a unique method of fabrication of both macro- and microcomposite materials. Erich (Ref 46) reviewed P/M applications for the production of metal-matrix composites. Advantages of a P/M approach in comparison with fusion metallurgy methods include low processing temperatures, unique materials, use of particulates or whiskers, and a wider capability for in situ formation of strengthening phases. Canned extrusions have been developed to fabricate powder mixtures and multicomponent systems that include arrays of both solid sections and powders. The reinforcing agent may be formed in situ by metallurgical reaction, or it may be introduced as a separate component during powder blending. Extrusion serves to align the reinforcing agent as well as consolidate the product.

Intimate mixtures of metal powders sealed within an evacuated canister have been extruded to make fibers having high aspect ratios. Rebundling of the primary extrusion into a second can, such as the method of Klein (Ref 47), is capable of producing filaments that are extremely fine. Depending on the application, these may be released by differential chemical attack or the composite structure formed may be the desired product.

Composite rods extruded from copper-niobium and copper-tin bronze-niobium powder mixtures are described by Foner (Ref 48, 49). These rods were drawn to wires using large section reductions, and the niobium particles were coreduced proportionally to small diameters and long lengths. Appropriate heat treatment of the bronze matrix wires resulted in the formation of the intermetallic compound Nb₃Sn having a β tungsten (A15) structure and excellent hard superconducting properties.

Although the superconducting filaments are long, they are discontinuous and therefore might not be expected to impart superconducting properties to the wire. However, extensive reduction in cross section will provide small filament

diameters with concomitantly finer interfilament spacing; a careful selection of particle sizes and section reduction schedules can provide interfilament spacing that is sufficiently small to permit electron pair tunneling as described in the theory of Bardeen et al. (Ref 50). The highly desirable fine diameters of the filaments together with this tunneling effect combine to produce excellent type II superconducting properties in the wire when it has received suitable processing. In addition to the fabrication of superconductors, this type of structure has other interesting applications. Foner (Ref 49) cites the possibility of making magnetic wire materials with this method, and indeed Levi (Ref 51) describes the formation of such wire structure involving filaments of iron in a copper matrix made by successive wire drawing and bundling steps. Although Levi uses neither powders or extrusion, the principle for successful coreduction of mechanically compatible materials is demonstrated, and structures offering a similar degree of reinforcement are feasible by the method of Klein (Ref 47).

Powder mixtures and powders mechanically mixed with chopped fibers can be extruded to produce fiber-reinforced structures. If all the components are metallic and possess similar flow strengths at the working temperature, they will elongate similarly as described by Roberts et al. (Ref 5, 22) and Klein (Ref 47). Ultimately, long fibers of one species in a matrix of another may provide a potent strengthening mechanism. Where the fibers and matrix have dissimilar elastic moduli, with that of the fiber being greater than that of the matrix, a complex stress distribution is developed during axial loading where the shear stress developed at the fiber/matrix interface and the axial tensile stress in the fiber may be represented graphically as shown in Fig. 17. Essentially, this figure shows that the fiber carries a tensile load produced by the shear stress developed along the fiber matrix interface. High allowable interface shear stresses permit the fiber to carry high axial tensile stresses. Shear stresses above some critical value at the fiber ends cause the matrix to deform plastically. To obtain the best use of the high-strength fiber, the plastic zone in the matrix should not extend from the fiber ends to its midpoint before the fiber is overstressed. A critical fiber length L_c is given by:

$$L_c = \sigma_f d / 2\tau_o \quad (\text{Eq 6})$$

where σ_f is the fracture stress of a fiber of diameter d in a matrix having a shear yield stress τ_o . When the fiber length is greater than L_c , composite failure occurs by fiber fracture and the system has developed its full strengthening potential. The critical aspect ratio L_c/d for fibers determines the minimum coreduction of section ratio; for all extrusion processing this will be the minimum value for R , the extrusion reduction ratio.

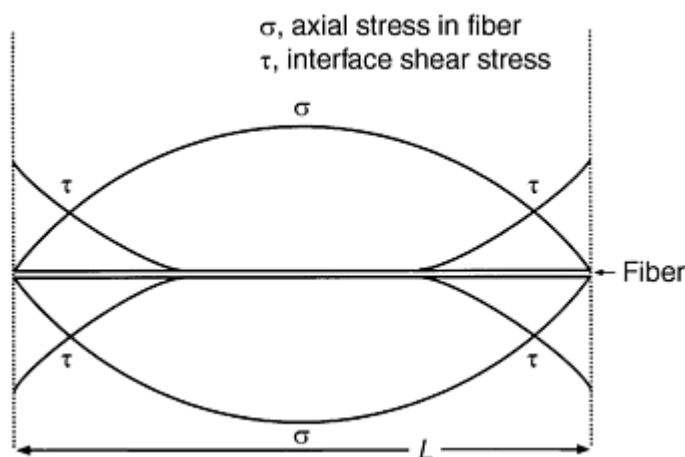

Fig. 17 Stress distribution along embedded fiber caused by uniaxial loading

Erich (Ref 46) cites an example of in situ composite fabrication by extrusion where tungsten powder was blended into a nickel powder matrix, compacted, and sintered. This blend can be sintered with a transient liquid phase technique. The sintered billet is then extruded and may be further worked by rolling or drawing to produce a composite with a microstructure of highly elongated tungsten grains in a nickel matrix. The resulting product is reported to equal the strength of a directionally solidified material of similar chemistry.

Extrusion of Metal Powders *

B.L. Ferguson, Deformation Control Technology, Inc.; P.R. Roberts, American Superconductor Corporation

Innovative Applications

Extrusion processes have been developed that serve special purposes or produce special products. In this regard, they may be considered to be innovative applications of the generic extrusion process.

A most ingenious development reported by Loewenstein et al. (Ref 3) involved the fabrication of materials that are usually considered to be difficult to work and are therefore not made in wrought forms. They cite the manufacture of chromium tubes and rods by a technique referred to as multitemperature extrusion in which the total extrusion billet is assembled rapidly at the press from separate components that have been heated to different temperatures. The parts exhibit a similar stiffness when the assembly upsets and is extruded so that good proportional coreduction and dimensional control are obtained. The success of the procedure depends in large part on the speed of the press and the skill of the press crew. The billet must be assembled and pushed rapidly before the effects of temperature decline and normal thermal conduction are significant. The method is shown schematically in Fig. 18. It is sufficiently versatile that it has been used to consolidate ceramics such as UO_2 heated into the temperature range 1750 to 2000 °C required for plastic flow and coextruded within a relatively cold steel can heated to 700 °C.

Fig. 18 Multitemperature extrusion of chromium

In an early development of electric lamp filament manufacture, tungsten powders mixed with organic binders or amalgams of mercury, bismuth, and cadmium were forced under pressure through diamond dies to make long, fragile "strings." These strings were subsequently heated to drive off the volatile components and to sinter the material in preparation for hot swaging, which was the major means of densification and section reduction (Ref 52).

Recently, the new technology of metal injection molding (MIM) has also emerged for making precision metal parts via injection molding and sintering (Ref 53, 54, 55, 56, 57). Mixtures of metal powders and polymers are forced under pressure into accurately sized molds so designed and proportioned as to provide a component that will shrink to the desired size and density after a sintering cycle. These developments, which initiated in the military and aerospace markets, now have moved into the wider civilian sphere of computer peripheral devices, business machines, automotive, and biomedical industries. Superalloys, stainless steels, and cemented carbides have been processed into precision metal parts using conventional screw and piston plastic injection molding equipment.

Metal powders and organic polymer mixtures have been coprocessed to provide high-performance plastic parts that are lighter than metal for the automotive industry. In other instances, the physical properties of the plastic, such as electrical conductivity, thermal conductivity, electromagnetic shielding, and static discharge capabilities, may be modified. Various workers have reported on the influence of particle shape, size, and distribution on the performance of these composites (Ref 58, 59, 60, 61). It is common practice to extrude or injection mold these materials because these methods provide continuous production and superior economics compared with compression molding.

Hydrostatic extrusion is a variant of the process that involves extrusion by the action of a liquid medium surrounding the billet being pressurized rather than direct axial loading by the ram. The liquid is pressurized to an extent that exceeds the flow stress of the billet material, and this is forced through the die. The principle was first expounded by Robertson (Ref 62) in 1894, but it was never applied until the work of Bridgman (Ref 63) and Pugh (Ref 64). The technique is

shown schematically in its simplest form in Fig. 19, where the extrusion exits into the atmosphere. Later developments have the extrusion passing from a high-pressure to a low-pressure chamber, which permits the processing of brittle materials that might otherwise break up at the die exit. The elevated pressure at the die exit in the two-chamber approach improves the ductility of the extrudant; however, in order for extrusion to proceed, the pressure in the first chamber must be increased over that which would be applied in the simple, single-chamber operation.

Fig. 19 Comparison of load profiles of simple hydrostatic extrusion and conventional extrusion. (a) Conventional. (b) Hydrostatic with conical die

Originally this was a cold process using oils as working fluids. More recent developments have used "quasi-fluids" operating at higher temperatures. These are actually solids that are much softer than the billet at the deformation temperature. Examples of these media are NaCl, CaF₂, and assorted glass formulations operating just below their melting points (Ref 65). It is reported that extrusion reduction ratios of 30 to 1 and 40 to 1 at pressures of 1240 and 2068 MPa, respectively, have been obtained with a tool steel and a high-speed steel at 1000 °C. At room temperature, the best reduction ratio attained was 3 to 1 (Ref 65, 66).

No specific references have been found to the application of this technique to metal powders, but with proper canning there is no obvious reason why canned powders could not be processed by this method.

Extrusion of Metal Powders*

B.L. Ferguson, Deformation Control Technology, Inc.; P.R. Roberts, American Superconductor Corporation

Continuous Extrusion Processes

The extrusion processes discussed up to this point are discontinuous; each involves a high-temperature, high-pressure operation performed on a single billet that is held in a closed-container system. Methods have been developed to provide continuous extrusion where the working principle employed involves driving a continuous supply of stock up to the die orifice by frictional gripping forces (Ref 67, 68, 69). The die is positioned at the far end of an open chamber admitting the continuous material feed. An ingenious method for making wires developed by Western Electric Company drives the feedstock with viscous drag forces exerted by a pumped viscous fluid (Ref 70, 71).

The "Conform" process (Fig. 20) achieves 160 to 1 reduction ratio in aluminum where 9.5 mm diam feedstock is driven by frictional contact with a grooved wheel up to a die arrangement to produce 0.75 mm diam wire (Ref 68). The machine capability to generate the wire at an exit speed of 3540 m/min was considered to be too fast for conventional spooling equipment. Pardoe (Ref 69) mentions that two of three developed Conform machines can accept either powder feedstock or rod stock. In this manner, either loose powder or compacted slugs may be fed into the machine.

Fig. 20 Conform continuous extruder

Materials processed have included commercially pure aluminum and copper, alloys of aluminum, and oxide-dispersion-strengthened aluminum and copper. Feedstock forms included granules, wire clippings, and atomized powder. Finer powder sizes produced material with higher strength than coarse feedstock. Bowers (Ref 72) reports that the use of a powder feedstock reduces the pressure developed markedly as compared with solid metal feedstock. In addition, the use of powder provides the opportunity to feed blends of different metal powders for production of composite wires.

The "Linex" process (Fig. 21) as described by Black et al. (Ref 67) involves a similar approach where rectangular section stock is held and forced forward toward the die by opposed continuous loops of gripper blocks arranged like caterpillar treads. Reduction ratios of 30 to 1 are reported. Avitzur (Ref 72) presents an analytical review of these concepts, consolidating them into a group that he refers to as "Extrolling"--an amalgamation of rolling and open-chamber extrusion.

Conclusions

While elevated-temperature direct extrusion is now a mature metalworking technique, its utility has not diminished with time. Loose powders or precompact slugs may be processed this way as well as cast billets, and the canned extrusion and filled billet approaches have extended the application of extrusion to powder metals for specific purposes. Examples of the benefits obtained from canned metal powder extrusions include the formation of composites and reinforced materials, near-net sections, sometimes complex in shape, that may be released by chemical removal of a coextruded

matrix, sound rods and sections in materials of limited ductility, and the safe containment of materials that may be toxic or reactive.

The mechanisms for powder extrusion have been studied extensively and reported by Sheppard and coworkers using upper-bound analyses and hodographic depictions of the process as material traverses the extrusion deformation zone. They demonstrated that powder is compacted to near-full density before the onset of extrusion, although at this stage the particles remain poorly bonded. As the densified material passes through the extrusion deformation zone, redundant work is expended in welding, breaking welds, and reforming them between particles while they are deforming; the emergent material has suffered considerable shear deformation, and the formation of metallurgically sound interparticle bonds produces full density and wrought properties. The redundant work factor in the process is a function of particle size so that fine powder with a large surface-area-per-unit volume requires a higher extrusion pressure than coarse powder. However, extrusion of powders generally requires lower pressures than cast billets of the same material because the final properties characteristic of the wrought material are developed only after it has passed through the deformation zone.

When powder mixtures or powder-solid combinations are to be extruded, successful coreduction of section depends on the metallurgical and thermomechanical compatibility of the various components. When flow stresses are well matched and the operating temperature does not cause the formation of liquid phases, uniform and proportionate coextrusion will be achieved. Within the broad confines of these simple criteria, it is possible to construct billet assemblies involving multiple components to make products that might otherwise be obtained with great difficulty, if at all.

The extrusion of metal powders is a useful industrial technique with a broad variety of applications that have been extended in part by inventive process and billet design. The obtainable material properties and product characteristics together with the relatively short process cycle involving melt-powder-extruded compact ensure that it will continue to be used well into the future.

Forging and Hot Pressing

Howard A. Kuhn, Concurrent Technologies Corporation (CTC)

Introduction

POWDER FORGING AND HOT PRESSING processes are similar in terms of their external physical characteristics. Each process involves the simultaneous application of pressure and heat to consolidate powders to full, or nearly full, density. Both processes occur within a die that gives shape to the final densified component.

At a more detailed level, forging and hot pressing are significantly different. Forging involves the deformation of a powder preform in which considerable lateral flow occurs (Fig. 1a). Forging is carried out on high-speed presses that are automated for mass production. Hot pressing, on the other hand, involves compression of loose powder or a powder compact fitted tightly in the die cavity, similar to repressing, resulting in very little lateral deformation, as shown in Fig. 1(b). Hot pressing generally is carried out at very low deformation rates in hydraulic presses.

(a)

(b)

Fig. 1 Deformation mode for (a) forging and (b) hot pressing

At an even finer scale, viewing the localized deformation of a representative unit of material containing a pore (or void space) between particles, the lateral flow of forging leads to considerable shear, which breaks up any oxide surfaces on the particles and enhances bonding (Fig. 2a). In hot pressing, pores and voids simply collapse under axial deformation; see Fig. 2(b) (Ref 1). Hot pressing is similar in this respect to cold die compaction.

(a)

Fig. 2 Stress conditions for (a) forging and (b) hot pressing

Because of the differences in speed and deformation mode between forging and hot pressing, the metallurgical mechanisms of densification are different. Forging relies primarily on plastic deformation to close the voids during the

few milliseconds that the material is under pressure. Hot pressing involves plastic deformation, creep, and diffusion mechanisms to cause localized flow of material into the pores.

Forging involves only axial compressive stress while the material is undergoing lateral flow, or upsetting. When the forged material reaches the die wall, however, lateral pressure acts on the material much like repressing (Fig. 1a). In hot pressing, the material is subjected to lateral pressure p' in addition to axial pressure p , similar to repressing (Fig. 1b and 2b). The numerical difference between p and p' diminishes as full density is reached. Closure of pores by plastic deformation becomes more difficult as the lateral and axial pressures approach equality; i.e., a hydrostatic stress state. Therefore, it is important in forging that most of the densification occurs by shear before the material reaches the die walls.

While both powder forging and hot pressing can consolidate most powder materials to full density, forging is applied primarily to high production parts in ferrous alloys, such as automobile connecting rods, transmission parts, and hand tool components. Hot pressing is used primarily for specialty materials such as tungsten carbide, beryllium, and ceramics. Hot pressing is also used as a consolidation process to produce billets for further processing by conventional forging or extrusion of materials such as high strength P/M aluminum alloys, tool steels, and superalloys.

Successful application of forging and hot pressing involves careful consideration of powder preparation (compaction, heating, and atmosphere protection) and forming process parameters (preform design, heating, tooling, and equipment). Computer modeling of these processes has been introduced recently to accelerate the development of the proper process parameters and tooling for new applications and the solution of problems in existing processes. The important process features are described here for both powder forging and hot pressing, along with specific applications and materials.

Powder Forging

Powder Preparation

The most extensive application of powder forging is automotive drive train parts using high strength steels. Water-atomized low alloy steel 4620 is commonly used as well as iron-copper-carbon blended elemental powders (Ref 2). Powder characteristics, such as size and shape, are unimportant in the forging deformation process itself, but they may have important effects on the compaction and sintering processes prior to forging. For example, whether the powders are spherical or irregularly shaped, fine or coarse in size, they will lose their identity through the extensive deformation and accompanying densification during forging, and will have little effect on the deformation process. For the preform compaction process prior to forging, however, irregularly shaped powders are preferred because of their ability to interlock during compaction and produce compacts with sufficient green strength for handling. Coarse powders might also be preferred over fine powders because of ease of flow during compaction die filling, and because they present less surface area for contamination during sintering or heating for forging.

The chemical composition of the powders involved in powder forging is important, primarily in terms of oxide content, because the volume fraction of contaminants strongly influences the final properties of the powder forged component. If the oxide appears on the surface of the particles, it can be readily reduced by proper sintering practice or broken up and dispersed by shear deformation during forging.

Preforms for forging are fabricated primarily by conventional die compaction, although dry bag isostatic compaction has also been used for some applications. The overall density of the preform has no significant effect on the density of the forged parts, but variations in density from region to region of the preform are often designed to control metal flow and

avoid defects during the forging process. Another consideration is the influence of preform density on the sintering process. Preforms of low density contain extensive interconnected porosity, allowing the sintering furnace atmosphere to reduce larger amounts of surface oxides on the powder particles. On the other hand, lower density preforms are more prone to internal oxidation and carburization during exposure to air while the preform is transferred from the furnace to the forging press. For this reason, protective coatings are generally applied to the preform before heating.

Control of the preform weight is critical because hot forging is carried out in a trap die without flash, as shown in Fig. 1(a). Excessive preform weight may lead to tool breakage or stalling of the press. Conversely, underweight preforms will not achieve full densification by forging and may not fill extreme corners of the die.

Sintering is the final critical step in preparation of preforms for forging. Sintering not only bonds the powder particles by diffusion, it also provides a protective or reducing atmosphere to prevent contamination and reduce the levels of oxide contamination that may be present in the particles. The oxygen level of the sintered preform, which depends on the sintering temperature, sintering atmosphere, dew point, and furnace type, determines the oxygen level of a forged part. The oxygen level of sintered preforms decreases with higher sintering temperature and lower dew point. Mechanical properties in general, and dynamic properties (impact and fatigue strength) in particular, are strongly influenced by the oxygen level of the forged part. Low oxygen levels lead to higher dynamic properties because the metallurgical bonds developed between particles during forging are stronger if the particle boundaries are free of oxides; see Fig. 3 (Ref 3).

Forging Process

A major key to successful powder forging is proper preform design because it has a significant effect on the metal flow and distribution of stresses in the material during forging. These factors, in turn, affect the densification and probability of fracture. In general, sufficient metal flow must take place to achieve full density and good bonding across collapsed pores. However, increasing the amount of metal flow also increases the possibility of fracture. Thus, preform shape design involves a tradeoff between the lower limit of deformation to achieve the required properties, and the upper limit that would cause fracture.

As shown in Fig. 1(a) and 2(a), the deformation during forging involves considerable lateral flow and shearing of the powder particles. This shearing action causes any oxide films on the powder particles to be broken up, exposing clean metal, and enabling a strong metallurgical bond across collapsed pore interfaces. As a result, the dynamic properties of the material are enhanced. Figure 4, for example, shows that the impact energy of as-forged alloy steel powder preforms increases steadily with increasing deformation up to $\sim 60\%$ reduction. Similarly, Fig. 5 shows that the fatigue limit for powder forged 4620 steel increases with increased deformation (Ref 4).

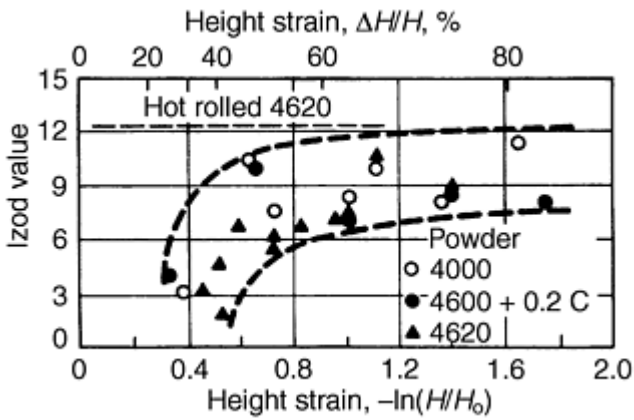

Fig. 4 Increase in impact resistance with increasing forging deformation of sintered nickel steel (4600 series) powder

Fig. 5 Axial fatigue of P/M forged 4620 steel for various levels of forging deformation. Fatigue limit increases as deformation level (height strain) increases. Source: Ref 4

Large deformation of sintered powder material can easily lead to fracture because tensile stresses usually develop, and pores in the material provide many sites for concentration of these stresses, leading to fracture. To overcome this limitation a fracture criterion has been developed for predicting fracture during powder forging. Based on the occurrence of fracture during upset compression testing, a locus of surface strains at fracture can be generated, as shown in Fig. 6 (Ref 5). For a given material, strain combinations in the material above this line will lead to fracture, while strain combinations below the line are safe. Such fracture lines can be generated for any material.

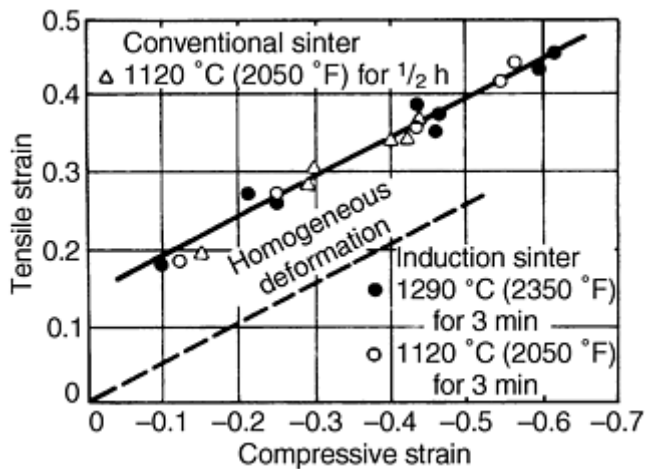

Fig. 6 Tensile strain vs. compressive strain at fracture of 4620 steel powder cylinders and sintered under various conditions. Dashed line represents homogeneous deformation (zero tensile stress).

To illustrate the important role of preform design on defect-free powder forging, consider the part shown by shading within the tooling configuration in Fig. 7. This part is axisymmetric, consisting of an outer rim (upper section) formed by the upper punch, and a hub (lower section) formed by the lower punch. A flange is formed between both punches, and an outer die and core rod complete the tool set. A preform containing the rim and hub features is not considered because metal flow would be limited, leading to incomplete densification. Rather, the preform for this part would simply be a cylinder with a hole at the center. Forging the part from a cylindrical preform will involve various combinations of back extrusion of metal into the rim, forward extrusion into the hub, and lateral (radial) flow in the flange. However, as seen in Fig. 8, for a given volume of material, the inside and outside diameters of a cylindrical preform can have a variety of combinations. Using the fracture criterion in Fig. 6 and knowledge of the stresses in the various modes of deformation, the proper preform can be determined.

Fig. 7 Prototype part for illustration of preform design

Fig. 8 Preform options for forging the part shown in Fig. 7. See text for discussion of (a) through (d).

In Fig. 8(a), the preform leads to successful forging because radial expansion of the outer surface is prevented, forcing inward flow to form the hub. This inward flow is in compression and does not lead to fractures. Meanwhile, the rim forms by backward extrusion without radial expansion and is also safe from fracture. The preform in Fig. 8(b) allows considerable radial expansion and flow of material around the upper corner radius into the rim, which easily leads to fracture on the inside of the rim. In Fig. 8(c), the preform is constrained from lateral flow on both the inner and outer diameters; the resulting forward extrusion into the hub section causes large tension on the surface of the hub, leading to fracture. The preform in Fig. 8(d), like Fig. 8(b), leads to fracture on the inside surface of the rim as material flows around the upper corner of the punch into the rim.

It is clear that, even though a cylindrical preform is the obvious choice for this part, the specific dimensions of the preform must also be determined. Subtle changes in the preform dimensions mark the difference between successful and unsuccessful forging. This observation is true in preform design for nearly every part.

For more complex shapes, preform design is a major challenge, since a wide variety of deformation modes and combinations may occur. Preform design for connecting rods, for example, requires specification of the preform dimensions for the circular sections at the pin end and the crank end, as well as the beam section connecting these ends. Lateral flow and extrusion occur locally in all three sections, and material flow may occur across the intersections as well. Preform design for this complex case requires careful determination of the weight of material in each section and detailed analysis of the localized metal flow in each section. Unlike most preforms, it is necessary to specify different densities in each of the three sections of the preform to ensure full densification and avoid defects in the finished connecting rods.

The tooling for powder forging is based on the trap die concept, an example of which is shown in Fig. 7. The material is completely trapped between the punches and die, with no flashland. While the trap die concept produces a near-net shape that does not require removal of excess metal in a flashland, it does lead to high stresses on the tooling. Combined with the high temperatures of forging, these stresses and metal flow lead to high wear rates on the punches and die. The most commonly used material for the dies is H13, a hot-working die steel. With proper preform design and cooling of the tools between press strokes, 50,000 to 100,000 parts can be produced before die refurbishment is required.

The temperature of the preform as it enters the forging process influences the mechanical properties of the forged parts as well as the life of the forging tooling. Higher forging temperatures enhance densification of the forged part because plastic flow occurs more easily, as shown in Fig. 9 (Ref 6). On the other hand, higher forging temperatures lead to greater

die wear. Typically, steel powder preforms are forged at 980 °C (1800 °F) as the optimum temperature to minimize die wear and ensure part densification.

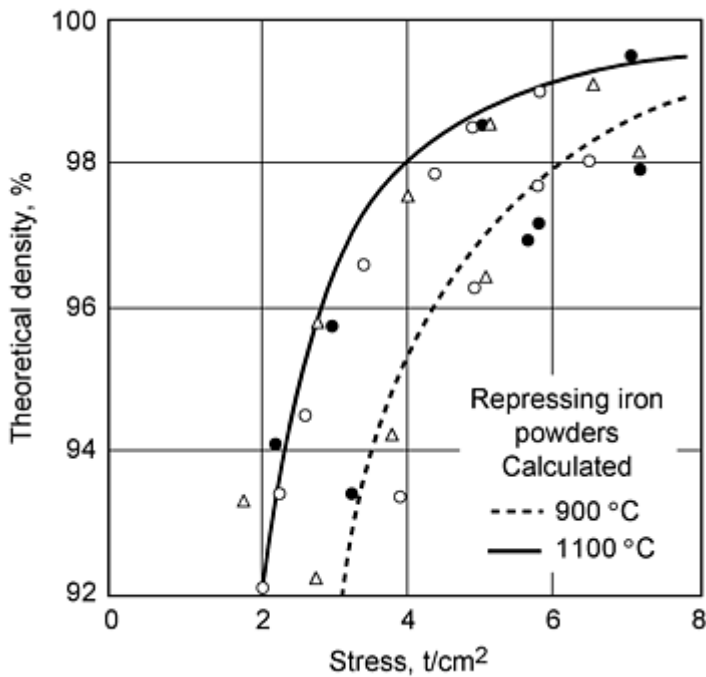

Fig. 9 Experimental and predicted increase in forming pressure with density during hot repressing of steel powder

The speed of forging also affects the quality of parts produced by powder forging. Since the preform is porous, rapid cooling of the hot preform surface by contact with the colder die surface will lead to residual porosity at these surfaces. To minimize this effect, the contact time between the preform and die must be as short as possible. For this purpose, screw presses with a very stiff frame are widely used for powder forging. The screw press motion ensures rapid withdrawal of the forging punch from the die, and the stiff frame minimizes contact time between the part and die at the peak load. The total contact time for forging by a screw press is ~ 30 ms, while the contact time for a typical mechanical crank press is 80 ms. This difference has a very large effect on local cooling of the preform and, consequently, residual surface porosity in the forged part.

Applications

Forging of P/M preforms to near-net shape or net shape parts has several advantages: material utilization is increased by eliminating or substantially reducing machining operations, energy efficiency is greater than conventional forging because operations such as hot rolling of bar stock are eliminated, and powder forging uses lower temperatures than conventional forging for the same alloys. As an example, a machine gun accelerator is conventionally produced by hot forging billets of 4340 steel to a rough shape in six operations, followed by 27 machining operations. Powder forging of the same part consists of compacting a preform from atomized 4600 steel powder, sintering the preform, and hot forging, followed by just seven machining steps. This leads to a net cost savings of $>50\%$ compared to the conventional approach.

Powder forging for mass-produced structural parts was developed to meet performance requirements beyond that available from conventionally pressed and sintered powder parts. A number of parts have been attempted by powder forging; however not all of these parts were successful, primarily for economic reasons. Currently, powder forged parts are produced mainly for automotive drive train applications. Powder forged connecting rods have been in use in U.S. automobiles since 1987, starting with the Ford Escort 1.9 liter engine. Powder forged connecting rods are now used in at least 13 engines among major U.S. automakers and are also used in some European and Japanese engines. The rods are typically forged from Fe-Cu-C powders to a minimum density of 7.84 g/cm^3 . At this density they have an ultimate strength of 760 MPa (110 ksi), a yield strength of 550 MPa (80 ksi), and endurance limit of 275 MPa (40 ksi). Powder forged connecting rods eliminate the surface defects inherent in conventional forging, have a uniform microstructure, are

dimensionally consistent, and have superior machinability. The uniformity of microstructure and material distribution also minimizes the amount of material removal required for balancing the connecting rods.

Powder forging has also been used for specialty materials, such as tungsten, molybdenum, and beryllium. Since these materials cannot be cast easily, powder forging is the best option for processing fully dense net shapes. Powder forging concepts are also emerging for the fabrication of ceramic parts. With the recent development of superplastic ceramic materials, forming of complex shapes from simple ceramic preforms has been developed for high temperature bearing and seal applications (Ref 7).

Process Modeling

As with many other manufacturing processes, several computer models have been developed for analysis of powder forging, including finite element analysis and expert design systems. These computer tools aid design of the process, including preform design. Such models were difficult to develop because of the complications introduced by porosity in the material. The existence of porosity and accompanying density change during deformation preclude the use of conventional plasticity equations, which are based on zero volume change. In addition, heat transfer rates in the material depend on the local density level, which changes throughout the preform during the forging process. Recently, material models giving accurate representations of porous material behavior during plastic deformation have been developed. Coupled with modern numerical methods, these material models have led to reliable simulations of the deformation during powder forging (Ref 8). The fracture criterion given in Fig. 6 has also been embedded in the computer code so that fracture predictions can be made.

A reliable simulation code is particularly useful for preform design for powder forging of new parts. Starting with an initial guess of the preform shape, a finite element simulation of the forging of that shape will indicate areas of incomplete densification as well as locations at which fracture may occur. Then modified preform shapes can be attempted in an iterative approach to eventually derive a preform shape that leads to defect-free forged parts. This trial-and-error procedure, however, can be very tedious, especially for complex parts. For this reason, an expert design system was devised to provide an initial guess for the preform design, based on experience with previously forged parts. The part to be forged is first subdivided into regions of primary metal flow, such as back extrusion, forward extrusion, and lateral flow (Fig. 10). This subdivision into regions is done automatically by the program, using geometric reasoning applied to computer-aided design (CAD) data representing the part. Preform design rules accumulated from experience on other parts are then applied to each region. An additional set of rules is applied to evaluate material flow between regions. Next, a decision tree methodology is followed to optimize the preform shapes in each region, based on the objective of minimizing defects, wear, and tool loads. Smoothing functions then blend the preform shapes prescribed for each region. Finally, the design details are determined through limited applications of a finite element simulation code (Ref 9).

Forging and Hot Pressing

Howard A. Kuhn, Concurrent Technologies Corporation (CTC)

Hot Pressing

Material Preparation

Hot pressing is similar to powder forging in that powder material is compressed at high temperature between opposing punches, but hot pressing occurs at a much lower rate than forging. Also, lateral flow of material does not occur in hot pressing, whereas this is an important requirement in powder forging. Hot pressing is also similar to conventional powder compaction at room temperature since powder is placed in a die and compacted by uniaxial compression.

Unlike powder compaction, feeding loose powder into the die is not practical. Since hot pressing is carried out with dies heated to the pressing temperature, loose powder particles entering the die cavity heat up rapidly, causing particles to bond together or weld to the tool cavity and impede further flow of powder into the die. In addition, the large free surface area of loose powder increases the likelihood of oxidation of the powder at the high temperatures of hot pressing.

One option is to fill the cold die with loose powder at a separate station, and then move the filled die to the press where the die and powder are heated simultaneously before pressing. A second option is to preform the powder into a porous green compact for easy handling. This approach eliminates powder flow at high temperatures and minimizes oxidation problems, which outweighs the additional step of preform pressing. The compact, which may be preheated or at room temperature, is placed in the die, which may also be at room temperature or preheated to the hot pressing temperature. With the powder compact in the die, the powder and die must be heated to the hot pressing temperature. Heating can be done directly through induction or electrical resistance heating, or indirectly by heat transfer from the die, which is heated by other means.

Resistance heating of the powder is accomplished by passing a low voltage, high amperage current through the powder while pressure is applied. A variation of resistance heating involves discharging an electric spark through the powder. High temperatures generated at the points of contact between adjacent powder particles cause bonding. Heating of the die and then indirect heating of the powder compact is the most common method for heating. In this case the entire tool set may be heated by induction or a resistance wire heated muffle furnace.

As with other high temperature processes involving metal powders, a controlled environment must surround the powder material during hot pressing. This atmosphere can be a gas contained in the die cavity, or the gas can surround the entire die assembly inside a chamber. A vacuum can also be used as the hot pressing environment. Inert gases (such as argon) can be used when hot pressing powders such as beryllium or titanium that are particularly sensitive to contamination by oxygen or nitrogen.

Hot Press Equipment

A wide variety of hot pressing equipment configurations have been devised for both production and laboratory applications. These installations combine indirect or direct heating with various tooling configurations and means for containing the tooling in a controlled atmosphere. Several examples are given in Ref 10. Two examples are shown in Fig. 11 and 12. Figure 11 shows graphite tooling, heated by resistance, with a telescoping enclosure for containing an atmosphere. The entire fixture is fitted to a hydraulic press (Ref 11). Figure 12 is an example of a vacuum hot press used

for beryllium consolidation. Graphite tooling is again used inside an induction coil for heating the tooling and powder. The assembly is mounted inside a double-walled chamber with vacuum seals for the rams and utility connections (Ref 12).

Fig. 11 Cross section of resistance heated graphite die assembly built into hydraulic press. Arrangement provides for telescoping controlled atmosphere enclosure and double-action hot pressing for steel, nickel alloy, and titanium alloy powders. Source: Ref 11

Fig. 12 Cross section of hydraulically activated, induction-heated graphite die assembly inside vacuum chamber. Arrangement permits double-action hot pressing of beryllium powder into blocks. Source: Ref 12

The material selected for hot pressing punches and dies is critical because these parts are subjected to high pressure and temperature for a sustained period of time. The punches must resist plastic deformation under the axial loads of pressing, while the die body must constrain the lateral pressure of pressing without yielding. As pointed out in the description of Fig. 2(b), as full density is approached, the lateral pressure nearly equals the applied axial pressure. As a result, the die must have a wall thickness great enough to withstand the circumferential stresses developed at peak axial loading.

Metals used for hot pressing tooling include molybdenum, a molybdenum alloy TZM (Mo-0.5Ti-0.1Zr), tungsten, superalloys, and alloy steels that are highly heat resistant. If steel or superalloy dies and punches are used, they must be kept at lower temperatures by water cooling through internal passages. Ceramic or graphite tooling is frequently used without cooling, but overloading must be prevented to avoid catastrophic failure of these brittle materials. Because thermal expansion occurs during heating, the dies and punches should be made of the same material. If the die expands at a greater rate than the punches, a gap will form between the die and punches into which pressed powder material will extrude, and lead to difficulty in ejecting the hot pressed material from the die. Conversely, if the punches expand at a greater rate than the die, the die will fit tightly around the punches, again preventing ejection of the hot pressed material.

The sustained processing time at high pressure and temperature during hot pressing also requires consideration of chemical reactivity between the powder material and tooling. Diffusion at the interface between the powder and tool surfaces may lead to welding of material to the die cavity. Graphite tools and molybdenum alloys require a controlled atmosphere to prevent oxidation. To avoid reactivity between the tooling and powder, as well as improve ejection of the pressed material from the die, die wall lubricants are frequently used. Colloidal graphite suspension in water or oil is applied to the die wall to reduce friction and wear. Ceramic or mica suspensions in hydrocarbons spray coated on the punch and die also inhibit diffusion bonding and welding.

Since hot pressing involves plastic deformation, creep, and diffusion, pressing times are extended to several minutes or even hours. For this reason hydraulic or pneumatic presses are used rather than mechanical presses. Generally a hydraulic press with a simple single action ram will suffice, as long as a means for ejecting the hot pressed material is provided. Hydraulic presses with side rams enable the use of split dies for easy extraction of hot pressed materials, particularly parts having multiple levels. In all cases, precise control of the axial load is necessary to ensure that a constant pressure or the required pressure-time profile is maintained during the pressing operation.

Applications

The material produced most widely by hot pressing is tungsten carbide. While small tungsten carbide parts, such as cutting tool inserts, are made by pressing and sintering, the density gradients resulting from such processes preclude their use for large parts. Tungsten carbide powders are hot pressed generally in graphite molds induction heated to 1400 °C (2550 °F) and pressed at pressures up to 17 MPa (2500 psi). Higher pressures may crack the graphite tooling, or cause the cobalt binder phase to extrude between the punches and die. If the pressure is too low, high levels of porosity remained and distortions will result during sintering to full density. Hot pressing is widely used for producing forming dies and wear resistant parts of simple geometries.

Hot pressing is also the preferred process for shapemaking of beryllium. Hot pressing of beryllium powders prevents grain coarsening, which is the major limitation in casting this material. Beryllium is hot pressed at 1050 °C (1920 °F) in graphite tooling in a vacuum. Hot pressed beryllium parts are used primarily in nuclear reactor modulators and in missile and aerospace applications.

Superalloys and titanium alloys have also been hot pressed to full density for simple geometry parts. However, serious problems occur due to reactions between these alloys and the tool materials. Such problems can be overcome by using hot isostatic pressing, where these interactions are more easily controlled.

Currently, hot pressing is a very important process in the development of new ceramics and metal matrix or ceramic matrix composites for a wide variety of applications. Materials include silicon carbide and silicon nitride in various metal or intermetallic matrices. A relatively new material known as System 2 has been produced by the U.K. Atomic Energy Authority for protection of the next generation space shuttle, Skylon. The material consists of 40% silicon carbide continuous fibers in a refractory glass ceramic matrix that has been processed by hot pressing (Ref 13). The material is self healing at high temperatures and is ideal for hot structures where weight reduction is required. This material serves as an effective substitute for titanium- and nickel-base alloys for advanced aerospace applications. Alumina-aluminum silicon composites have been fabricated by in situ reaction of molten aluminum with aluminosilicate ceramics (Ref 14). This reactive metal penetration process is driven by a strongly negative Gibbs energy for reaction. In the aluminum-

mullite system, aluminum reduces mullite to produce alpha alumina and elemental silicon. Ceramic-metal composites containing up to 30 vol% Al(Si) were prepared by reacting molten aluminum with dense aluminosilicate ceramic preforms, or by reactively hot pressing aluminum and mullite powder mixtures. Bulk metal matrix composites have also been produced by hot pressing blended prealloyed powders of aluminum alloy 6061 with 15 vol% of silicon carbide particles (Ref 15). In the T6 heat treated condition, yield strengths of 400 MPa (58,000 psi) were obtained with elongations of 2.5%. Sliding wear resistance of the metal matrix composite was also greatly superior to that of monolithic aluminum alloy 6061. A variety of ceramic components such as heat shields for space reentry vehicles are also produced by hot pressing in graphite molds heated by induction. Aluminum silicon carbide composites produced by hot pressing are used for kiln fixtures as well as high performance aerospace vehicle structures.

Pneumatic Isostatic Forging

Thomas W. Reddoch, AMETEK, Inc.

Introduction

PNEUMATIC ISOSTATIC FORGING (PIF) is a technology for consolidating powder metal, or metal powder preforms to near or full density. The PIF process is a low-cost patent-pending technique for achieving high density and high performance in a range of materials. The short-time thermal exposure and lower processing temperature requirements relative to conventional processes provide a control of microstructure and related mechanical and magnetic properties.

The PIF process is a true forging process in which material is plastically deformed to achieve high density. The use of the term pneumatic is derived from the fact that argon or nitrogen gas is used as the pressure medium and is dispatched at pressures up to 415 MPa (60,000 psi), where the gas has fluid characteristics. The consolidation of the material is achieved by forging a workpiece with a gas hammer to high density. The workpiece is pressurized isostatically at a prescribed temperature in a uniform and rapid manner with a cycle time of 2 to 5 min. As such, PIF is a relatively high-strain-rate process that plastically deforms the workpiece. Selection of process parameters such as pressure, strain rate, temperature, and time at pressure is material dependent.

Pneumatic isostatic forging (PIF) and hot isostatic pressing (HIP) are similar to the extent that a gas-pressing medium applies isostatic pressure to the workpiece. Densification in HIP is achieved primarily through creep and diffusion with very limited use of plastic deformation. The PIF process uses plastic deformation and limited diffusion to achieve its goal. Furthermore, the strain rate for HIP is low and for PIF it is high.

Pneumatic Isostatic Forging

Thomas W. Reddoch, AMETEK, Inc.

Process Description

A flow diagram of the PIF process is shown in Fig. 1. Beginning on the left, P/M materials are prepared in one of two forms: a preform or a loose powder. A preform is consolidated to a near-net- or net-shape workpiece by one of several approaches, including conventional die pressing, cold isostatic pressing (CIP), or metal injection molding. The green pieces are often sintered before they are introduced to the PIF process. As a preform, the workpiece is prepared for PIF processing by a range of techniques including with and without coatings, limited encapsulation, and full encapsulation. The appropriate preparation is chosen to match the material and its initial compacted characteristics. All such choices are material dependent and proprietary in nature.

Materials preparation

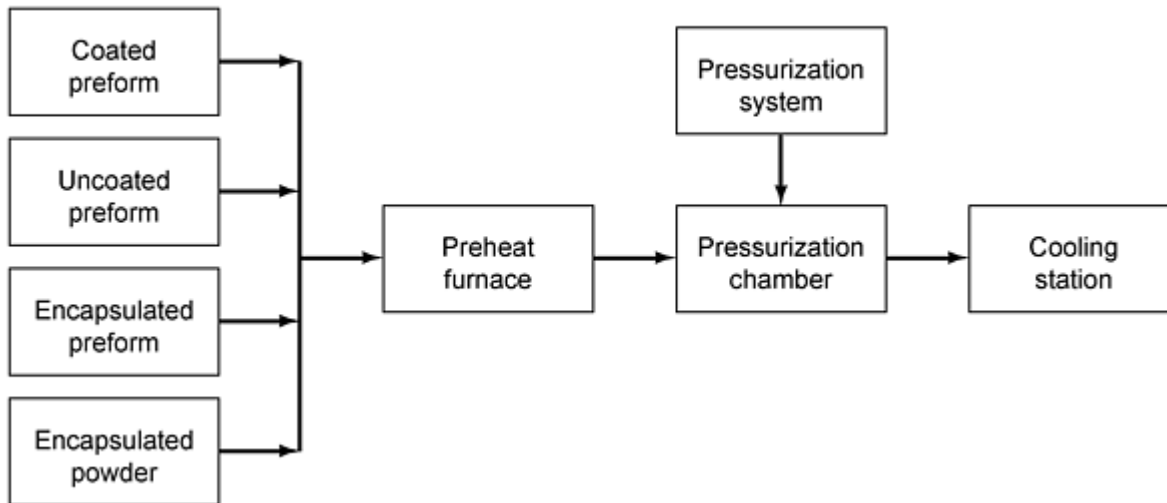

Fig. 1 Flow diagram of the PIF process

As an alternative to preform preparation, the free-standing powder is encapsulated in a thin-walled metal container and evacuated, typically in a simple geometric form as a cylinder or rectangular slab. The encapsulated material is then PIF densified. Various powders (including nickel compositions, copper compositions, and chromium, among others) have been processed by PIF.

After the material is prepared, it is preheated to a designated temperature. The temperature choice is selected based on the candidate material and is coordinated with a planned pressure cycle. As a typical value, the temperature choice will be 50 to 200 °C (120 to 390 °F) below a corresponding choice for a HIP transaction. Once the workpiece is in thermal equilibrium, it is transferred to the pressure system. Immediately following the transfer, the pressure system is energized to values up to 415 MPa (60,000 psi). A proprietary pressurization technique is used to increase the pressure and pressurization rate to the desired value. Once the desired pressure is achieved, it is held for periods up to 1 min. Depressurization strategy follows specific rules based on the materials being processed, but in most instances the pressure is relaxed within 1 to 5 min. Once consolidated, the workpiece can be cooled under pressure when seeking a specific desired end effect or the workpiece can be removed from the pressure chamber shortly after consolidation and cooled in a supplemental cooling station.

Densifying Materials by PIF. Because PIF is isostatic in nature and uses either argon or nitrogen gas as the pressure medium, it is often confused with hot isostatic pressing. The PIF process uses plastic deformation with high-strain-rate forces as its consolidation mechanism, whereas HIP uses very limited plastic deformation and primarily relies on diffusion and creep with low strain rate to achieve its end goals. Therefore, PIF is a true forging process utilizing a gas hammer to rapidly transfer energy to form the workpiece. Some materials cannot be forged to full density and may require the creep mechanism to achieve results, thereby requiring HIP.

Consolidation by PIF requires satisfying two critical conditions:

- The surface condition of the workpiece must be free of significant defects or holes and/or interconnected porosity where gas can be absorbed, causing a loss of pressure differential and therefore negating the effect of PIF. Experience has shown, however, that properties of high-pressure gas, particularly argon, enable full densification of preforms having densities as low as 87% of theoretical.
- In order to consolidate the workpiece to full density, its temperature must be of sufficient value to reduce the flow stress requirement of the material for forging such that the applied pressure or force "can collapse the material" in on itself or impart plastic flow. Experience indicates that some nonisostatic preform compaction techniques can produce uneven density profiles that can limit achieving full density by PIF.

Pressure/Strain Rate/Temperature/Time. The deployment of the PIF process is a careful orchestration of the process variables including pressure, strain rate, temperature, and time. Typical pressures used in the PIF process range from 310 to 415 MPa (45,000 to 60,000 psi). For each cycle, an end pressure is chosen where a pressure level is maintained for a period of 10 s to 2 min. Temperature plays the key role by reducing the flow stress requirement, thereby reducing the consolidating pressure and increasing the sensitivity of the deformation speed by means of the strain rate. Time is a factor in the preheat step where the material is heated to a homogeneous value before pressurizing. Typical temperatures include 525 °C (975 °F) for aluminum, 900 °C (1650 °F) for copper, and 1225 °C (2235 °F) for iron. A strain rate is chosen to develop the appropriate shear stress levels to consolidate the workpiece.

Dimensional Properties. A natural consequence of consolidation is the shrinkage of the workpiece. The changes in size and the character of the change are a direct result of the applied force and the prior conditions of the workpiece. Preexisting work hardening and density distributions within a workpiece significantly, if not uniquely, determine any efforts to consolidate a workpiece by PIF.

As a true isostatic compacting technology, PIF provides a uniform force in all directions to the workpiece. Therefore, the workpiece contracts in a volumetric manner. A typical consequence of nonisostatic compaction is the hourglass distortion of cylindrical forms. Fundamentally, PIF does not distort; however, properties installed in the workpiece from first-stage compaction and sintering influence the final dimensions and any distortions. It is well recognized that the constraining nature and uniaxial forces of die compaction produce density distributions in the workpiece. Sintering can amplify the effects of these density distributions. Applying supplemental treatments such as coining can further disturb the natural properties of the workpiece. None the less, PIF maintains dimensions within a few thousands of an inch from its starting condition.

Consolidation by PIF of die-compacted and sintered components tends to move the material in a proportional manner. As such, distortion is avoided when the same density distribution is maintained pre- and post-PIF. This occurs when the density distribution is uniform or when any area of the workpiece moves to the extent that it is either attaining just full density or less. Distortions during consolidation are a direct consequence of nonuniform properties. For example, isostatically or metal injected molded compactions have few, if any, density distributions; therefore, these specimens consolidate with little or no significant distortion.

The PIF process uses isostatic force to sustain dimensional properties; that is, no dies are used to constrain the workpiece. Tooling and fixturing can be used to influence the movement of the workpiece, thereby holding particular geometric positions similar to that provided by dies in first-stage compaction, coining, and powder forging. Care must be exercised to avoid bonding the workpiece to the fixture. Insulating materials and thermal properties of the fixture material are considered.

Estimates of Dimensional Shrinkage. The actual shrinkage of a workpiece by PIF is estimated using some simple relationships. Because PIF is volumetric movement in nature, a cubic variation in parameters prevails. The formula used to forecast dimensional change is:

$$d_f = d_i^3 \sqrt{\frac{D_i}{D_f}} \quad (\text{Eq 1})$$

where d_i and d_f are pre- and post-PIF dimensions (i.e., radius, length, width, or thickness), respectively, and D_i and D_f are pre- and post-PIF density, respectively. This empirical formula is very effective for estimating dimensional changes on geometries with a length-to-diameter ratio of 5 or less.

Some trial and error is required when applying the formula because the final density of the workpiece is a factor in the total dimensional change. Length-to-diameter ratio also influences specific dimensional changes. Materials consolidating to full density conform best to the formula estimates. Some materials and workpiece configurations do not attain full density, and therefore they must be calibrated to determine final density and the actual dimensional changes. Preforms with uniform density satisfy formula predictions very accurately.

Process Advantages. The pressure and temperature of the process are controlled and managed independently of one another, thereby providing an opportunity to control microstructure and properties of the material. As an additional

consideration, lower processing temperatures and shorter exposure time to elevated temperature reduce grain growth in many materials. The short processing time at pressure expedites material throughput and maximizes the availability of the pressure vessel, therefore reducing the capital equipment requirements. Further, the pressure vessel size requirements are reduced. Material handling and processing requirements are simplified, thereby facilitating automated actions. Overall, the process is well suited to automated transactions where sustained throughput of workpieces is desired.

Process Limitations. The PIF process is used to enhance the properties of a workpiece through forging by improving the density and attaining various mechanical and magnetic properties. As a forging process, PIF relies on its pressing media to exert sufficient force to overcome any resistance movement by the material. In short, the force must overcome the flow stress requirements of the material in order to consolidate it. If the preform has density distributions, the PIF process will not significantly alter these distributions.

As a true forging process, plastic deformation by application of stress is the consolidation technique. If the material requires diffusion or creep to attain its consolidation goals, then PIF will not satisfy those needs.

Pneumatic Isostatic Forging

Thomas W. Reddoch, AMETEK, Inc.

Materials Processed by PIF

A range of materials have been processed by PIF for a variety of applications. Early applications of the technique were for automotive applications for iron-base parts where high performance in either mechanical or magnetic properties was sought. Various aluminum applications for automotive use were also evaluated. In both applications, near-full density (98% or better) was achieved. Nickel and nickel aluminides have also been consolidated by PIF with good success (100% dense) by direct densification of powders in encapsulation containers. Various other nickel alloys have also been consolidated from powder preforms as well. Titanium and titanium/aluminum systems have also been consolidated very effectively by PIF. One such application has been sputtering targets. Other applications for sputtering targets involve direct consolidation of chromium powders. Work has been done on spinodal (copper/tin/nickel) alloys for thick-section material applications. The PIF process has also been used to consolidate various other materials including cobalt/chrome, stainless steel, aluminum silicon carbide, aluminum boron carbide, tungsten, and tungsten carbide, among others.

Example 1: Iron Carrier Pinion Gear.

This application focuses on the densification and microstructure properties of an iron carrier pinion gear (Fig. 2) manufactured from the iron composition FLN 4-4405. A product evaluation was done to determine the effectiveness of PIF at improving overall density and density at key areas of known lower value. A typical gear in the as-received condition has a density of 7.3 g/cm^3 , which after sintering became 7.34 g/cm^3 . Final density was evaluated under two sets of conditions:

- Press and delube (at a presinter of $815 \text{ }^\circ\text{C}$, or $1500 \text{ }^\circ\text{F}$)
- Press, delube (at a presinter of $815 \text{ }^\circ\text{C}$), and sinter at $1150 \text{ }^\circ\text{C}$ ($2100 \text{ }^\circ\text{F}$)

The gear exhibits a density gradient with the center at the lowest value when compared with the top and bottom values.

Fig. 2 Iron carrier pinion gear, dimensions in inches

The primary findings of the study are summarized in the tables and figures discussed below. The fully sintered gears provided the best overall density, at 7.84 g/cm^3 (see Table 1). Sectioning the gear into top, middle, and bottom shows that the density gradient present in the pre-PIF condition remained but density in each area significantly improved. The delubed (or presintered) gears showed lower average density than the fully sintered parts. The overall average density was 7.8 g/cm^3 . The gradient remains although, as in the sintered gears, each area shows significant improvement.

Table 1 Pinion gears densified by PIF

Heat treat condition	Weight, g	Density, g/cm^3			
		Average	Top	Middle	Bottom
As-sintered	133.25	7.340	7.343	7.270	7.346
Sinter/PIF	133.72	7.836	7.854	7.760	7.863
Sinter/PIF	133.92	7.837	7.836	7.812	7.862
Sinter/PIF	133.75	7.837	7.836	7.800	7.860
Presinter/PIF	132.19	7.802	7.849	7.712	7.851
Presinter/PIF	131.56	7.796	7.853	7.712	7.851

Hardness is a significant characteristic of the quality of a gear. In Table 2, the hardness values are charted for the full sintered and delubed (or presintered) conditions after PIF. As a matter of comparison, a sinter/PIF gear shows improvement in hardness over sinter only. The presinter/PIF shows lower values for hardness simply because of the absence of sintering.

Table 2 Pinion gear hardness (Rockwell B) in post-PIF condition

Heat treat condition	Section top/bottom	Hardness reading, HRB	Average
As-sintered	Top	83, 83, 84, 85	84
	Bottom	83, 84, 84, 85	84
Sinter/PIF	Top	100, 99, 100, 100	100
	Bottom	100, 100, 101, 102	101
Sinter/PIF	Top	100, 99, 100, 100	100
	Bottom	102, 101, 100, 101	101
Sinter/PIF	Top	101, 100, 99, 99	100
	Bottom	102, 101, 101, 101	101
Presinter/PIF	Top	89, 89, 88, 90	89
	Bottom	88, 89, 88, 86	88

The metallographic observations also confirmed the findings in Table 1. Figure 3 shows the pronounced effect of combining sintering and PIF.

Fig. 3 Unetched microstructure of iron carrier pinion gear. (a) As-sintered condition. (b) Top surface of the tooth after pneumatic isostatic forging. 48×

Example 2: Iron with 45P-1000B Alternator Rotor.

As-received alternator rotors (Fig. 4) uniaxially pressed from iron powder containing 0.45 wt% P were densified by PIF to enhance magnetic and mechanical properties. The rotors were in various states including as-delubed, delubed and steam treated, delubed and electroless nickel coated (less than 1 mil), and debindered plus microwave sintered. Each specimen was presintered at 980 °C, 1150 °C, or 1205 °C (1800 °F, 2100 °F, or 2200 °F).

Fig. 4 Alternator rotor

The PIF parameters evaluated were: pressures of up to 415 MPa (60,000 psi) and temperatures to 1200 °C (2190 °F) at hold times of 10 to 120 s. The most consistent results were obtained with pressures of 310 MPa (45,000 psi) at 1200 °C (2190 °F), with a 10 s hold time at temperature and pressure. Taguchi experiments were conducted to select the optimal parameters for compositions of 0.45, 0.60, and 0.80 wt% P, as well as to evaluate the roles of pressure, temperature, and hold times at the various parameters on the densification achieved. Magnetic and mechanical properties were evaluated as a function of density and processing parameters.

One key objective was the enhancement of magnetic properties during densification. Figure 5, in which B (flux density in kilogauss) is a function of H (field excitation in Oersted), compares specimens of single press, single sinter (SPSS), double press, double sinter (DPDS), and conventional wrought material (12L15) with those of SPSS/PIF processed samples. The average bulk density of the as-received rotor was 7.15 g/cm³ with local density variations of 6.8 g/cm³ to 7.25 g/cm³. The bulk density after PIF was 7.81 g/cm³. For a field excitation value of about 60 Oe, the PIF material has a flux density at about 9% larger than SPSS, 3% larger than DPDS, and a 1.5% larger value than wrought material. For larger values of field excitation (around 130 Oe), the PIF material and the wrought material approach one another in flux density while the SPSS and DPDS are sustained at their respective percentages.

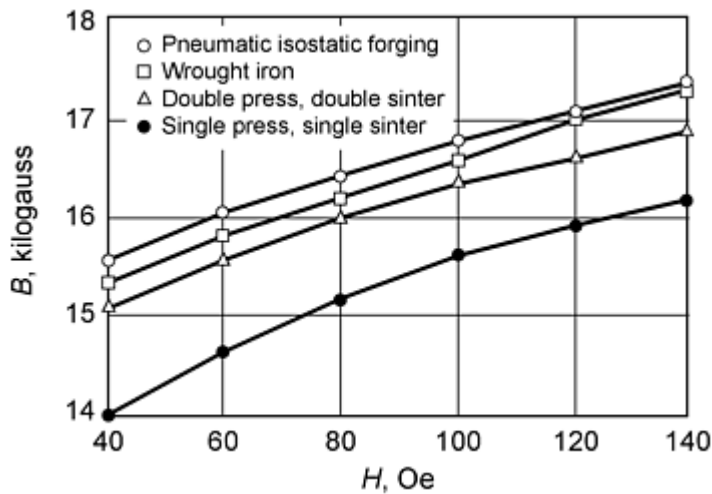

Fig. 5 Induction curve comparing the magnetic properties of sample specimens

Example 3: Aluminum-B₄C Billets.

Pneumatic isostatic pressing has been used to achieve controlled microstructure, improved properties, and interparticle bonding in aluminum-, copper-, and titanium-matrix composites. The densification of aluminum composites by PIF through rapid plastic movement of mating particle surfaces allows the oxide films to break up on the aluminum during densification. This promotes interparticle bonding before the surface film can re-form, which would block interparticle bonding. The formation of the oxide film can occur in pressure-assisted diffusion-driven processes, such as HIP and sintering. These processes require vacuum processing to achieve density; however, this will not prevent oxide film formation during these processes. The mating of particle surfaces must be moved a sufficient amount during PIF to break up the oxide film and improve properties. A previously encapsulated, evacuated, and hot isostatically pressed aluminum-matrix composite would show only slight improvement in interparticle bonding if subjected to PIF.

Another advantage of PIF for aluminum-matrix composites is demonstrated in the analysis of predictable dimensional changes during PIF. This demonstrates the ability to fabricate net or near-net shapes from powder blends and retain the geometric spacing of the reinforcement material in the green-pressed shape. This ensures uniform fracture toughness properties in all directions, and a uniform stress state in the part. The uniform stress state in the part improves machining properties and minimizes distortion during heat treatment or secondary processing, such as joining by diffusion bonding or welding.

The as-received material had a bulk density at 93% of theoretical (pore-free) density from CIP and sintering. The density after PIF was 99.5% of theoretical. The PIF processing broke up oxide films and produced both interparticle bonding and high density levels while dispersing B₄C uniformly throughout the microstructure. All results are summarized in Table 3.

Table 3 Properties of aluminum-B₄C

Sample	Fabrication condition	Density	Interparticle bonding	Machining properties	Uniformity of B ₄ C dispersion
Billet 29	Cold isostatically pressed and low-temperature vacuum sintered	Average density 93%. Estimate density variation of 89 to 94% over entire piece	Limited by surface oxide films on the particles of the pressed billets	Limited by density and weak particle bonding properties	Very good
Billet 30	PIF at 310 MPa (45,000 psi) and forged without total encapsulation	99.5% average	Interparticle bonding was achieved with oxide coating breakup during forging	Very good machining and polishing properties	Very good after forging
Billet 31	As-forged at 310 MPa	99.5%+	Excellent interparticle	Very good	Very good after

(45,000 psi) with billet
encapsulated and
evacuated in aluminum

bonding and oxide film
breakup during forging

machining and
polishing properties

forging

The mechanical properties with this uniform microstructure and B_4C dispersion retained during PIF can be further improved by heat treating. Using the PIF process can produce net and near-net shapes of aluminum alloy composites in a very effective manner. In addition, the as-received material can be densified without the encapsulation required by HIP, which permits near- and net-shape fabrication. Similar results with other additives such as nitrides and other carbides contained in an aluminum alloy matrix would be produced by PIF. The breakup of oxide films during PIF of P/M copper-matrix alloys has been accomplished previously. This was confirmed by improved thermal conductivity and electrical conductivity of PIF composites, compared to P/M composites fabricated by other techniques.

An evaluation of the densification and interparticle bonding evaluation of Al- B_4C is shown in Fig. 6(a, b, c). In the as-received condition (Fig. 6a), the most dense areas in the specimen are shown as light shades, as these areas polish and etch the best. The areas in Fig. 6(b) and 6(c) represent more typical microstructures, as polishing and staining have been accomplished with ease after PIF densification. Two forms of encapsulation were used: limited and complete (Fig. 6b and 6c, respectively).

Fig. 6 Microstructure of AlB_4C sample. (a) As-received condition. (b) Sample after PIF with limited consolidation. (c) Sample after PIF with full encapsulation. 108 \times

Example 4: Stainless Steels Exhaust Flanges.

Pneumatic isostatic forging has been shown to be very effective at densifying 400 series stainless steels. Exhaust flanges are typically made from the 400 series materials where they are die compacted and sintered. Sample specimens were pressed and sintered to about 91% density. In turn, the flanges underwent PIF at 310 MPa (45,000 psi) at 1225 °C (2235 °F) producing a 98.5% dense component.

Powder Shaping and Consolidation Technologies

B. Lynn Ferguson, Deformation Control Technology, Inc.; Randall M. German, The Pennsylvania State University

Introduction

POWDER METALLURGY PARTS are formed by several methods that range from high-pressure die compaction to pressureless shaping methods, such as slip casting. Die compaction at high pressures where densification and shaping occur simultaneously is the dominant approach. However, shaping of P/M products is also accomplished by various low-pressure methods using binders to maintain part shape for further consolidation by sintering. Another alternative is full-density processing, where the application of high pressure at high temperatures leads to P/M components with mechanical properties approaching and sometimes exceeding those of wrought forms. Finally, P/M part technology also includes spray forming of metal powders into high-density parts.

In all of these methods, the basic purpose is to consolidate powders into useful forms. As simple as this sounds, however, shaping and consolidation of powders is a complicated subject. The selection of a shaping/consolidation method involves many decisions, which may include:

- The type of powder to be used (i.e., spherical, sponge, flake)
- The chemistry of the powder (i.e., prealloyed, elemental blend, partially alloyed)
- The use of rigid or flexible tools
- The use of a binder or lubricant
- The use of a directed powder spray to directly consolidate the powder as it is being made

This article briefly introduces and compares powder shaping and consolidation methods, which are described in more detail in subsequent articles of this Section. The emphasis here is to introduce methods for shaping of powder forms and to briefly describe common powder compaction methods, such as those listed in Table 1. The differences between compaction and shaping technologies are determined by many production and application factors, such as part size, desired final density, and shape complexity.

Table 1 Compaction options

Process	Cold isostatic compaction	Cold forging	Die compaction	Explosive compaction	Roll compaction	Warm compaction
Pressure	Moderate, 400 MPa	Very high, >800 MPa	High, 700 MPa	Very high, >1 GPa	Low	High, 700 MPa
Temperature	Ambient	Ambient	Ambient	Very high	Ambient	Warm
Tooling	Soft	Hard	Hard	Soft	Hard	Hard, heated
Deformation rate	Low	High	High	Very high	Low	High
Continuous	No	No	No	No	Yes	No
Pressing direction	3	1	1	1	1	1

Powder Shaping Technologies

General categories of powder shaping methods are as follows (Ref 1):

- Binder-assisted extrusion: long structures, small powders, constant cross section, relatively simple shapes
- Injection molding: complex, small components, high-performance materials
- Slip casting: very large structures, constant wall thickness, low precision
- Tape casting: flat sheets, small powders, very simple shapes

In general these methods employ binders that hold the particles together in the desired shape; the particles are then consolidated to higher densities by sintering. The part is shaped at relatively low pressures (compared to die compaction) with green (unsintered) porosity ranging from ~ 40 to 60% (ignoring the binder that is sacrificial) (Ref 1). Most binders are polymers such as mineral oil or polyethylene. The following binders are used in powder shaping:

Extrusion

- 56% water, 25% methyl cellulose, 13% glycerine, 6% boric acid
- 72% water, 12% hydroxypropyl methyl cellulose, 8% glycerin, 4% ammonium polyacrylate, 4% ammonium stearate
- 65% polyethylene glycol, 30% polyvinyl butyryl, 5% stearic acid

Injection molding

- 69% paraffin wax, 20% polypropylene, 10% carnauba wax, 1% stearic acid
- 75% peanut oil, 25% polyethylene
- 50% carnauba wax, 50% polyethylene
- 55% paraffin wax, 35% polyethylene, 10% stearic acid

Slip casting

- 96% water, 4% sodium lignosulfonate, trace calcium nitrate
- 93% water, 4% agar, 3% glycerine
- 99% water, 1% ammonium alginate
- 97% water, 3% polyvinyl alcohol

Tape casting

- 77% water, 9% polyacrylate emulsion, 9% glycerin, 3% ammonium polyacrylate, 2% ammonium hydroxide
- 80% toluene, 13% polyethylene glycol, 7% polyvinyl butyral
- 47% mineral spirits, 24% isopropanol, 8% polyvinyl butyral, 8% dibutyl phthalate, 5% polyethylene

glycol, 5% stearic acid, 3% menhaden fish oil

In most cases, the shaping process requires four steps:

- Formation of a powder-binder feedstock
- Shaping of feedstock using customized tooling
- Extraction of the binder
- Sintering densification

Feedstock formulation involves small powders and selected binders that are mixed in a ratio dictated by the desired rheology. Shaping may be conducted by several techniques, but powder lubrication by the polymer is key to fabrication of the desired shape. Low-pressure molding concepts, such as slip casting, require an excess of binder. On the other hand, high-pressure shaping is possible with high-viscosity mixtures that contain more powder. If necessary, the polymer viscosity can be controlled by either heat or solvent.

After shaping, the binder is removed (debinding), and the remaining powder structure is sintered. These last two steps can be combined into a single thermal cycle. Since significant shrinkage is associated with sintering densification, the final dimensions rely on uniform shaping to hold tight final tolerances.

Slip Casting. In this method, a low-viscosity slurry (typically from 10 to 50 Pa · s) is prepared with a liquid carrier and powder. The slurry mixture is then poured into a porous mold usually fabricated from plaster of paris. The carrier is evaporated and absorbed into the porous mold, and a free standing shape is thus achieved. In the case of cements, a chemical bond can be created during the drying or curing process. For many powders, sintering is required to achieve particle bonding and to produce a part having useful mechanical properties. This process is more applicable to ceramic powders, and the most popular application is the production of ceramic bathroom fixtures. Slip casting is not commonly used for metal powders. For steels, the largest application is rapid fabrication of prototype shapes and pilot tool steels (Ref 1). Slip casting is very cost effective for large shapes due to inexpensive tooling. More information on this method can be found in the article "Slip Casting of Metals" in this Volume.

Tape casting uses a similar low-viscosity mixture of powder, water, and polymer, but the forming step is via deposit of the mixture on a moving Mylar film. As the water evaporates, the particles are glued together into a thin sheet. It is used to generate homogeneous long, thin, and flat structures, such as sheets. Many of the characteristics of the binder and powder are the same as encountered in slip casting. After forming, the solvent or water is evaporated, leaving residual binder to hold the particles in place.

Tape casting is widely used to form battery electrodes, brazing layers, microelectronic substrates, and small production levels of steel sheets. In tape casting, the powder-binder slurry is fed onto a moving paper or plastic sheet that passes through a controlled opening. A doctor blade levels the slurry to form a continuous thin sheet (Fig. 1). Subsequently, one constituent of the binder is evaporated, leaving bonds of binder behind to provide strength during separation of the tape from the substrate before final sintering. Binders for tape casting are similar to those discussed earlier. Acrylics, waxes, polyvinyl alcohol, and polyvinyl butyryl are common components.

Fig. 1 In tape casting, a thin layer of powder-binder mixture is formed on a moving Mylar substrate, which carries the tape into a drying oven prior to sintering. The technique is used to form thin sheets. Source: Ref 1

Freeze Casting. A novel shaping technique relies on water and freezing to form a shape. The water contains polyvinyl alcohol or latex. After casting into hard tooling, the powder-binder mixture is frozen in the tool set. Subsequently, the ice is extracted by vacuum evaporation (freeze-drying or sublimation) from the compact, leaving behind a polymer component to hold the particles in place for subsequent handling. Sublimation of the water is slow and requires at least a few hours. Finally, the powder is sintered to a high density. The process is known by several names, including adiabatic forming, freeze-firing, and quick set. This freeze-sublime-sinter approach is mostly used for large structures; stainless steel is a preferred material. Current production targets components >1 kg (2.2 lb) in mass with modest production volumes--typically a few per day. This is dictated by the time to freeze the component in the tooling, which limits the cycle time to ~ 1 h.

Injection Molding of Metals and Ceramics. Injection molding is now the most widely employed shaping technique for steel powders. The molding process competes with many other shaping technologies. It overcomes the property limitations inherent in plastics, the shape limitations of traditional powder compaction, the costs of machining, the productivity limits of isostatic pressing and slip casting, and the defect and tolerance limitations of casting.

Part production by injection molding is used with various metals, alloys, and ceramic materials, such as the following (Ref 2):

Elements

- Beryllium
- Copper
- Iron
- Gold
- Molybdenum
- Nickel
- Niobium
- Silver
- Titanium
- Tungsten

Alloys

- Bronze
- Cobalt-base
- Copper-base

- Gold-base
- Hastelloy
- Inconel
- Invar
- Iron-nickel
- Iron-silicon
- Kovar
- Nickel-base
- Niobium-base
- Stainless steel
- Steel
- Stellite
- Sterling silver
- Superalloys
- Tool steel
- Tungsten heavy alloy

Ceramics and compounds

- Alumina (Al_2O_3)
- Alumina-chromia ($\text{Al}_2\text{O}_3\text{-Cr}_2\text{O}_3$)
- Aluminum nitride (AlN)
- Ferrites (MnFe_2O_4)
- Hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$)
- Mullite ($3\text{Al}_2\text{O}_3\text{-2SiO}_2$)
- Nickel aluminide (Ni_3Al)
- Silica (SiO_2)
- Silicon carbide (SiC)
- Silicon nitride (Si_3N_4)
- Spinel (MgAl_2O_4)
- Titania (TiO_2)
- Yttria (Y_2O_3)
- Zirconia (Zr_2O_3)

Cermets and composites

- $\text{Al}_2\text{O}_3\text{-SiC}$
- $\text{Al}_2\text{O}_3\text{-ZrO}_2$
- Mo-Cu
- NbC-Ni
- $\text{Ni}_3\text{Al-Al}_2\text{O}_3$
- $\text{Si}_3\text{N}_4\text{-SiC}$
- $\text{SiO}_2\text{-Si}$
- TiC-Ni-Mo
- W-Cu
- WC-Ni
- WC-TaC-Co
- $\text{ZrO}_2\text{-MgO}$
- $\text{ZrO}_2\text{-Y}_2\text{O}_3$

Noticeably absent are magnesium and aluminum; these reactive metals develop powders with surface oxides that are difficult to remove during sintering. Stainless steel is the most widely used material for injection molded parts, as shown

by the relative ranking in Fig. 2. Stainless steel 316L is the most commonly used alloy. Ferritic and duplex stainless steels are also used.

Injection molding moved quickly from a laboratory development to a commercial process for two reasons. First, a precision shape could be achieved at a significant cost reduction compared to a conventional manufacturing process. Second, the use of fine powders promoted densification during sintering, and high properties could be achieved. The high potential of the process added a third reason that sustained growth. Availability of fine powders and pellet feedstock from suppliers increased as the process showed early successes. There is still a great deal of development work toward more efficient and economical production of fine powders ($<20 \mu\text{m}$) specifically to supply the injection molding industry.

In the as-molded state, the green part is typically ~ 65 vol% powder and ~ 35 vol% binder. Therefore, upon removal of the binder, considerable densification is required to achieve density levels of ~ 95 to 98% of full density. This densification must be accompanied strictly by size change because unwanted shape distortion would render the part useless. Therefore, uniform particle distribution in the binder is essential. Also, to minimize contamination, the binder must either be removed completely before sintering, or it must participate in alloying during sintering.

A binder/plasticizer has also been used to extrude long shapes rather than just mold individual shapes. A heated barrel plasticizes the binder, and a die gives shape to the powder being extruded. With this technique it is possible to form fluted shapes, hollow tubes, tubes with multiple cavities, and other complex shapes. More information is in the article "Powder Injection Molding" in this Volume.

Rapid prototyping technology includes quick methods for making templates, models of parts, prototype molds and dies, and fully functional components. Rapid prototyping methods rely on variants of powder metallurgy capabilities such as selective sintering, powder spraying, ink jet techniques for directed spraying, and deposition. Several methods are discussed in the article "Powder Metallurgy Methods for Rapid Prototyping" in this Volume.

Powder Compaction Methods

Powders are compacted under high pressure by various methods (Table 1) where the application of pressure packs the powders and reduces porosity. Unlike shaping methods, compaction techniques cause particle deformation. Many compaction methods are used, but the most prevalent method for P/M parts production is uniaxial compaction in a rigid die. This method is cost effective with relatively straightforward tooling.

However, compaction methods inherently produce parts with density variations that result in dimensional variations of the final sintered part. This occurs because the transmittal of stress through a mass of powder particles is not uniform, even in isostatic pressing. In the case of compaction in a rigid die, the uniformity of stress transmitted through the powder mass and the density distribution in the green compacts produced in rigid dies are much less uniform than in isostatic compacting. This can be understood by considering flow around corners. When a liquid is subjected to hydrostatic pressure inside a confined, rigid die, the stress transmitted by the liquid upon the interior surfaces of the die is uniform, regardless of whether the liquid must flow around corners. This is not so when a powder is pressed; it flows only in the direction of the applied pressure and not around corners. This phenomenon is illustrated in Fig. 3, which schematically shows the compaction of powder in a die with a sidearm. If pressure is applied only to the top punch, the powder is compacted only in the vertical section of the die, but remains loose in the horizontal section. Compaction in the sidearm is obtained when pressure is applied to both the top punch and the side punch.
